The graphical depiction of the results in terms of ROC and micro-average ROC curve is shown in Fig. 22. The above output is completely different from the rest classification models. We will draw a graph of Fig. 23 for the Multinomial NB classifier to show the training set outcome. The classifier will determine whether a brain tumor is malignant or benign.

F. Extreme Gradient Boost (XGB) Classifier

This classifier is treated as a boosted classifier for tabular as well as structured training samples. At the same time, it has the characteristic to handle complex and huge databases. It is a technique for ensemble modeling.

The F1-score for healthy and brain tumor categorization is 92% and 95%, respectively in Fig. 24. In Fig. 25, a confusion matrix is used to determine the correct and incorrect guesses, with $3+0=3$ erroneous forecasts and $17+31=48$ accurate predictions.

The graphical depiction of the results in terms of ROC and micro-average ROC curve is shown in Fig. 26. To display the training set outcome, we will create a graph for the XGB classifier in Fig. 27. The classifier will determine whether the brain tumor is malignant or benign. XGBoost is more than 10 times quicker.

G. Stochastic Gradient Descent (SGD) Classifier

A gradient is the slope of a function. It assesses the degree to which one variable changes in response to changes in

Fig. 25. Confusion Matrix for XGB Classifier

Fig. 26. ROC for XGB Classifier

Fig. 29. Confusion Matrix for SGD Classifier

Fig. 30. ROC for SGD Classifier

another one. The steeper the slope, the higher the gradient value. It computes gradient using a single training sample. It is quicker and less computationally costly than batch gradient descent.

The F1-score for healthy and brain tumor categorization is 73% and 87%, respectively in Fig. 28. In the graph of Fig. 29, a confusion matrix is used to determine the correct and incorrect guesses, with 8+1=9 incorrect forecasts and 12+30=42 accurate predictions.

The graphical depiction of the results in terms of ROC and micro-average ROC curve is shown in Fig. 30. The above output is completely different from the rest classification models. We will plot a graph for the SGD classifier in Fig. 31 to visualize the training set outcome. The classifier will determine whether a brain tumor is malignant or benign.

H. Bagging Classifier

Bagging lowers over fitting (variance) by averaging or voting; nevertheless, this increases bias, which is offset by the decrease in variance. Bagging builds n classification trees from the training data using bootstrap sampling and then combines their predictions to get a final meta-prediction. Bagging and decision trees can be combined and used to eliminate overfitting.

The F1-score for healthy and brain tumor categorization is 90% and 94%, respectively in Fig. 32. In the graphic of Fig. 33, a confusion matrix is used to calculate the correct and incorrect guesses, with 2+2=4 incorrect predictions and 18+29=47 accurate predictions.

The graphical depiction of the results in terms of ROC and micro-average ROC curve is shown in Fig. 34. The above

utilizing it to build research applications. LGBM should not be used to small datasets.

The F1-score for healthy and brain tumor classification is 86% and 92%, respectively in Fig. 36. A confusion matrix is used in the graph of Fig. 37 to calculate the correct and incorrect guesses, with 4+1=5 incorrect predictions and 16+30=46 accurate predictions.

The graphical depiction of the results in terms of ROC and micro-average ROC curve is shown in Fig. 38. The above output is completely different from the rest classification models. To illustrate the training set outcome, we shall draw a graph for the LGBM classifier in Fig. 39. The classifier will evaluate whether a brain tumor is benign or malignant.

VI. EXPERIMENTAL ANALYSIS AND RESULT

We compared all the techniques used for the prediction of brain cancer by different parameters in grid search CV (Fig. 40) and randomized search CV (Fig. 41), respectively. The proposed method was implemented in Python by using 5-fold cross validation techniques. Our experimental result proves that all the nine classifier are providing good results with respect to different parameters values. However, for both GridSearchCV and RandomizedSearchCV bagging classifier is giving best results.

VII. CONCLUSION

Our article employs data augmentation approach prior to classification to avoid overfitting. We surveyed some popular state-of-the-art machine learning approaches to reach at a conclusion. Our work is experimented on T1-weighted contrast-enhanced MRI images. However, this study reveals the importance of supervised learning approaches on devising CAD systems to reduce the burden of radiologists. A future exploration can be extended in collecting some larger brain MR images to generalize the classifier systems.

Abstract—The high level of usability achieved by voice biometrics compared to other biometric authentication modalities has promoted the widespread use of automatic speaker verification (ASV) systems as authentication tools for several services in various domains. Despite their satisfactory performance, ASV systems are vulnerable to malicious voice spoofing attacks. Hence, voice spoofing countermeasures have emerged as essential solutions to stop such harmful attacks and protect ASV systems as well as users' confidentiality. Typically, these countermeasures classify utterances into genuine and spoofing categories. In this research, we propose two voice spoofing countermeasures that mainly aim to improve the generalization of supervised learning models. This goal is achieved through the adaptive handling of the high variance of both utterance classes, i.e., genuine and spoofing classes. The proposed spoofing countermeasure addresses the poor generalization problem by identifying the hidden structure of each utterance category prior to the classification task. Specifically, fuzzy clustering algorithms were deployed to mine the hidden partitions of utterance classes. The conducted experiments showed that the proposed approach outperforms the state-of-the-art approaches in the ASVspoof 2017 dataset, with a testing EER equal to 1.07%.

Keywords—Voice spoofing; spoofing countermeasure; classification; clustering

I. INTRODUCTION

At present, biometric authentication along with other identification features is widely deployed to manage, administrate and control systems' accessibility in order to secure the applications and stored data [43]. In particular, the widespread use of biometric recognition systems has prompted research efforts to consider various modalities such as retinal, facial and speech data. Speaker verification (SV) has been introduced as a biometric recognition paradigm that uses human voiceprints to identify individuals every time they access a given service or system. SV-based identification is typically meant to compare the speaker's voice with the voiceprints previously recorded, then grant access to the identified persons only. The advent of voice assistant and smart home devices boosted the interest in automatic speaker verification (ASV) systems as promising alternatives to ensure the security of various smart

home applications, smart devices, online payment processes and phone banking [30]. However, these ASV systems have proven to be vulnerable to voice spoofing attacks [41]. In fact, such attacks have been defined as presentation attacks (PA) according to the International Organization for Standardization (ISO) and the International Electrotechnical Commission (IEC) [15]. In fact, spoofing attacks occur when a fraudster falsifies another identity to access some personal or secured resources [26]. For instance, they can be achieved through replay attacks which consist of collecting voice samples of a particular person, manipulating them to produce a spoofing voice, and replaying the resulting spoofing voice to mislead an automatic speaker verification (ASV) system. This kind of voice manipulation can be performed using data voice conversion or speech synthesis algorithms [41, 48]. Obviously, in order to prevent these spoofing attacks, audio anti-spoofing countermeasures are required. A voice spoofing countermeasure is a classification system that can automatically categorize voice records into two predefined categories: genuine and spoofing. Typically, it comprises two main components: (i) an audio feature extractor, and (ii) a supervised learning model. In this context, various audio features have been investigated for designing highly discriminative descriptors. Namely, the constant Q cepstral coefficients (CQCC) [45] and the linear frequency cepstral coefficient (LFCC) [42] were proposed to better discriminate between spoofing and genuine voice records. Similarly, diverse classifiers, such as the Gaussian mixture models (GMMs) [39] and deep neural networks (DNNs) [36] have been extensively used to build models that can accurately map unseen voice records into the two predefined classes. Although different deep learning architectures, such as the residual neural networks (ResNets) [22] and the recurrent neural networks (RNNs) [9] have been adapted and used for anti-spoofing, GMM-based solutions overtake the state-of-the-art anti-spoofing recognition systems [41]. Nevertheless, one of the major unsolved issues affecting the reliability and accuracy of anti-spoofing recognition systems is the poor generalization of the learned models [41]. In other words, the learned model failed to predict unseen data instances. Generalization characterizes the model's ability to predict unseen data instances.

This limitation can be attributed to the high variance in both the genuine and the spoofed utterances. Specifically, genuine speech instances exhibit high interspeaker variance, owing to the discrepancies between speaker voices, as well as an intraspeaker variance because of the inconsistency in the human voice that can be affected by aspects such as the emotional state [1, 29]. These two types of variations also apply to spoofed speeches. Moreover, spoofing utterances witnessed other types of variations caused by the recording devices used to collect the original voice records and the algorithms used to manipulate them [1, 2, 9, 15, 22, 26, 29, 36, 39, 41, 42, 45, 48]. Hence, better handling of the high variance of the genuine and spoofed classes would improve the generalization of the spoofing countermeasures and, consequently, enhance the detection performance. In this paper, we propose to improve the recognition of voice spoofing utterances by tackling the problem of intraclass variation for two categories: genuine and spoofed. More specifically, we propose learning the underlying structure of each category (genuine/spoof) by clustering them into homogeneous sub-categories. The rest of the paper is organized as follows: In Section II, existing voice-spoofing countermeasures are surveyed. In Section III, background knowledge on clustering techniques is provided. The proposed approach is presented in Section IV. The experiments conducted are described in Section V along with the reported results and their analysis.

II. LITERATURE REVIEW

Recently, several spoofing countermeasures have been proposed. The development of these systems was boosted by contests in 2015 and 2017 [30, 43], which provided challenging data for anti-spoofing systems. More specifically, the training set contains five types of spoofing attack algorithms, referred to as known attacks, whereas the evaluation set, used for testing, contains the known attacks and five more types of attacks called unknown attacks. The proposed system amounts to classification systems for genuine and spoofed utterances. They aimed to discriminate spoofing utterances from genuine utterances. One of the main aspects that has been exploited is the presence of noise in the spoofing records [23]. During the playback and re-recording phases used by the replay attack, different types of noise are generated. These types of noise are mainly from the recording environment and recording device. They can potentially allow for differentiation between spoofed and genuine signals. In this context, both conventional and deep learning approaches have been reported.

A. Conventional Countermeasures

Typically, conventional spoofing/genuine recording classification comprises a feature extraction component followed by a classification component. The system proposed in [23] extracts the cepstral coefficient (CQCCs) [7] feature. A GMM [5] classifier was employed for the classification task. This system has been considered a baseline approach for recently proposed research for evaluating anti-spoofing systems [30, 43]. Alternatively, the system reported in [39] combines cochlear filter cepstral coefficients (CFCC) [33] and the instantaneous frequency (IF) [40]. The combined feature aims to capture the speech synthesis and voice conversion, thus characterizing spoofing utterances. It was then fed to the GMM classifier.

TABLE I. SUMMARY OF CONVENTIONAL APPROACHES FOR SPOOFING / GENUINE CLASSIFICATION

Reference	Feature	Classifier	Dataset	Training EERor rate (%)	Testing EERor rate (%)
[45]	CQCCs	GMM	ASVspoof 2015 [49]	0.048	0.462
[27]	CQCCs	GMM	ASVspoof 2017 [27]	10.35	24.77
[39]	MFCC CFC-CIF	GMM	ASVspoof 2015 [49]	0.408	2.013
[42]	LFCC	GMM, SVM	ASVspoof 2015 [49]	0.11	1.67
[37]	MFCC, MFPC, CosPhasePCs	SVM with i-vectors	ASVspoof 2015 [49]	0.008	3.922

Similarly, the work in [42] focused on segregating spoofing records generated by voice conversion or speech synthesis algorithms. For this purpose, the authors in [42] conducted an empirical comparison of 19 different features to determine the most appropriate one for classifying spoofing versus genuine records. These features are then conveyed to both GMM [5] and SVM [6] classifiers. The experimental results reported in [42] showed that the system comprising the LFCC [53] feature extraction component and GMM classifier component outperformed all other considered systems. On the other hand, the work in [37] used SVM as a classifier [6] for different extracted features. In addition, the i-vector was used for each feature and then integrated into a one-centered i-vector with a normalized length. The experimental results in [37] showed that the MFCC [11], Mel-frequency principal coefficients (MFPC) [14], and CosPhase principal coefficients (CosPhasePC) [47] fed into the SVM classifier had better classification performance. Table I presents a brief summary of conventional approaches for spoofing/genuine classification. All of these systems have experimented on the ASVspoof 2015 dataset [49].

B. Deep Learning based Countermeasures

The successful achievement of deep neural networks (DNN) in classification tasks has motivated the application of such approaches for anti-spoofing. Recently, deep learning approaches have been proposed for voice spoofing classification. In particular, the residual network model (ResNet) found recent success in the works of [8, 30, 36]. Moreover, as voice spoofing data can be considered as a sequence classification task, recurrent neural networks (RNNs) [35] were also investigated in the works [9, 19, 31, 51, 52]. Furthermore, while raw audio data were considered as inputs to the DNN model in some studies [9, 19, 30], engineered features were considered in others [8, 31, 36, 52].

1) *Residual Network based Approaches*: The proposed system in [30] employs a dilated residual network (DRN) deep-learning architecture [21]. The latter is based on the ResNet model, and an attention-filtering mechanism. More precisely, the DRN uses convolution layers instead of fully connected layers, and alters the residual units by adding a dilation factor. The attention component aims to select important parts while ignoring unrelated ones, such as the background noise segments [50]. Similarly, the system proposed in [8] employed the ResNet [21] deep-learning model. However, the proposed approach applies a deep-learning architecture in conjunction with two low-level cepstral features. In fact, the input conveyed

TABLE II. SUMMARY OF DEEP LEARNING APPROACHES FOR SPOOFING / GENUINE CLASSIFICATION

Reference	Feature	Classifier	Dataset	Training EERor rate (%)	Testing EERor rate (%)
[30]	Signal Logspec via FFT	ResNet	ASVspoof 2017[27]	6.09	8.54
[8]	CQCC and MFCC	GMM, ResNet	ASVspoof 2017[27]	2.58	13.30

[52]	Spectrogram features	CNN + RNN	ASVspoof 2015 [49]	0.40	3.33

to the network is not raw audio data but features extracted by MFCCs [11] and CQCCs [45]. Moreover, a GMM classifier is used at the back end of the network. The work in [36] uses a similar model, but it exploits high-frequency cepstral coefficients (HFCCs) instead of MFCCs [11] at the input of the network.

2) *Recurrent Neural Network based Approaches*: The authors of [9] used recurrent neural networks (RNN) [35] for spoofing/genuine record classification. More specifically, the proposed system employs long short-term memory (LSTM) [24] and a gated recurrent unit (GRU) [10]. LSTM has also been used in [44], where the proposed architecture consists of multiple dense layers followed by one or more LSTM layers. Similarly, the works in [19, 52] exploited the RNN [35] deep-learning model. However, an RNN is used with a convolutional neural network (CNN) [20]. More precisely, CNN is used as a feature extractor and RNN is used for processing long dependencies. The work in [19] crops the input records and trains the two models separately and uses a linear discriminant analysis (LDA) [25] as a back-end classifier. However, the work in [52] uses an end-to-end model. It uses a context window for input, and trains both models simultaneously by conjointly optimizing them through backpropagation. The combination of CNNs and RNNs was also exploited in [31]. Specifically, it fuses three approaches: the i-vector [12] approach, light convolutional neural network (LCNN) [46] approach, and CNN+RNN approach. Three inputs were considered separately in the first convolution layer yielding three variants of the LCNN-based model. More precisely, the first input consists of truncated normalized fast Fourier transform (FFT) spectrograms [34], the second is constant Q transform (CQT) [7], and the third is FFT with a sliding window. Table II provides a brief summary of deep learning approaches for spoofing/genuine classification.

C. Discussion

Previous studies tackled the generalization problem by mainly investigating various feature selection and fusion ap-

proaches [31, 36, 37], studying feature representations and diverse classification approaches [30, 39, 42, 45], and applying diverse deep learning architectures such as ResNet [8, 30, 36] and RNN [9, 19, 31, 51, 52]. Furthermore, for deep learning approaches both raw audio data [9, 19, 30], and engineered features [8, 31, 36, 52] are considered. Nevertheless, neither the engineered features nor those learned automatically by deep learning succeeded in alleviating the generalization problem. In fact, there was a discrepancy between the training and testing performances; they improve the prediction for seen utterances, but they are not able to generalize to unseen ones. Nevertheless, the baseline approach [45], which is based on extracting the CQCC feature and GMM-based classification approach, outperforms the other state-of-the-art approaches in terms of generalization on the ASVspoof 2015 dataset but failed on the ASVspoof 2017 dataset. On the latter dataset, the approach proposed in [31] is the best reported approach with a testing EERor rate of 6.73%.

III. CLUSTERING

Clustering is an unsupervised learning approach that groups unlabeled instances into homogeneous clusters based on certain criteria or similar functions. This allowed the exploration and analysis of the data. There are three main approaches to clustering: (i) hierarchical clustering, (ii) partitioning, and (iii) density-based clustering approaches [5]. Hierarchical clustering [17] creates a hierarchy of clusters following either a top-down (divisive) or a bottom-up (agglomerative) strategy. Alternatively, partitioning or centroid-based clustering [32], is characterized by learning a representative of each cluster such as the cluster centers. Accordingly, data instances were assigned to the cluster corresponding to the closest representative. For this purpose, the distance to the representatives is calculated using distance metrics such as the Euclidean distance or Manhattan distance. On the other hand, density-based clustering approaches [28] consider the density rather than distance to assign an instance to a cluster. Clustering is performed in such a way that dense instances form clusters, whereas sparse instances are considered noise and outliers. Density-based approaches are characterized by the arbitrary shapes of the clusters. Clustering approaches can also be categorized as crisp or fuzzy. Although crisp clustering approaches assign an instance exclusively to one cluster, fuzzy clustering can assign an instance to more than one cluster using a membership degree. The latter can be perceived as an instance's probability of belonging to a given cluster. In this way, fuzzy approaches can deal with real-world applications in which clusters exhibit overlapping boundaries [5]. In the following section, we describe three fuzzy clustering approaches that will be investigated to uncover the underlying structure of voice-spoofing data. Specifically, we consider fuzzy c-means (FCM) clustering [4], simultaneous clustering and attribute discrimination (SCAD) [18], and competitive agglomeration CA [17] algorithms.

A. Fuzzy C-Means

Fuzzy c-means (FCM) [4] clustering performs a fuzzy partitioning of the unlabeled data by minimizing the intra-cluster distances. More precisely, for a set of instances, x_j , it simultaneously learns the cluster representatives (centers), c_i ,

and the fuzzy memberships, (u_{ij}) , by minimizing the objective function:

$$J(\mathbf{B}, \mathbf{U}; \mathcal{X}) = \sum_{i=1}^C \sum_{j=1}^N (u_{ij})^m \|x_j - c_i\|^2 \quad (1)$$

subject to

$$u_{ij} \in [0, 1] \& \forall i, j \text{ and } \sum_{i=1}^C u_{ij} = 1 \& \forall j \quad (2)$$

In Equation (1), x_j and $c_i \in R^d$ where d is the dimension of the vectors, m is a fuzzier that controls the membership fuzziness, C is the number of clusters and N is the number of instances.

B. Simultaneous Clustering and Attribute Discrimination

Simultaneous clustering and attribute discrimination (SCAD) [18] is an extension of FCM that addresses the problems of feature selection and aggregation. It learns the relevance feature weights, $\nu = [\nu_{ik}]_{i=1\dots c, j=1\dots d}$ with respect to each cluster. In addition to the centers, $C = [c_{ik}]_{i=1\dots c, j=1\dots d}$, and fuzzy membership, $U = [u_{ik}]_{i=1\dots c, j=1\dots N}$. This is achieved by minimizing the objective function, as follows:

$$J(\mathbf{C}, \mathbf{U}, \mathbf{V}; \mathcal{X}) = \sum_{i=1}^C \sum_{j=1}^N (u_{ij})^m \sum_{K=1}^d v_{ik} (x_{jk} - c_{ik})^2 \quad (3)$$

subject to

$$u_{ij} \in [0, 1] \& \forall i, j \text{ and } \sum_{i=1}^C u_{ij} = 1 \& \forall j \quad (4)$$

and

$$v_{ik} \in [0, 1] \& \forall i, k \text{ and } \sum_{i=1}^d v_{ik} = 1 \& \forall i \quad (5)$$

where C is the number of clusters, N is the number of instances and d is the feature size, and v_{ik} , c_{ik} and $u_{ij} \in R^d$ where d is the dimension of the vectors.

C. Competitive Agglomeration

Competitive agglomeration (CA) [17] is another extension of FCM that addresses the problem of estimating the number of clusters in an unsupervised manner. In fact, it learns the number of clusters while learning the cluster representatives and the fuzzy memberships. It combines hierarchical and partitioning clustering approaches, and thus benefits from their advantages. Specifically, CA applies the competitive agglomeration in order to select the best number of clusters. It begins by dividing the instances into small clusters. During the optimization process, the clusters compete over instances, and the empty clusters disappear gradually. The CA optimizes the following objective function:

$$J(\mathbf{B}, \mathbf{U}; \mathcal{X}) = \sum_{i=1}^C \sum_{j=1}^N (u_{ij})^2 \cdot d_{ij}^2(x_j, \beta_i) - \alpha \sum_{i=1}^C [\sum_{j=1}^N u_{ij}]^2 \quad (6)$$

where $B = (1, \dots, c)$ are the cluster representatives, $d_{ij}^2(x_j, \beta_i)$ is the distance between feature vectors x_j and prototype β_i , and u_{ij} is the fuzzy membership of instance j with respect to cluster i . As can be seen, the objective function in (6) incorporates two terms: the first one is inherited from the FCM objective function (1). On the other hand, the second term in (6) is the competitive term that allows cluster competition to enclose data instances.

IV. PROPOSED APPROACH

Owing to the high intra-class variance of the spoofing and genuine categories, the sub-groups of these two categories are scattered. Moreover, spoofing subgroups overlap with genuine subgroups, and vice versa. This renders the classification problem even more challenging. In fact, the learned classification model is too complex and may result in the overfitting of the training dataset. This reflects the low generalization of the supervised learning model. Therefore, we propose splitting each category into homogeneous groups, and then classifying unknown instances by considering the closest sub-group. The proposed spoofing countermeasure based on homogeneous subcategories is illustrated in Fig. 1. As one can see, it starts by extracting audio features from the genuine and spoofing utterances. Then, the genuine instances are clustered separately to determine the representatives of the genuine sub-categories in an unsupervised manner. Similarly, spoofing instances were clustered in order to obtain the spoofing representatives. The learned sub-category representatives are then used to classify unknown instances. Specifically, for the clustering task, we propose employing prototype-based fuzzy clustering approaches. This choice is motivated by the need to learn cluster representatives, and the fact that fuzzy memberships are better at handling the overlapping boundaries of clusters. In other words, we intend to investigate several prototype-based fuzzy clustering approaches such as FCM [4] and SCAD[17, 18]. In fact, FCM-based clustering approaches learn the cluster centers which is not the case for other types of clustering approaches such as density or hierarchical-based clustering algorithms. Moreover, SCAD learns the relevance feature weights while clustering the data. This allows for the automatic selection and aggregation of the features. Similarly, CA automatically estimated the number of clusters while clustering the data. The three clustering algorithms under consideration are optimized iteratively by alternating the update of the centers, the fuzzy memberships, and eventually the relevance feature weights and the number of clusters through the use of closed-form update equations. Furthermore, we plan to explore the number of clusters that generate the optimal subcategories for the spoofing and the genuine classes. In fact, estimating the number of clusters allows the correct structure of the data to be uncovered. Therefore, it yields a better local classification which helps to lessen the generalization issue for unseen instances. An illustrative example of the proposed spoofing countermeasure based on homogeneous subcategories is shown in Fig. 2. As it can be seen, the spoofing utterances are clustered into six clusters ($S1, S2, S3, S4, S5$, and $S6$), while genuine utterances are clustered into four clusters ($G1, G2, G3$, and $G4$). Then, the blue unseen instance was compared to the ten learned representatives before assigning it to one of the clusters. Because $G1$, one of the representatives of the genuine category, is the closest to the blue unseen instance, the latter

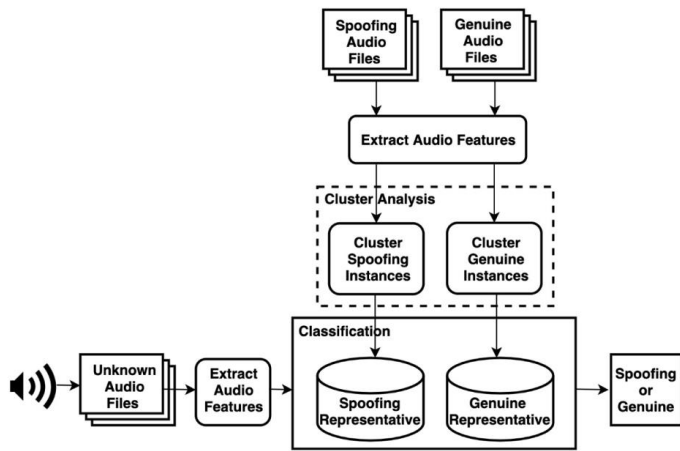

Fig. 1. General Overview of the Proposed Approach.

is classified as genuine.

Fig. 2. Illustrative Example the Proposed Spoofing Countermeasure based on Homogenous Sub-Categories.

V. EXPERIMENTS

The dataset used for the experiments was ASVspoof 2017 version 2.0 [13]. The dataset contained audio files with a sampling rate of 16 kHz and a 16-bit resolution, which were divided into three subsets: a training set containing 3016 files, a development set containing 1710 files, and an evaluation set with 13,306 files. The training set had 1507 genuine and 1507 replay files, the development set had 760 genuine and 950 replay files, and the evaluation set had 1298 genuine and 12,008 replay files [13]. The Mel-frequency cepstral coefficients' (MFCCs) [11] and the constant Q cepstral coefficients' (CQCCs) [45] features are extracted from the audio files. MFCC is computed by applying the discrete cosine transform (DCT) type 2 on a 20 ms audio frame. This generates an audio spectrum that reflects energy in different frequency bands. After spectrum computation, a bank of triangular filters was employed to warp the spectrum into the Mel-scale. Finally, the results of a Mel-scale filter bank are logarithmized and decorrelated by applying the DCT. Alternatively, CQCC is based on a constant Q transform (CQT). The latter is a time-frequency analysis tool for short-time Fourier transform (STFT) [7]. The number of bins per octave was set to 12, and the sampling frequency was set to 44,000 Hz. The CQCCs' spectrum was derived by first performing CQT transform on the audio frame. Next, the logarithm non-linearity and linearization of the CQT's geometric scale were applied. Then, the final 167 CQCC cepstral coefficients were obtained by

applying the DCT [45]. Similar to the approaches described in Section III, the performance of the proposed approach is evaluated using an equal error rate (EER) [38]. It was calculated using a receiver operating characteristic (ROC) curve. More specifically, the EER is defined as the operating point where the false acceptance rate (FAR) and false rejection rate (FRR) are equal [16, 38].

A. Experiment 1: Discovering the Underlining Structure using Fuzzy C-Means

In this experiment, we clustered the genuine and the spoof classes from the training subset separately, using fuzzy c-means [4]. The same number of clusters was used for both classes, and it was tuned from 2 to 16 with a step of 2. The learned sub-category representatives were then used for the classification of unknown instances from the testing subset, using the K-nearest neighbor classifier KNN [3] with $K = 1$. The experiment was conducted on the CQCC, MFCC, and a concatenation of the CQCC and MFCC independently. The EER with respect to the number of clusters on the considered features is shown in Fig. 3.

Fig. 3. EER with respect to the Number of Clusters when using Fuzzy C-Means [20] on CQCC, MFCC and the Concatenation of CQCC and MFCC.

As shown in Fig. 3, the EER varies with respect to the number of clusters and features considered. The best result is obtained when using a number of clusters equal to 2 for both classes on the CQCC feature. It reached an EER of 4.46%.

B. Experiment 2: Discovering the Underlining Structure using the Competitive Agglomeration

In this experiment, the underlining structure was learned using the competitive agglomeration (CA) [17] clustering algorithm in order to simultaneously cluster the training data and learn the optimal number of clusters. The same number of clusters was initially set to 100 for both classes (genuine and spoofed). Similar to Experiment 1, the learned cluster representatives are used for the classification of unknown instances from the testing subset, using the K-nearest neighbor classifier KNN [3] with $K = 1$. Moreover, an experiment was conducted on the CQCC, MFCC, and concatenation of the CQCC and MFCC independently. Table III reports the obtained EER, and the learned number of clusters with respect to the considered features.

As shown in Table III, the CQCC exhibited the lowest EER of 2.46%. Moreover, the optimal cluster learned by CA

TABLE III. EER AND THE LEARNED NUMBER OF CLUSTERS WHEN USING COMPETITIVE AGGLOMERATION (CA) [17] ON CQCC, MFCC, AND THE CONCATENATION OF CQCC AND MFCC

	CQCC	MFCC	CQCC+MFCC
EER	2.46%	14.86%	9.24%
No of genuine clusters	2	3	3
No of spoof clusters	2	2	3

TABLE IV. LEARNED FEATURE WEIGHTS WITH RESPECT TO EACH CLUSTER

	CQCC	MFCC
Cluster 1 (genuine)	0.92	0.08
Cluster 2 (genuine)	0.92	0.08
Cluster 1 (spoof)	0.91	0.09
Cluster 2 (spoof)	0.91	0.09

when using CQCC is two clusters for the genuine class and two clusters for the spoof class. This is similar to the result obtained in the first experiment using fuzzy c-means by tuning the number of clusters. We can then conclude that the CA clustering approach can learn the underlying structure of both the genuine and spoof classes while learning the optimal number of clusters.

C. Experiment 3: Discovering the Underlining Structure using Simultaneous Clustering and Attribute Discrimination

In this experiment, partitions of the genuine and spoof classes are mined using simultaneous clustering and attribute discrimination (SCAD) [18]. It aims to discover the underlying partitions while learning the optimal relevance feature weights of CQCC and MFCC audio features. In fact, the weights of each of these two considered features are learned with respect to each class. The number of clusters was set to two for the genuine class and two for the spoof class according to the results obtained in Experiment 2. The obtained partitions were then used for the classification task using the K-nearest neighbor classifier KNN [3] with K = 1. Table IV presents the obtained EER, and the learned number of clusters with respect to the considered features.

As reported in Table IV, the feature weights with the largest relevance were learned for the CQCC. This is in concordance with the results obtained in the previous experiments, which showed that the CQCC is more relevant for the classification of genuine/spoof utterances. To further investigate the CQCC feature, we applied SCAD to its 167 CQCC cepstral coefficients. In other words, each dimension of the CQCC is considered as a single feature. A feature relevance weight was then learned for each dimension. For Experiment 1, the number of clusters was tuned from 2 to 16 in steps of 2.

As shown in Fig. 4, when using the same number of clusters, the lowest EER, equal to 1.07, was obtained for the number of clusters equal to two. We can conclude then that performing SCAD on the CQCC yields better results. This is because it deals with the high dimension of CQCC by performing an optimal weighted sum of the coefficients. Fig. 5 shows the relevance feature weights for each cluster.

Fig. 4. EER with respect to the Number of Clusters when using SCAD [18] on CQCC Dimensions.

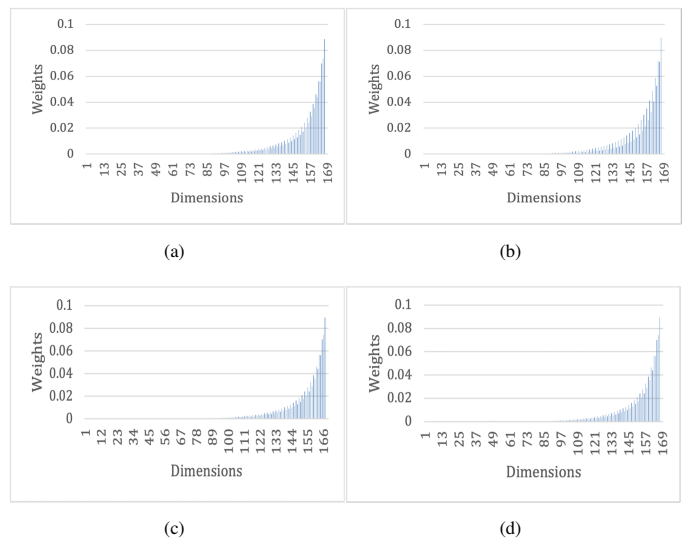

Fig. 5. Relevance Feature Weights with respect to (a) Cluster 1 (Genuine), (b) Cluster 2 (Genuine), (c) Cluster 1(Spoof), (d) Cluster 2 (Spoof).

D. Experiment 4: Performance Comparison with the State-of-the-Art Approaches

In this experiment, the performance of the proposed approach was compared to that of the state-of-the-art approach in the ASVspoof 2017. More specifically, the best results obtained using the considered clustering algorithms are compared to the conventional KNN [3] approach and to the countermeasures reported in the literature [8, 9, 27, 30, 31, 36]. To compare the proposed approach to KNN, we classified ASVspoof 2017 using KNN while tuning the neighboring parameter from 3 to 9. The experiment was conducted on MFCCs, CQCCs, features, and their corresponding concatenation. As shown in Fig. 6, the lowest EER (EER=3.62%) was obtained when using CQCC with K equal to 9.

Table V reports the training EER and the testing EER of the state-of-the-art approaches, the best KNN result, and the best results of the proposed approach with respect to the different clustering approaches under consideration.

As shown in Table V, the proposed approach outperforms the KNN classifier and the methods reported in the literature, regardless of the considered clustering algorithm. Moreover, it solves the generalization problem by reducing the performance

TABLE V. PERFORMANCE COMPARISON IN TERMS OF EER BETWEEN THE PROPOSED APPROACHES AND THE STATE-OF-THE-ART APPROACHES

Countermeasures	Training EER %	Testing EER%
Reported work in [30] (Features: Signal Logspec via FFT, Model: ResNet)	6.09	8.54
Reported work in [8] (Features: CQCC and MFCC, Model:GMM + ResNet)	2.58	13.30
Reported work in [36](Features: Fusion of HFCC and CQCC, Model:DNN + SVM)	7.6	11.5
Reported work in [9](Features: MFCC, Fbank, Model: LSTM + GRU RNN)	6.32	9.81
Reported work in [31](Features: CQT and FFT, Model: LCNN, SVM, CNN + RNN)	3.95	6.73
Reported work in [27](Feature: CQCC, Model: GMM)	10.35	24.77
KNN (K=9, Feature: CQCC)	1.05	3.62
Proposed approach based on Fuzzy C-Means (No of genuine clusters= 2, No of spoof clusters=2, Feature: CQCC)	3.15	4.46
Proposed approach based on CA (feature: CQCC)	2.67	2.46
Proposed approach based on SCAD No of genuine clusters= 2, No of spoof clusters=2, Features: coefficient of CQCC)	0.13	1.07

Fig. 6. EER with respect to the Number of Neighbor Parameter K when using KNN [3] on CQCC, MFCC, and the Concatenation of CQCC and MFCC.

gap between the training EER and the testing EER. This is achieved by mining the underlying structure of both genuine and spoof utterances. Furthermore, the lowest EER is obtained when using SCAD with a number of genuine clusters equal to 2, and a number of spoof clusters equal to 2 on CQCC coefficients. The achieved EER was 1.07%. This improved the result by a ratio of 5.66% compared with the best reported work [31], which achieved an EER of 6.73%.

VI. CONCLUSION

Voice spoofing is a prominent security risk that requires effective countermeasures to protect the user’s information when using ASV systems. These countermeasures amount to the classification of the utterances into genuine or spoofing categories. However, this classification problem is challenging because of high class variance. In fact, genuine utterances are subject to variability due to the differences in speakers’ voices and the discrepancies within the human voice due to emotions or other effects. Similarly, spoofing utterances are subjected to the same variability, in addition to the variability caused by the recording devices employed. Moreover, the diversity in the methods that produce spoofing utterances, such as voice manipulation and synthesis, contributes significantly to the variance in the spoofing class. This high variance in utterances drastically affects the performance of the spoofing classification task. Specifically, it limits the model’s generalization and yields a less accurate system. Recently, considerable attempts have been made to address the low generalization of spoofing countermeasures. The reported works focused mainly on investigating various feature selection and fusion approaches, studying feature representations, and applying diverse deep learning architectures. However, neither handcrafted features nor deep learning-based descriptors have succeeded in alleviating the

generalization problem. In fact, although they have shown slight improvements in the prediction performance of the models, they fail to generalize to unseen utterances. In fact, they are prone to overfitting, as indicated by the discrepancy between the training and testing performances. In this study, we devised a new countermeasure to address the low-generalization problem. Specifically, the proposed approaches mined the understructure of the genuine and spoofing utterances. This was achieved by integrating the clustering component into the classification process. The experimental results showed that mining hidden partitions of voice utterances using fuzzy clustering yielded a better generalization of the voice-spoofing countermeasure. In fact, the proposed approach outperformed the state-of-the-art approaches. Specifically, when using the CA clustering approach, the training and testing EERs were similar. Moreover, when using SCAD on the CQCC feature for a number of genuine clusters equals to 2, and a number of spoof clusters equal to 2, the performance is drastically improved with an EER of 1.07%. In future work, we suggest investigating additional audio features. Moreover, we intend to use CA as the first step in order to learn the number of clusters and the initial fuzzy memberships. Then, SCAD would be performed using the obtained results.

Abstract—Machine learning-based anti-phishing solutions face various challenges in collecting diverse multi-modal phishing data. As a result, most previous works have trained with little or no multi-modal data, which opens several drawbacks. Therefore, this study aims to develop a phishing data repository to meet the diverse data needs of the anti-phishing domain. As a result, a gap-filling solution named PhishRepo was proposed as an online data repository that collects, verifies, disseminates, and archives phishing data. It includes innovative design aspects such as automated submission, deduplication filtering, automated verification, crowdsourcing-based human interaction, an objection reporting window, and target attack prevention techniques. Moreover, the deduplication filter, used for the first time in phishing data collection, significantly impacted the collection process. It eliminated the duplicate data, which causes one of the most common machine learning errors known as data leakage. In addition, PhishRepo enables researchers to apply modern machine learning techniques effectively and supports them by eliminating phishing data hassle. Therefore, more thoughtful use of PhishRepo will lead to effective anti-phishing solutions in the future, minimising the social engineering crime called phishing.

Keywords—Cyberattack; crowdsourcing; internet security; phishing; machine learning; multi-modal data

I. INTRODUCTION

Industry 4.0, or the fourth industrial revolution that marks the beginning of the imagination age, has opened various opportunities for human beings through automation and data exchange. However, it is a double-edged sword where criminals also optimise the revolution change to effectively operate their criminal activities on the Internet. Phishing is an illegal activity that relies on the Internet, which has gained a top rank in the cyber threat landscape [1]. It is a social engineering threat that damages Internet users illegally using digital assets—incidentally personal and confidential information [2]. Phishing is known as ‘identity theft’ because it impersonates one’s identity in cyberspace for the phisher’s benefit [3], [2].

The phishing threat first occurred in 1996 [2], and initially, online banking and e-commerce services were popular among phishers [4]. The direct or indirect financial gains motivate phishers in phishing, and fame and notoriety are also attractive [3]. Phishers are constantly moving with technology. Therefore, they are keen to experiment and improve attacking strategies in the phishing domain without failing in front of the available security countermeasures [5], [6]. The number of phishing attacks is still rising. Interestingly, the Anti-Phishing Working Group (APWG) has stated that phishing attacks had doubled in 2020, and in October 2020, only they have detected 225,304 unique phishing websites [7].

In phishing attacks, phishers commonly send an email to a user with an embedded link to redirect the user to a phishing site [5], [2]. This email often denotes a specific scenario like updating account details or security upgrades and creates a way to convince users to believe it [2]. The phishers recently used the Coronavirus pandemic (COVID-19) to raise phishing campaigns to fool Internet users [2]. However, by accepting, an unsuspecting user might click on the given link and move to the phishing website, which is very similar to the legitimate website, to feel more confident about his previous action [5], [2]. Then, the most dangerous thing happens in the process. By believing this is the legitimate website, the unsuspecting user enters his vital information to the phisher’s website that impersonates the legitimate website. That information could be bank details, login credentials, a social security number, a credit card number, or other personal or confidential information [2]. However, this would be the main harvest of the phisher of this phishing process, and he might use it or sell it for his benefit.

According to the literature, 95% of phishing attacks were succeeded due to human errors [2]. Therefore, numerous solutions [8], [9], [10], [11], [12], [13], [14], [15], [16], [17], [18], [19] were introduced in the last two decades to safeguard humans from this prevalent Internet threat by detecting phishing attacks. Those solutions could be mainly categorised into user education and software-based solutions [20]. Out of those categories, software-based solutions were more prominent in the past since user education is associated with a high cost and requires fundamental knowledge of computer security [2]. The software-based solutions also use different approaches when finding an effective anti-phishing solution [20]. Of those approaches, machine learning shows promising results due to its unique advantages like handling frequent data changes and automating the learning process [6]. However, machine learning studies in the phishing domain suffer from labelled phishing data [21], [22]. Therefore, researchers primarily work with their data [12], [15], [17], [16], [23] due to a lack of benchmark datasets available in the current anti-phishing domain and their limitations [22].

The current study mainly focuses on finding an effective solution to the difficulty of getting labelled data or training with a limited amount of features in the phishing domain. It is essential in the present context since advanced techniques like deep learning can work effectively with many high-dimensional data when identifying complex attacks like phishing [24]. Further, these labelled data may be more effective in retraining the trained machine learning models since phishing

attacks are rapidly changing over time [21], [22]. The proposed solution to fill the identified research gap in the phishing domain is an online repository that can constantly collect, verify, disseminate, and archive real-time phishing data. This solution allows automatic submission of phishing data by anti-phishing solutions and guarantees the diversity of data through different filters like deduplication.

Further, it effectively uses existing phishing verification systems and crowdsourcing techniques to review the labelling of those collected data. Moreover, it manages the essential aspects of the submitted phishing records to open data to the scientific community, especially for anti-phishers. The main contributions of this study are an online phishing data repository for collecting, validating, disseminating and archiving real-time phishing data; a large-scale, diverse phishing data in raw format for research purposes; and a set of design artefacts to have in a real-time phishing data repository.

This article aims to introduce the gap-filling solution that touches the data needs in the anti-phishing domain and demonstrates the effectiveness of the used architecture of PhishRepo in the problem domain. The other sections of this paper include Section II - a high-level description of the problem domain; Section III - a review of the literature; Section IV - the architecture of the proposed solution; Section V - experiments were performed on the collected data to demonstrate the diversity and effectiveness of the machine learning process; Section VI - a discussion of the significance and usage of PhishRepo, and finally, Section VII - the concluding remarks of the study.

II. PROBLEM DEFINITION

Machine learning-based anti-phishing solutions mainly have two steps [17]. First, the features required to detect phishing attacks are extracted and then a machine learning model is trained using the extracted features. The feature extraction happens based on multiple information sources available on a website. The Uniform Resource Locator (URL) of a website is the popular source for many of the recent anti-phishing solutions [12], [15], [25], [23], and third party-based features like Alexa ranking and age of the domain are also used in different solutions [26], [27], [28], [29]. The website content, either human-readable or markup content, refers to HTML content, another vital source for extracting features. It has been used in many recent studies [14], [16], [17], [18], [19] to extract different features for the learning model. Further, several studies [13] already used captured images of the web page (i.e., a screenshot) when training machine learning-based anti-phishing solutions.

Supervised learning is the dominant practice with many existing anti-phishing solutions in the machine learning area [12], [14], [15], [17]. Therefore, the labelled data is essential for training the learning model. However, constructing a large-scale, diverse phishing dataset effective in training is impossible in one night since the phishing websites are short-lived [30], [31]. Therefore, it should be a continuous process and take time. However, phishing verification systems such as PhishTank (<https://phishtank.org/>) and OpenPhish (<https://openphish.com/>) collect many phishing URLs [30], including optional information like the screenshot of the website page

and network information (i.e., WHOIS information). Although these systems contain the URLs, those do not include all information sources required to extract the most recently exercised feature vectors directly [22]. It is a downside of these verification systems, and it negatively impacts research since the researchers need a systematic way to collect data in the initial step of their methodology. Since the data collection takes much time, many machine learning-based anti-phishing studies used less data during the training phase [28], [32], [33]. For example, [32] used 1,428 phishing data, and [28] used 2,000 phishing data during their experiments. However, some of the accessed solutions that used more data in model training are URL based solutions, and those may not be effective due to the challenges that exist only with URL based information [21]. Therefore, multi-modal features, marked as effective in phishing detection due to the representation of many phishing attack characteristics [34], are essential in the present phishing detection context. Free public access to such data sources is necessary for better detection solutions in future.

Moreover, the literature has shown that the researchers use old datasets due to the lack of new public datasets [22]. It results in inept learning models on recent phishing attacks [22]. These factors highlight the importance of an organised way of acquiring the latest multi-modal feature enabled diverse phishing data for future phishing detection. Therefore, the difficulty of getting labelled data or training with a limited number of features or data has become a significant problem in the machine learning-based phishing detection area that should be resolved to expect promising results in future research [21]. This study will resolve the identified issues by answering two questions: how can a phishing data repository be made to support anti-phishing research effectively? and what are the most effective design strategies that could be used in a real-time phishing data repository to collect, verify and disseminate large-scale, diverse phishing data?

III. RELATED LITERATURE

As highlighted in the problem definition, the difficulty of getting the latest, labelled phishing data with multi-modal features is a significant research challenge in machine learning-based phishing detection. This challenge could be overviewed closely by the three most related topics to the current study: data collection for phishing websites detection, feature selection for phishing websites detection, and data labelling in machine learning.

A. Data Collection for Phishing Websites Detection

Phishing techniques are constantly evolving due to technological improvements, enhanced security countermeasures and educated public [2]. Early days, phishers used untargeted attacks, and unsuspecting users were caught [2]. However, now phishers are more into target attacks, and techniques like spear-phishing are more prominent in the phishing domain [2]. The literature highlighted that the success rate of untargeted phishing attacks is less than 5%, while 19% of target attacks like spear-phishing get success [6]. However, when the phishing threat grew, many different parties like brand owners, researchers, and law enforcement were interested in these attacks from different perspectives [35]. Therefore, numerous organisations like APWG, Phishing Incident Response Team,

Phishing Report Network, and Digital PhishNet started to collect phishing attack-related data, resulting in different levels of data collection [36]. Further, an organisation like APWG mainly depends on the public, anti-phishing working groups, Internet service providers and brand owners when collecting phishing data [36].

In contrast, the Phisherman project [36], [35] addressed this phishing data collection process differently. It changed the present way of collecting phishing data and introduced a web-based system to collect, validate, disseminate and archive real-time phishing data. It is a global data collection system and fulfils three basic requirements: submitting suspicion records, saving the records for future use and outputting historical phishing data to interested parties. Phisherman has used an automated phishing records verification process, and the submitted records are verified in two steps. However, the first step is only for the submissions collected from individuals and high-volume spam feeds. The important feature in Phisherman in the current study's perspective is the dissemination of the collected data. Phisherman supports the data distribution in two ways: subscription and queries. However, these options allow downloading a blocklist or a full incident report in XML format.

PhishTank is one of the favourites to collect phishing data by many anti-phishing tool introducers [15], [34], [33], [23]. PhishTank was launched in 2006, and it is a community-based phishing verification system [30]. The PhishTank facilitates submitting phishing URLs, and the community votes those submissions to be a phishing website or marked as a legitimate website. However, when looking at those studies, the researchers used the PhishTank only to get phishing URLs and have not been used to extract other information sources like the screenshot of the phishing website and WHOIS information present in some of the submitted phishing records. The data distribution strategy used by the PhishTank might be the closest reason for such a trend.

OpenPhish is another phishing verification system that collects phishing data via an autonomous phishing detection algorithm shaped through research. It is also popular among anti-phishers [30], and it distributes the collected data like URL, target brand and screenshot to interested parties. However, OpenPhish is not for free, and a free account gets only the phishing URLs, which also gets in every twelve-hour frequency.

The UCI Phishing dataset available in the University of California - Irvine's (UCI) repository is also popular among researchers in the phishing domain [31]. However, it is an old dataset with limited data (i.e., 11,055 maximum). Further, it has a preprocessed set of features and bounds the research scope to those features. It is one of the main drawbacks of this dataset, and the heuristics used to preprocess those data [37] are also not examined in the current environment. Similarly, [22] presented high quality, a diverse phishing data source for benchmarking purposes, and one output of their study is implementing a benchmarking framework called PhishBench. The dataset was constructed using the sources like PhishTank, OpenPhish, and APWG and a systematic approach was undertaken when collecting data. However, it needs such an approach again when collecting new data, which may be costly and time taken.

Furthermore, Web2Vec [19] and PhishPedia [38] are another two datasets collected with the support of PhishTank and OpenPhish. PhishPedia collected phishing records from OpenPhish using a premium account to get additional information like target brands. However, these datasets also contain old data compared to today and since these studies are not focused on updating these datasets, implementing anti-phishing tools to detect the latest phishing attacks is problematic.

Phisherman project is the only landmark for a deliberate phishing data collection and dissemination approach. However, Phisherman is not publicly available [39]. Therefore, it is not a solution for the identified data collection problem. The solutions like PhishTank and OpenPhish have different intentions, such as maintaining blocklists and identifying target brands. Those data collections are more into URL related information extraction in phishing detection, therefore not effective in the data collection problem mentioned in this study. The individual data sources are an excellent approach to donating phishing data to others; however, the relevancy depends on the frequent update and the ability to support multi-modal features in the present machine learning-based anti-phishing domain.

B. Feature Selection for Phishing Websites Detection

Feature selection is essential in phishing detection research since it impacts detection accuracy [6], [22]. The researchers in the literature introduce different feature sets that represent the essential information sources that need to include in a dataset. A more complex categorisation of phishing features is found in [22]. They used more than 250 phishing detection-based studies and divided the phishing features mainly into two classes: URL and website. Again, those two classes divide into lexical, network and script level features. Then these features were furthermore analysed based on the format and categorised into three. 1). Syntactic - syntactic correctness (i.e., port number and Term frequency-inverse document frequency referred to as TF-IDF), 2). Semantic - the meaning and interpretation of the content (i.e., presence of the target brand in URL and web page), and 3). Pragmatic - the features do not directly relate to syntax or meaning (i.e., backlisted words in a URL, WHOIS information, and script loading time).

In a similar study, phishing features were primarily categorised into four feature sets [6]. 1). URL-based lexical features like the length of the URL and the presence of the HTTPS protocol, 2). URL-based host features like WHOIS information, 3). web page content features like page rank, hyperlinks and forms in the HTML content, and 4). visual similarity-based elements like images and colours. Further, [14] used only URL and web page content features in their study, and HTMLPhish [17] is a particular case that used superior web page content features in phishing detection. Furthermore, [40] introduced another set of features in their research on machine learning-based phishing attacks. In that, they have mentioned four main groups of features, namely, URL-based features (i.e., number of subdomains, length, and number of digits), domain-based features (i.e., age of the domain, and whether it is blocked in reputed services), page-based features (i.e., page rank, and Alexa rank) and content-based features (i.e., page title, body text, a web page screenshot, and images).

After analysing the available feature sets in explored literature, it is clear that the URL and the web page are the most

important information sources to extract different features for model training. Although a website could be callable if the URL is saved in general, the phishing web pages cannot be recovered only from the URL since those are short-lived [30], [31]. Therefore, the instant saving of the phishing page and relevant resources like the web page screenshot, images, CSS, and JavaScript when the attack is active and online is essential for future use [22].

Moreover, the screenshot of the web page is an essential feature to consider in the machine learning-based visual similarity area [13]. Therefore, the study identified three primary sources for feature extraction for machine learning-based phishing detection. These are URL, web page, and third-party services. Further, those information sources are essential to consider when constructing an adequate dataset for future research since it supports the extraction of all the required features from one dataset.

C. Data Labelling in Machine Learning

Machine learning-based anti-phishing solutions are more toward the supervised learning paradigm. Therefore, labelled data is essential for model training [21], and expert labelling is a popular approach when labelling data in machine learning [41]. However, expert-based labelling is often costly and time-consuming since modern machine learning needs large-scale datasets [41]. Due to the limitations of the expert approach, crowdsourcing has become a widespread technique in data collection [42], [41], [43]. Crowdsourcing is based on collective intelligence, which beliefs together is better than a single entity [44]. It has advantages like low cost, fast labelling and diverse opinions than the expert approach [43]. However, the main drawback is getting high-quality labelled data [41], [43]. Factors like the poor commitment of workers, uncertainty in the tasks, prior knowledge of the given task, and novice workers are some of the reasons for imperfect quality labels in crowdsourcing based data labelling [41].

However, the quality of labels in crowdsourcing could be improved through several techniques discussed in the literature. Those are pre-training [41], task pricing [41], [43], calculation of labelling quality of workers [45], [46], and peer review of the crowd worker work [47]. As mentioned in [46], identifying incorrect labelling data points is not sufficient in crowdsourcing since the labelling quality of the workers also matters. In another study, [42] proposed a relabeling strategy called absolute cumulative majority relabeling (ACMR). It allows relabeling of the same data point multiple times. It uses a voting mechanism to select majority voting, and if a label achieves more than 50% voting, it sets that as the correct label for that data point. However, if none of the labels could earn more than 50% are discarded in the ACMR strategy. Revolt [41] is another solution that uses crowdsourcing when collecting data for machine learning tasks. In revolt, the dataset is divided into multiple batches for the crowd workers' easiness, and groups collectively contribute to each batch. From a different perspective, [48] studied the effect of cognitive biases in crowdsourcing. The study identified that the anchoring, bandwagon, and decoy effects occur in crowdsourcing, and an experiment has shown that a 28% accuracy loss was recorded due to the anchoring effect.

As identified, crowdsourcing is a practical approach to phishing data labelling. Further, the quality of the workers needs to be evaluated, and peer review of the workers' work is essential to maintain the quality. ACMR is a better strategy for phishing labelling since it allows adding many labels to a single record, and a majority voting technique is used when selecting an appropriate label. Multiple batches in the labelling process are also aligned with the current study since it reduces the overhead of seeing more labelling tasks simultaneously. Further, avoiding the dependency on one information or specific people is vital in crowdsourcing-based labelling and getting a quick explanation about the submitted label, as Revolt [41] proposed, is essential in current work to avoid doubtful labels. However, the task pricing and pre-training are not applicable here since the cost is incurred with those techniques, and the proposed solution is freeware.

IV. PHISHREPO

PhishRepo is an online phishing data repository for collecting, validating, disseminating and archiving real-time phishing data. The researchers and other interested parties would use it for their customised needs associated with data. PhishRepo architecture consists of three primary modules: input, verification, and distribution.

PhishRepo is a data collection solution for industry 4.0. Therefore, it introduces a safe architecture to integrate with autonomous anti-phishing tools to submit their phishing data directly to the repository for others' use. Therefore, this solution can provide effective results by collaborating with existing anti-phishing solutions. The other speciality of the repository is the type of data it collects. The repository is designed to collect most information sources, namely URLs, web pages and third-party service information relevant to a submission. However, when collecting third-party service information, the repository limits the free account level and possible third-party details are stored in the phishing records. Following is an in-depth explanation of PhishRepo modules.

A. Input Module

The primary task of the input module is the collection of phishing data which includes collecting phishing URLs from outside, acquiring the relevant information sources and archiving those in the repository, as shown in Fig. 1. Phishing data collection seems challenging since 63% of the phishing campaigns last within the first two hours [20]. It is not challenging to archive only the URLs [22]. However, PhishRepo is responsible for collecting URLs, web pages and possible third-party information sources for each inputted phishing record. Therefore, the detection time and reporting time are crucial in data collection. Thus, as a specific design consideration, PhishRepo allows external anti-phishing tools to submit their findings (i.e., phishing URLs) automatically. Then, it minimises the difference between detection and reporting time. It also helps collect the most active and online phishing URLs to effectively acquire the required information sources. Although the manual submission exists in PhishRepo, as in Fig. 1, PhishRepo encourages automated submissions to get the most active and online phishing URLs in the data collection process.

Fig. 1. Workflow Diagram of the Input Module

PhishRepo’s input module consists of five components: authentication, accumulation, deduplication, targeted attack prevention (TAP), and manual submission. The followings discuss these components in detail.

1) *Authentication*: PhishRepo has five users: administrator, editor, reporter, beneficiary, and guest. The administrator is the primary account holder with full privileges, and the editor is responsible for verifying the submitted phishing records. There are three levels in the editor account: newbie, competent, and expert. These levels are achieved by each user based on their performance. However, the expert editor is a chief editor type in PhishRepo and is responsible for the final decision of incorrect submission. The expert editor can modify the records if required and report phishing instantly. Therefore, the automatic account upgrade is turned off when upgrading a competent account, and the administrator is involved in forming an expert editor based on the recommendations provided by the system. Other levels are automatically upgraded based on the points earned through the correct marking of records. Next, the reporter can submit phishing records in PhishRepo, either manually or automatically. The beneficiary user connects with PhishRepo to download phishing data only. Since the data distribution process needs a registered user type, the beneficiary type is added to the proposed solution. Consequently, the guest user can only view the public information related to phishing records and use search facilities to search available phishing web pages in the repository. Fig. 2 shows the landing page of PhishRepo that is visible to all the accounts mentioned above.

A valid email is required when creating a PhishRepo account, and the administrator is responsible for the final confirmation of a new account. Since a human user or an anti-phishing tool could become a reporter, the reporter account has two subscriptions: individual or corporate. The anti-phishing tools always act as a corporate reporter, and those accounts own an application key for authentication. Further, the cor-

Fig. 2. The Landing Page of PhishRepo

Fig. 3. A Captured Screenshot of a Visible Web Page

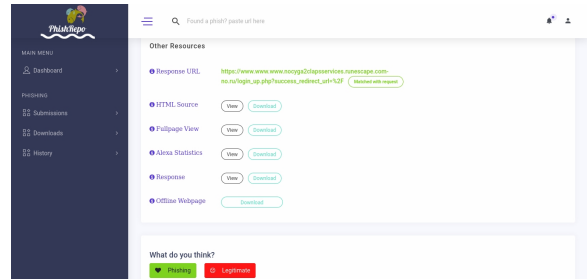

Fig. 4. PhishRepo Displays Additional Information Sources under the Other Resources Section. The Registered user can Download or View that Information Relevant to a Submission.

porate account has an optional field called ‘return address’, which sends daily updates about the submissions. Section IV-C discusses this option in detail.

PhishRepo uses two authentication methods. 1). A login form 2). An application key. The first method is the standard approach in most scenarios, and it uses a username and a password for the verification process. The second one is only applicable to corporate accounts like anti-phishing tools and is only used when an automatic submission is processed with PhishRepo. In that case, the corporate account user must follow the predefined data format to submit a phishing record.

However, one request can submit only one phishing record, and multiple requests are required for numerous submissions. After the authentication is done, it checks for duplication within the repository through URL string matching, and if no duplication is found, the URL is added to the Initial Phishing Records (IPR) queue alongside the submitter information. In PhishRepo, the IPR queue is a double-ended queue (deque) that uses first-in, first-out (FIFO) logic.

2) *Accumulation*: This component is crucial in PhishRepo since it is responsible for the data collection. It starts once a request comes from Server A (Fig. 1). First, it tries to download the complete web page of the submitted URL. If the download process fails due to any exception, the accumulation component skips that URL and moves to the next since the web page is a vital and mandatory information source in PhishRepo. Meanwhile, the data collection process captured the response details and saved them under the record because, in some cases, there can be some mismatches in request and response details which may be helpful in the verification process. After the web page download is done, the screenshot of the web page is captured in full view and visible level (Fig. 3). Then, the possible third-party information is downloaded. This information is kept as additional information (Fig. 4) in PhishRepo and is not mandatory due to the service limitations that exist in the third-party services.

3) *Deduplication*: Deduplication is crucial in PhishRepo that eliminates redundant data such as duplicate phishing pages with the same target. At the beginning of the input module, the authentication component takes the necessary actions to eliminate duplications based on the URL. However, the different URLs do not guarantee that duplications could be avoided in a phishing dataset since most phishing pages are created using phishing kits [4] and released to the public. Therefore, a dataset could have different URLs for similar page structures, as shown in Fig. 5 and make duplicates to machine learning processes that cause data leakage at the end.

In that context, PhishRepo's deduplication component is responsible for eliminating such duplicates with the support of the Perceptual Hashing (pHash) technique [49] that was exercised in the literature for similar scenarios [50]. The component handles the elimination of duplicates as an inline task that affects before saving the accumulated phishing records to the local storage or database, as shown in Fig. 1. Therefore, none of the submissions is identified as duplicate records kept in PhishRepo's repository.

The deduplication process depends on the visual level screenshot downloaded during the accumulation process. It uses the pHash technique to determine the similarity of two phishing pages, and PhishRepo maintains a list of hashes computed for the saved records. During the filtering process, a perceptual hash value is first generated for the newly captured screenshot and compared with the already stored hash values to check whether the new one is a duplicate of an already saved web page. The comparison is made through the distance factor (d) calculated using the two instances' hash values. However, if an exact matching is found ($d = 0$), one of the records will be removed from the repository to address the redundancy factor. In that case, which one to eliminate is dependent on the PhishRepo's setting called 'Dedup Action'. The Dedup Action has two values: new and old. If the value 'new' is enabled, the component will save the new record and remove the old one from the repository, and in the other way, it is not going to save the new record, and the old will remain. The setting is introduced just to have a flexible deduplication process within the PhishRepo, and the administrator is responsible for activating a specific Dedup Action to have a diverse phishing data collection.

Since the deduplication process depends entirely on

the screenshot captured during the accumulation process, PhishRepo is configured to check for near-duplicates for a given period to eliminate any page loading issues during screen capturing. However, it is not practical to check near-duplicates of a new screenshot with all the available records in PhishRepo since the comparison process takes time. Therefore, the deduplication component checks for near-duplicates only for the last three days since most phishing attacks end within three days [51], [31]. Then, theoretically, PhishRepo assumes that the near-duplicates that may exist out of the three days are different phishing attacks.

However, there should be an optimal distance threshold (d_α) for a meaningful selection for the near-duplicates. Therefore, d_α is selected based on 1,000 random samples from an older version of PhishRepo that does not include the deduplication component. Then, pHash values of the screenshots available in the sample were computed, and each pair's d values were calculated. After that, a manual investigation was carried out to examine the accuracy and noted that the accuracy of the similarity of a pair had been decreased drastically when d became more than 10, as shown in Fig. 6. Therefore, d_α was selected as 10, and $0 < d < 10$ are considered near-duplicates in PhishRepo. However, the near-duplicates elimination process does not affect the Dedup Action setting, and if a near duplication is found, the new submission will be entirely discarded from PhishRepo to maintain a diverse phishing data repository.

4) *Targeted Attack Prevention (TAP)*: The main intention of PhishRepo is to collect phishing data to strengthen future anti-phishing tools against phishing attacks. That intention creates opponents (i.e., phishers) to PhishRepo. Therefore, PhishRepo may become a victim of some targeted attacks to disrupt the data collection process of the repository. The denial of service (DoS) attack is a possible threat [36], and there can be other specific attacks like false data injections. However, the network architecture presented in Fig. 1 strengthens the network level protection to a certain extent, and the implemented TAP component provides application-level protection to PhishRepo. The TAP component uses four strategies to have additional application security other than the standard security practices.

- Application key-based authentication – only the users with an application key can submit records automatically
- High-volume restriction – limit number of submissions from one corporate account
- Maximum IPR queue length – limit the number of request processes by the accumulation component
- False ban – Bans the reporters who have falsely recorded submission trend

As described in the authentication component, all the reporters should have an application key when submitting a phishing record automatically to PhishRepo. It limits the attacking trend since the attacker must obtain a valid application key to enter the system. If an attacker comes with a proper application key, then the subsequent countermeasures try to minimise the impact of those attacks. First, a high-volume restriction policy is implemented in PhishRepo to submit only

(a) <https://cbahospitalar.com.br/002WG/well-fargo-RD528-detail/>

(b) <https://mail.cbahospitalar.com.br/002WG/well-fargo-RD528-detail/>

Fig. 5. Different URL Examples for the Same Phishing Target

Fig. 6. Estimation of Distance threshold d for Near-Duplicate Detection

a limited number of records for a given period from one reporter. Since the chance of seeing a phishing URL is lower than a legitimate one [22], there is no possibility of submitting many records within a given period since PhishRepo requires real-time submission and discourages batch processing. As previously mentioned, the submissions come as requests, and one request carries only one submission. Therefore, the number of submissions equals the number of requests from a reporter side. Then, if he exceeds the limit (i.e., ten requests per minute), his account is automatically banned for five minutes, and if it is frequent, the account is blocked permanently by the TAP. Further, TAP is responsible for reporting abnormal behaviour to the administrator, and the administrator can take necessary actions on those.

In a specific situation, if an attacker bypassed both the mentioned countermeasures, the maximum IPR queue length is used to maintain a fixed-length queue to avoid overloads of the memory. Then there may be no performance hits, and PhishRepo may function without interruption. However, since the accumulation component takes URLs from the IPR queue, some submitted records may be removed without processing in a special attack. Although it seems wasted, PhishRepo does not intend to collect all the submitted phishing records and work only with the possible submissions when expanding the available phishing records.

In addition, the false ban strategy is another security consideration used in PhishRepo to avoid wrong data injections. The incorrect data may damage the proposed solution's trustworthiness and waste many resources. Therefore, PhishRepo is used to verify whether the collected phishing records are correct. That process is discussed in detail under Section IV-B. This false ban strategy checks the validity of the submitted phishing records week by week for each reporter and calculates an accuracy percentage. If the rate is less than a defined threshold value for an account, that account is suspended automatically and reported to the administrator for further actions.

5) *Manual Submission*: This component is implemented to cater to the generic manual submission needs. However, manual submission is not entertained in PhishRepo since real-time phishing records are required to store correct information sources. In some cases, a manual submission may be a particular need. Therefore, this component is added to the PhishRepo. Manual submission is a simple component, and the primary responsibility is to collect the phishing URL from the interface and send it to the accumulation module to process it further.

B. Verification Module

PhishRepo verifies all the submitted phishing records regardless of the source it gets. It is a two steps process named alpha verification and beta verification. Fig. 7 represents the workflow of the verification process, and the main two steps are explained in detail in the following sub-sections.

1) *Alpha Verification*: It is the first verification done by the PhishRepo after a record is successfully added to the repository. This alpha verification is done using two popular phishing verification solutions in the current context: Phish-Tank and Google Safe Browsing (GSB) [30]. These solutions have free Application Programming Interface (API) support to get information about phishing sites. Therefore, the collected URLs are submitted to both these services. If one or both marked the submissions as phishing, the verification module flags the relevant records as 'verified'. When the verification solutions do not provide any result for a specific submission, in that case, that record is marked with a 'processed' flag. It indicates that the alpha verification is processed on the record

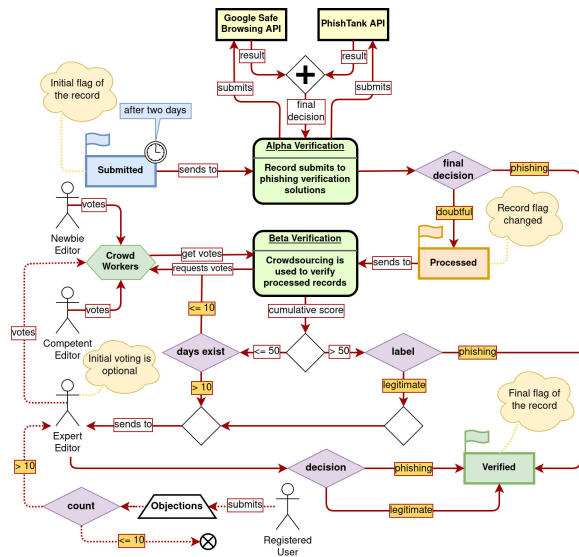

Fig. 7. PhishRepo's Record Verification Process

but is yet to be finalized. However, this alpha verification is not executed immediately after adding a new phishing record to the repository. It waits 24 hours because phishing URLs are not added instantly to the blocklists, and 47%-83% are added after 12 hours [20].

2) *Beta Verification*: Beta verification manages only the 'processed' flagged phishing records—i.e. the records which have an unsuccessful alpha verification attempt. As the name implies, beta uses a crowd to collect opinions about the submitted record. Therefore, it is a crowdsourcing approach. As explained in Section III, crowdsourcing could be a tool to gather collective intelligence for a specific task like data labelling. Therefore, PhishRepo strategically uses this crowdsourcing technique to verify 'processed' flagged phishing records in beta verification. The editor is the leading actor in the beta verification. Out of the available editors, the expert editor is the final decision maker of an incorrect submission and gets a record if it gets majority voting as legitimate by a newbie or competent editor, or the record passed ten days from submission. However, the newbie, competent and expert levels have different impact points in the voting process. For example, suppose there is an incorrect submission. If a newbie marked it as legitimate, it has a 10% impact. If a competent level user is marked, the impact is 25%. However, the expert editor is the chief editor in PhishRepo; thus, he receives a 100% impact point.

Beta verification is done through a voting scheme. As seen in Fig. 8, each 'processed' flagged record appears to the editors to vote as phishing or legitimate (Fig. 4). Then, the editor can select either phishing or legitimate to award points for the verification process. For example, if a newbie selects one record as phishing, then the record gets 10 points to the phishing label. If a competent level user selects the same, the record receives 25 points. However, based on the ACMR strategy, the record needs to collect more than 50 points on the phishing label to become a verified record in PhishRepo.

In PhishRepo, the voting is both positive and negative.

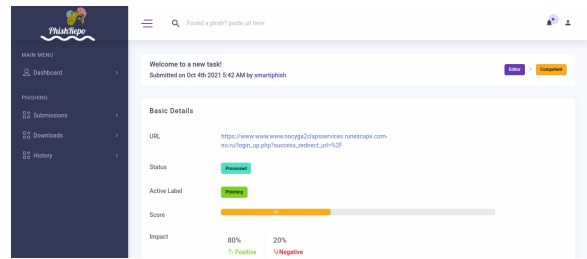

Fig. 8. PhishRepo has Displayed Basic Information to an Editor, such as the URL, Current Status, Active Label, Score, and the Impact of the Submission.

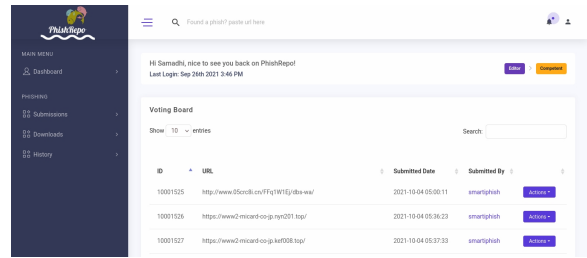

Fig. 9. Editor's Voting Board

After a newbie marked a record as phishing, suppose that the same is recorded as legitimate by a competent user in the scenario mentioned above. Then, the PhishRepo checks the voting trend in that record, and since the voting trend is now on the phishing label, the record gets the new mark of -25, and the final score becomes 15 on the legitimate side. However, as a general rule in PhishRepo, if a record contains less than 50 points either in phishing or legitimate remains as a 'processed' flagged record and any record with more than 50 points on the phishing label upgrade verified state automatically. Further, if a record achieves more than 50 points on the legitimate side, the record is sent to an expert editor for review and is responsible for the final decision. However, after a record comes to a verified state, PhishRepo welcomes objections through the objection reporting module in the proposed solution. Therefore, all the user accounts except guests could raise objections to a verified phishing record, and if there are several objections, the expert editor reviews the record again. The expert editor could disable future objections at the review time to avoid misuse of the objection process. However, if a record exists in the repository for more than ten days without being verified, it appears in the expert editors' voting board to get their attention. Fig. 9 shows the voting board interface of an editor.

Further, PhishRepo uses unique design considerations to avoid cognitive bias throughout the beta verification. That hides the scoring history from all the editor levels and displays only the final score through a progress bar. Then the editor does not get to know any past editors. However, the expert editor gets an additional detail called impact, which describes how many negative (i.e., legitimate) and positive (i.e., phishing) votes were earned by a record when it comes to the current state. Further, PhishRepo always receives a brief explanation about the submitted label to avoid doubtful labels by asking a simple question from the editor such as *Can you find the targeted website?*, and *Can you find this website in the Google*

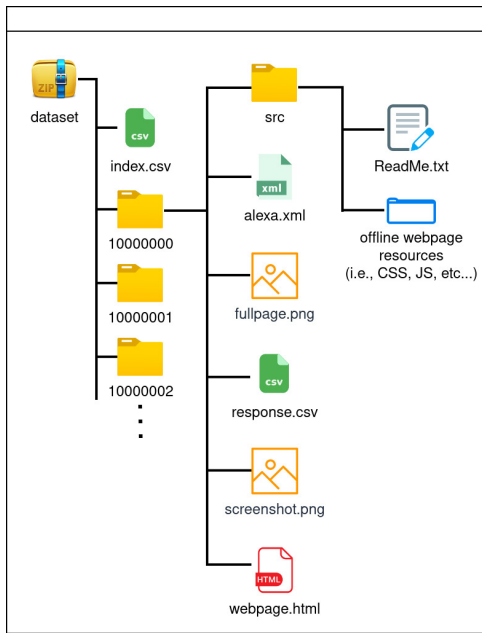

Fig. 10. The Hierarchical Structure of the Zip File

search engine?. The ultimate goal of these questions is to give a second chance to the editor to think about the decision before submitting it to PhishRepo.

C. Distribution Module

Data distribution is the primary goal of PhishRepo. Therefore, the distribution module plays a vital role in the proposed solution. However, the distribution module is only available for registered accounts, and as mentioned before beneficiary user type is specifically designed to support this process. PhishRepo provides several diverse information sources in raw format for each download. Those are the HTML page, visible level and full-page screenshots, response return for the made request, Alexa statistics and offline web page. Further, PhishRepo facilitates the data distribution in two ways: user queries and reporter subscriptions.

1) *User Queries*: The registered users can log in to PhishRepo and query for phishing data. PhishRepo requests data duration and the information sources required by the user. The full dataset could be downloaded from a separate menu item, and it includes all verified phishing records available in PhishRepo. The user query is either for total data or selected data; the final output of the download process is a zip file that includes an index file for easy navigation. Then it is available for users to download. Fig. 10 shows the hierarchical structure of the downloadable zip file.

However, there could be situations like the information sources missed in some folders due to exceptions in the accumulation process. In that case, the index file is vital to find out what is missing since it has columns like an eight-digit number that holds the mapping between the index file and the dataset folders, the request URL, the response URL, the data collection date, and attributes indicating the presence of the visible level screenshot, full-page view, Alexa statistic file, the offline web page, and response header file.

TABLE I. DETAILS OF THE USED PHISHING DATASETS

Dataset Name	Number of Data	
	Phishing	Legitimate
PhishRepo	5,275	0
Ex-PhishRepo	2,029	0
Web2Vec [19]	21,296	24,800
PhishPedia [38]	29,048	22,252

2) *Reporter Subscription*: The reporter subscription module's primary purpose is to give corporate reporters a unique benefit for their vital contributions. So far, it is clear that the corporate reporter is the key user who runs the proposed solution for the long term. Therefore, the PhishRepo is designed to automatically send feedback on what they have reported to the repository to encourage and admire the corporate reporter. As mentioned earlier, the reporter account has a particular field called 'return address'. PhishRepo uses this field value and sends daily feedback to the corporate reporter for their submission. However, feedback for a particular record waits until PhishRepo confirms the records label and keeps track of the sent feedback to avoid any duplication of feedback. The feedback report is sent as a CSV file in PhishRepo.

V. EXPERIMENTS AND RESULTS

The study used two main experiments to evaluate PhishRepo from diversity and its effectiveness in machine learning-based anti-phishing studies. Four primary datasets were used in those experiments, including two recently used public phishing datasets that include the URL, HTML page and screenshot of the relevant phishing instances.

A. Datasets

The four datasets used in the experiments are Web2Vec, PhishPedia, Ex-PhishRepo and PhishRepo. Table I presents the details of those datasets.

The PhishRepo and Ex-PhishRepo datasets were downloaded from the online phishing data repository presented in this paper. However, the Ex-PhishRepo dataset was downloaded before the deduplication component (Section IV-A3) was introduced to the proposed solution. Therefore, duplicate or near-duplicate phishing web pages were not filtered in the Ex-PhishRepo data. The PhishRepo dataset was downloaded after the deduplication filter was influential in the presented work. Therefore, the impact of the filter should be visible in the PhishRepo dataset. The initial level phishing URLs for both the Ex-PhishRepo and PhishRepo datasets were downloaded from PhishTank and OpenPhish. Therefore, the phishing data available in both datasets were valid phishing instances, and both datasets were available online [52] for further reference. Moreover, the Ex-PhishRepo dataset data were collected by the PhishRepo system from 29 September 2021 to 17 October 2021, and the PhishRepo dataset data were collected from 23 October 2021 to 02 February 2022.

The Web2Vec dataset is an online phishing dataset (<https://github.com/Hanjingzhou/Web2vec>) recently used by [19] when developing their anti-phishing solution. The dataset contained 21,303 phishing instances from PhishTank from September 2019 to November 2019 [19]. However, the current

work only could use 21,296 instances out of the total phishing instance of the dataset due to some data extraction issues. Similarly, the PhishPedia dataset is also a recently used phishing dataset by [38]. It contained 29,496 phishing web pages, and OpenPhish's premium account was used when downloading those data. The authors have publicly shared the dataset and are available online (<https://drive.google.com/file/d/12ypEMPRQ43zGRqHGut0Esq2z5en0DH4g/view?usp=sharing>) for anyone to download. The study could only use 29,048 phishing items from the PhishPedia phishing dataset since few data items reported some issues during the extraction.

Since the proposed PhishRepo solution distributes only phishing attack-related data, the PhishRepo and Ex-PhishRepo datasets do not contain legitimate data, as shown in Table I. However, recent anti-phishing studies already used the Web2Vec and PhishPedia datasets. Therefore, both these datasets were attached legitimate data used by those studies, and Alexa was the source for legitimate data in both cases.

B. Diversity of PhishRepo

The main objective of PhishRepo is to provide a diverse phishing dataset for machine learning-based anti-phishing studies. Therefore, PhishRepo output was evaluated from different perspectives to check whether the proposed solution achieved a diverse dataset. However, there is no widely accepted method to check the diversity of a dataset [22], but [22] have proposed two main criteria to use when measuring the diversity of a phishing dataset. Those are the number of different domains and the number of different top-level domains (TLDs). However, literature has shown that the HTTPS based phishing attacks and URL character length distribution are also essential to consider in the current phishing attack nature to have unbiased, accurate model training at the end [53], [7].

Even though these four could be taken as standard criteria to check the diversity, none of the studies in the literature considered the tendency of data leakage in a dataset that has been discussed in Section IV-A3. However, the current study has identified it as an essential factor and used it as the fifth criterion to check the diversity of the PhishRepo dataset. Although Table I presents four datasets, the PhishRepo and Ex-PhishRepo datasets had the exact behaviour in one to four experiments since the deduplication filter was the only noticeable difference in those two datasets. Therefore, the Ex-PhishRepo dataset was not used as a separate dataset during one to four experiments, and it was effectively used in experiment five to show the impact of the deduplication filter.

1) *Distribution of Domains and TLDs*: The domain and TLDs distribution of a dataset depends on the URL of the phishing page. Therefore, the study first extracted unique domains and TLDs from each dataset. Then frequencies of those were calculated separately. After that, the top fifty domains and TLDs were selected from each dataset. Finally, the percentage of the selected domains proportionally to the size of the relevant dataset was calculated, and those values were plotted in ascending order to have the relevant distribution. Fig. 11 and 12 shows the distribution of domains and TLDs, respectively.

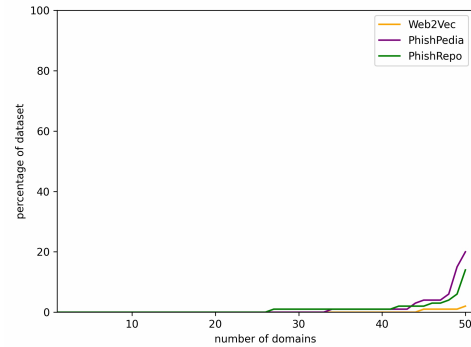

Fig. 11. Distributions of Domains in each Dataset

Fig. 12. Distributions of TLDs in each Dataset

As shown in Fig. 11, all the datasets have used more than fifty different domains and TLDs. PhishPedia had a high percentage of the same domain among all datasets, and it was 20% relative to the entire dataset. The PhishRepo dataset had 14% of the same domain, and Web2Vec recorded the lowest number of the same domains. However, the situation is slightly different regarding TLD distribution, as illustrated in Fig. 12. The three datasets have used more than 50% of the '.com' TLD, and it is acceptable because the popular TLDs like '.com' are more often used in phishing nature [22]. Although '.com' acquired a high percentage in all three datasets, more than 50 different TLDs have been included in Web2Vec, PhishPedia, and PhishRepo datasets. Such distribution in domains and TLDs signifies a diverse dataset [22]. Therefore, PhishRepo's dataset is diverse in the perspective of the distribution of domains and TLDs.

2) *URL Character Length Distribution and Percentage of HTTPS*: The current anti-phishing domain is more toward representation learning approaches like deep learning [12], [17], [18], [19], and it results in black box models that do not visualize the features used during the decision making [12]. Therefore, if a phishing dataset does not have a standard distribution in URL character length as presented in [14] work, it may result in inadequate models for real scenarios [53]. Further, as shown in the APWG report [7], more than 80% of present phishing attacks have come with the HTTPS label, indicating that a high percentage of HTTPS in a phishing dataset is also vital to have a realistic scenario during the model training. Therefore, the number of characters in a URL and

Fig. 13. Character Length Distribution in each Dataset

Fig. 14. Percentage of Secure Phishing URLs in each Dataset

percentage of secure phishing URLs proportionally to the size of the relevant dataset was calculated to have URLs character length distribution and percentage of secure phishing URLs.

According to Fig. 13, the URL character length in all three datasets has shown a standard distribution. The highest number of PhishRepo URLs belonged to the 20 to 40 character length category. The other two datasets had a high percentage of 40 to 60 character length URLs. However, all three datasets had URLs under different categories, indicating that these three datasets are diverse in terms of URL character length. In contrast, the secure URLs were deficient in the Web2Vec and PhishPedia datasets. Fig. 14 visualised that the Web2Vec and PhishPedia datasets had 3% and 33% secure URLs. However, current statistics highlighted that nearly 80% of phishing URLs are used HTTPS in the current phishing context [7]. Since it is not reflected in the Web2Vec and PhishPedia datasets, it may lead to inadequate models when these datasets are used in training. However, PhishRepo is shown a high percentage of secure phishing instances, and it has more than 70% of the used dataset. It indicates that the PhishRepo dataset is up to date, and the present phishing nature is sufficiently absorbed.

3) *The Tendency of Data Leakage:* Data leakage is one of the leading machine learning errors and results in poor prediction outcomes. It happens when the information used in the model train appears during testing time. In the context of phishing data, this can happen in two ways. First, the same data is used multiple times, like the phishing website <https://xyz.com> appears on many occasions in the dataset. Next, it can happen due to different URLs for the same

Fig. 15. Percentage of Duplicates and Near-Duplicates of each Dataset

phishing website, as shown in Fig. 5. In both cases, data leakage could happen if the percentage of duplication pairs is high. Therefore, the current study's data leakage tendency is measured based on the number of duplication pairs available in the used datasets. However, none of the previous studies used such a test to check the tendency of data leakage, which may be the first of its kind.

The experiment used the captured screenshots of phishing web pages since the phishers are always trying their best to have a similar fake page compared to the target page. Therefore, the current study assumed that web pages with similar appearances have the same HTML structure. The assumption is valid in most cases since most phishing websites are coming through phishing kits nowadays [4]. However, the failure of the mentioned assumption will not affect the result of the experiment since the tendency of data leakage is calculated using the number of duplicates. Further, the experiment used a commercial tool called pixolution Flow (<https://pixolution.org/>), an AI-powered visual search engine for managing and searching visual data when finding duplicates and near-duplicates. The pixolution Flow has a docker image that could index up to 5,000 images free, and that docker is used during the experiment. Therefore, 5000 random samples were selected from each dataset using the pixolution docker before starting the experiment.

The experiment used a 1.0 threshold when searching for duplicates, and the near-duplicates search was configured to use a 0.9 threshold since it is the recommended threshold by the tool. The duplicates and near-duplicate percentages of each dataset are presented in Fig. 15. However, during the indexing step of the tool, the Web2Vec dataset could not index all the screenshots listed since twenty-two images had some issues. Therefore, the presented percentages of the Web2Vec dataset are calculated from 4,978 data items.

After introducing the deduplication component, PhishRepo has improved by decreasing the duplicate images to 0 and keeping the near-duplicate percentage around 20, as shown in Fig. 15. Further, the experiment shows that the other datasets, Web2Vec, PhishPedia and Ex-PhishRepo, have higher duplication percentages (Fig. 15) than PhishRepo. Therefore, the study can claim that the present version of the PhishRepo dataset does not tend to leak data since it does not contain any duplicate pairs. However, phishing cannot eliminate the near-duplicates since phishers mainly target popular web-

TABLE II. ANTI-PHISHING SOLUTIONS USED IN THE EXPERIMENT

Solution	Description
URLNet ^a [54]	A deep learning approach that detects malicious URLs directly from the URL.
StackModel ^b [14]	Detect phishing attacks with the support of URL and HTML content features.
HybridDLM ^c [16]	A deep learning model uses direct URLs with manually extracted HTML content features.

^a<https://github.com/Antimalweb/URLNet>

^bhttps://drive.google.com/drive/folders/1T4uHRxb_Uk5_kXcJrq68mZ-ezWSQgs_e

^c<https://github.com/sna-hm/HybridDLM>

sites, and those attacks may have slight differences. Although PhishRepo’s deduplication filter is configured to discard near-duplicates, it checks near-duplicates only three days from a given date due to the previously mentioned practical limitations (Section IV-A3). Therefore, this experiment concludes that the PhishRepo dataset is well-suited for machine learning-based anti-phishing tasks from the perspective of data leakage.

Additionally, based on the experiments mentioned above, the study has shown that the proposed solution, PhishRepo produces a diverse dataset, and it is more suitable for machine learning-based phishing detection studies.

C. PhishRepo’s Effectiveness in Anti-Phishing Studies

The ultimate goal of PhishRepo is to provide a phishing dataset for machine learning-based anti-phishing studies. Therefore, a different experiment was performed to prove the effectiveness of PhishRepo’s output compared to recently used public phishing datasets. The Web2Vec and PhishPedia datasets were selected for this purpose since both are similar to a certain extent to the PhishRepo dataset from the perspective of the available information. Further, these two datasets were already exercised with two recent anti-phishing solutions [19], [38] that have shown high performances. Therefore, these two datasets, alongside the PhishRepo dataset, were used to train several existing machine learning-based anti-phishing solutions (Table II) separately and evaluated those against the latest phishing attacks.

1) *Train and Test Datasets:* PhishRepo is an online phishing data repository that expects to grow with time. Although PhishRepo is in the early stage of its journey, it managed to collect around 5000 latest phishing data, and this experiment was planned with these data to compare the effectiveness of PhishRepo data with the state of arts phishing datasets.

Generally, a machine learning model needs a training and test dataset. Therefore, as the first step, the required datasets were constructed. However, the primary intention of the proposed PhishRepo solution is to produce the latest phishing data for anti-phishing studies. Therefore, the experiment required the latest phishing data for the evaluation process. Out of all the selected datasets, the PhishRepo dataset had the latest phishing attacks since it collected phishing attacks up to 02 February 2022. Therefore, the last ten days of phishing attacks were initially separated from the PhishRepo dataset and had 518 records. Those 518 records were added to the test dataset under the phishing label, and the remaining data (i.e. data up to 21 January 2022) were selected as PhishRepo’s training dataset.

Fig. 16. Legitimate URL Character Length of Web2Vec and PhishPedia

It had 4,757 data, and the amount is reasonable to train a machine learning-based anti-phishing solution since [18] also did a successful anti-phishing study with 4,700 total phishing instances.

The experiment was planned to change only the phishing examples during the training. Therefore, other factors such as the dataset’s size, the legitimate examples seen by the solutions and the test dataset, including phishing and legitimate, were kept constant. Since the number of phishing examples needs to be the same in all three cases, 4,757 phishing data were randomly selected from the Web2Vec and PhishPedia datasets to construct the Web2Vec and PhishPedia training datasets.

Next, the experiment required legitimate examples for effective learning. Table I shows that the Web2Vec and PhishPedia original datasets had a legitimate collection. However, those legitimate data were collected from Alexa. If a legitimate dataset is constructed using Alexa without a specific strategy and mixed with a phishing dataset collected from PhishTank, the URL character length plays a significant role and may produce malfunctioned classifiers [53], [22]. Therefore, the Web2Vec and PhishPedia datasets were initially examined by plotting the character length of available legitimate URLs. Fig. 16 shows the character length distribution of those legitimate URLs. It visualises that the mentioned URL character length issue exists with both Web2Vec and PhishPedia legitimate data compared with phishing URL character length available in Fig. 13. Since it affects the final evaluation process of the planned experiment, Web2Vec and PhishPedia legitimate data were not used to construct the training dataset. Therefore, an online phishing dataset named Phishing Websites dataset [55] was used to collect the required legitimate data since it had a reasonable URL character length distribution compared to the [14] work, as shown in Fig. 17.

The experiment planned to have a balanced dataset during the training. Therefore, 4,757 and 518 legitimate data were randomly selected from the Phishing Websites dataset for the training and test datasets. Finally, the training and test datasets contained 9,514 and 1,036 data. Since the experiment wanted consistent legitimate data to effectively evaluate the PhishRepo dataset performance, the same legitimate training samples were added to the Web2Vec, PhishPedia and PhishRepo training datasets. The test dataset was similar in all the experiments, and it has used to evaluate the selected model’s performance in each case.

Fig. 17. Legitimate URL Character Length of Phishing Websites Datasets

TABLE III. TRAINED MODELS' PERFORMANCES WITH EACH DATASET

Solution	Dataset	Accuracy	f1-Score	FNR*
URLNet	Web2Vec	72.20%	70.79%	0.326
	PhishPedia	78.09%	77.72%	0.236
	PhishRepo	82.24%	83.45%	0.104
StackModel	Web2Vec	58.11%	36.55%	0.759
	PhishPedia	75.87%	69.96%	0.438
	PhishRepo	89.00%	88.97%	0.112
HybridDLM	Web2Vec	67.18%	51.98%	0.645
	PhishPedia	88.22%	87.07%	0.207
	PhishRepo	93.92%	93.89%	0.066

*False Negative Rate (FNR): The number of phishing instances is marked as legitimate proportionally to all existing phishing instances.

2) *Performance Evaluation:* First of all, Table II anti-phishing solutions were separately trained using the Web2Vec, PhishPedia and PhishRepo training datasets. Then, these models were evaluated using the test dataset. The obtained results during the evaluation process are shown in Table III. However, the URLNet experiment had different models based on the used embedding values, and the best-performed model was selected to present the final results.

As shown in Table III, the PhishRepo dataset has shown high accuracies and f1-score and low FNR in all three cases where the PhishRepo dataset was used. Since the datasets size, legitimate examples, and test dataset were constant in all cases, the phishing examples made the performance difference in each dataset. It implies that the models effectively learned most phishing scenarios with the PhishRepo dataset, and it is more effective when presenting phishing examples for the used models.

Although the PhishRepo dataset has shown some significant performance, one might argue that it is due to the latest phishing examples it contained. However, that is the main objective of the current work. The machine learning-based anti-phishing studies lack the latest phishing data. Therefore, most models are trained with old phishing data, and those models may not perform well with the latest phishing attacks since phishing characteristics constantly change over time. That is what exactly happened during the performed experiment. Since the test dataset contained the latest phishing attacks and both Web2Vec and PhishPedia had old phishing examples, current significant phishing characteristics might not be captured during the training. However, PhishRepo is constantly collecting these phishing examples. Therefore, it contained the latest

phishing examples, and more significant characteristics are existed in PhishRepo examples to detect the latest phishing attacks. Thus, the model trained with the PhishRepo dataset captured these new characteristics and performed well with the latest attacks.

Furthermore, as shown in Fig. 15, the PhishRepo dataset does not contain duplicate phishing examples. However, in Web2Vec and PhishPedia, duplication is over 50%. Therefore, compared to the PhishRepo dataset, the Web2Vec and PhishPedia datasets may contain fewer unique phishing examples. Then, although the training dataset size is equal, the amount of learning a model can gain through the training set becomes lower in the other two datasets than in the PhishRepo dataset due to the high duplicate phishing instances available. Therefore, PhishRepo output is more suitable for machine learning-based anti-phishing studies since it produces the latest diverse phishing examples for an effective learning process.

VI. DISCUSSION

Machine learning-based phishing detection desires labelled phishing data at present. The unavailability of such data directs anti-phishing research into many challenges. Some of them are, lingered data collection, data obsolescence, low-quantity data, low-quality data, and lack of multi-modal feature representation. These challenges result in inept learning models, weakening the effort to combat phishing. Therefore, it is essential to fill the current gap in the anti-phishing domain to strengthen future detections. As a result, PhishRepo is introduced as a gap-filling solution to deliver future phishing data needs in the anti-phishing domain. However, it is not just a way of storing data; it is responsible for the latest quality data dissemination to enrich the effectiveness of the anti-phishing solutions.

Phisherman [36], [35] is the only solution in the literature with the same aim as PhishRepo. However, PhishRepo is conceptually superior to Phisherman in many design aspects. Some examples include a deduplication filter, a crowdsourcing-based verification process, malicious submission detection, and the ability to report objections. PhishRepo generally benefits from automated submission architecture, and its design allows it to access a variety of information sources in raw format. Furthermore, the deduplication filter ensures diverse data collection and the elegant verification process used in PhishRepo results in high-quality data. The objection reporting helps to maintain the quality even more. Moreover, the innovative data distribution structure is purposely designed in PhishRepo to attract users, primarily autonomous anti-phishing tools. These tools could integrate PhishRepo more thoughtfully to handle the constantly changing phishing attacks. Further, the proposed network architecture and TAP strategies are critical for the solution's smooth operation from a security perspective.

PhishRepo is a phishing data repository that is accessible online. As a result, anyone interested in the solution could gain access to it and obtain the final benefit, the data. The primary audience for PhishRepo is anti-phishing researchers. They can use this solution effectively to eliminate the phishing data hassle. Since the repository includes multi-modal features, the researcher could use PhishRepo to take their research in a new direction. Furthermore, the raw format in PhishRepo supports

representation learning approaches such as deep learning to design differentiated anti-phishing solutions. It is further intended to support reinforcement learning (RL) environments because PhishRepo includes an interactive feedback facility. With this facility, an implemented RL environment could submit its actions for specific observations and receive quality feedback from PhishRepo. Therefore, the data collected by PhishRepo could aid anti-phishing researchers in various ways, allowing them to conduct more effective research. In addition to such, PhishRepo is an excellent solution for data drifting, which mainly affects machine learning models' performance [21], [22]. Therefore, the latest data collected by PhishRepo could be used to retrain existing models to retain their performance in the fast-evolving nature of phishing.

Moreover, PhishRepo is the first study to examine the tendency of data leakage in a phishing dataset in the anti-phishing domain. It found that the deduplication filter introduced in this study causes no data leakage. The experiments conducted to demonstrate the efficacy of the PhishRepo data have also demonstrated that the data are diverse and do not contain duplicate data, which could lead to a data leakage problem. Furthermore, PhishRepo has been compared with two recently used public datasets using three anti-phishing solutions. There also, PhishRepo outperformed other datasets by achieving high detection accuracy, f1-score and low FNR by showing the strength of the proposed solution.

However, the reliability of PhishRepo is primarily determined by the submissions it receives. Therefore, reporters are essential to the proposed architecture, and corporate reporters are critical because PhishRepo encourages real-time submissions rather than manual ones. Another essential role in PhishRepo is the editor, particularly the crowd user, who is always critical to the success of the beta verification process. However, alpha eliminates the need for a beta. Therefore, PhishRepo assumes that few editors can manage beta verification in the early stages. However, the contributions of the reporters and editors are critical for PhishRepo to continue its process and achieve its ultimate goal.

As a general limitation of the solution, the third-party services' availability is critical in PhishRepo, and the failure of some may affect the solution's continuity. Therefore, PhishRepo expects a collaborative effort against phishing rather than individual combat. Further, a few more anti-phishing communities could be integrated into the alpha verification process to strengthen the alpha process and reduce the human workload in the verification. Moreover, archiving some erroneous pages (e.g., 403 pages, 404 pages, and content not found pages) impacts the PhishRepo data quality. Therefore, additional work will be required in the future to automatically detect erroneous or unwanted pages via web page screenshots and remove such data points from the repository. Then, the quality of the PhishRepo data could be improved further, providing researchers with significantly less noisy data.

VII. CONCLUSION

While machine learning methods are gaining popularity in phishing detection, the lack of labelled data limited the viability of machine learning-based anti-phishing solutions. Large-scale, diverse data sources are essential in phishing

detection in today's context, and it helps researchers have effective machine learning models to combat phishing in the future. PhishRepo comes under these circumstances, and it is an online phishing data repository that collects, verifies, disseminates, and archives real-time phishing data. PhishRepo uses a tactical approach from collection to dissemination. Therefore, it always guarantees the quality of data it saves. Further, automated submission, deduplication filtering, automated verification, crowdsourcing-based human interaction, objection reporting window, and security considerations outperform PhishRepo over similar solutions in the phishing domain.

However, the proposed gap-filling solution's reliability depends on its submissions. Although it is a limitation, PhishRepo identifies its importance and promotes specific tactics to bind users to the solution. Therefore, PhishRepo will be an essential service to provide quality labelled multi-modal feature-based phishing data to detect phishing attacks effectively in the future.

A Novel Code Completion Strategy

Abstract—Programmers rely on a multitude of techniques to speed up the development process. Among these techniques is code completion, a productivity improvement technique widely used by developers to explore APIs and automatically complete a word being typed by providing a progressively refined list of candidate words (or recommendations). Still called auto-completion, it reduces incorrect calls to APIs. Several techniques have been developed to obtain the list of candidates. Some methods use the history of the code, others neural networks or artificial intelligence; some exploit the program's structure through AST. Often the recommendation list is long, and finding suitable candidates comes at a cost. In this work, we propose a strategy that improves the accuracy of recommendation list offered by code completion. We present a sorting approach based on the popularity and importance of the elements (suggestions) of the list by analyzing the usage data of classes, methods, and variables of projects in the same development environment. We implemented our sorting strategy in Pharo (IDE and language), an immersive modern programming environment to show its applicability. The empirical evaluation results of this strategy show that our approach improves the quality of the suggestions.

Keywords—Integrated development environment; code completion; API; code completion tool; pharo

I. INTRODUCTION

Integrated Development Environments (IDEs) have become a critical paradigm for software engineers to speed up the coding process and reduce typos and other common errors. An IDE brings together tools for developing software such as mobile applications, computer or game console applications, web applications, etc. There are more IDEs than programming languages. However, most IDEs are specific to a given language [1]. A modern IDE has various tools distributed together, which are among others: the text editor, the graphical interface, the debugger, the compiler, testing and versioning tools, ... helping the programmer to write code efficiently and accurately by providing it with a set of valuable services such as automatic indentation of code blocks, highlighting of language keywords by color or bold characters, code completion, etc. Code completion is the mechanism allowing from part of a word entered by the user to offer him a progressively refined list of candidates (complements) which could suit the remaining string of characters of the word. This functionality can be found in several applications : text editors (for entering source code, for word processing, etc.), web browsers, as well as specific intuitive input systems installed on smartphones. This work will focus on code completion in IDE editors, highlight its shortcomings, and propose an improvement.

A. Context

Murphy [3] published an empirical study on how 41 Java developers used the Eclipse IDE. One of their findings was that every developer in the study used the code completion feature. Among the top commands executed by the 41 developers, code completion came in sixth with 6.7% of the number of commands executed, sharing the top spots with basic editing commands such as copy, paste, save and delete. Not surprisingly, this has been little discussed: Code completion has become second praxis to implementation activity. Nowadays, every major IDE offers a language-specific code completion system; according to [4] any text editor must provide at least word completion to be considered usable for programming. In the same vein, we did an online survey in June 2020 with local developers. The survey focused on quality practices and measures in software development companies [5].

B. Motivations

Now-a-days, software development has become highly complex and very difficult to master due to the increase in the scale of the projects, the increasingly short development time, the requirements and the quality of the software product. To successfully manage the development of software, it is necessary to consider many parameters, including material resource constraints, the programming languages used, and the human factor. The latter greatly influences the progress of software development. The software production cost includes the hardware cost, the training cost, and the effort required for the development and maintenance. However, the most significant cost is that of the construction effort (software development) because it represents more than 80% of the software production time [6]. Cost overruns and delayed product delivery deadlines are often encountered during software development. To provide an element of the solution to these problems, engineers should strive to act to ease the development process by reducing costs (effort) and development time. Thus, we could increase the productivity of programmers by automating part of the activities (reducing keyboard input by code completion) and by simplifying operations (rapid debugging, less or easily consults the documentation) to achieve the qualitative objectives (quality, cost and time). The code source is the essential element of the software. It is done during implementation and is reviewed during maintenance, representing more than 80% of the software cost. The code completion mechanism takes center stage. Jin [1] highlighted the hidden cost of auto-completion, which mainly impacts developers when code completion techniques produce long recommendations. They show how the length of the recommendations list affects other factors that can lead to inefficiencies in the process. The idea of improving and adapting the completion mechanism is relevant

to provide support to developers by providing considerable time savings and reducing the number of typing errors during development. So software developers will write code more effectively and efficiently.

C. Description of the Problem

Automatic code completion is considered the most used feature in integrated development environments [14]. The recommendations (suggestions) are presented to the programmer during the completion process in a pop-up window in a specific order. A study on the length of self-completion suggestion lists [1] found that around 17% of the lists were 250 items long. In the same study, they showed that the median position of the selected item is beyond the 100th spot. So given the multitude of suggestion possibilities offered by code completion and the way these suggestions are sorted, finding a candidate's place in the list can be tedious or slower than typing in the full name of the element to be completed. Generally, it takes too long to locate the word in the suggestions list. In that case, code completion loses all its importance because, instead of being a tool that increases the coder's productivity by reducing the entry time, it slows down and slow motion. This highlights weaknesses in the suggestion sorting strategies implemented in most code completion systems in development environments. These strategies do not rank the results relevance according to the programmer's context. This work will propose a sorting strategy that improves the precision of the list of suggestions.

D. Structure of the Document

Our main contributions are summarized as follows:

- We propose a new prioritization method.
- We propose a discriminator model on top of the IDE code completion engine that uses contextual scope information for precise code completion.
- We do an extensive experiments showing performance in terms of precision.

The rest of the paper is organized as follows: Section II presents the details of the RBSS strategy. Section III reports the experimental results. Section IV investigates related work. Section V discuss threats to validity of our approach. Section VI concludes the document.

II. THE STRATEGY: RELEVANCE BASED-SORTING STRATEGY

In this section, we present the candidate list refinement strategy called Relevance Based- Sorting Strategy (RBSS). Fig. 1 show an overview of the approach. The idea is to measure the relevance score of each of the list elements (method name, variable name, class name, etc.) according to the number and weight of the links that it receives to refine its position in the suggestions list depending on the context. We need the static and structural information from the source code to do this. Thanks to of the Abstract Syntax Tree (AST) analysis, which returns the syntactic information of the element to be completed, we are able to sort the completion options (names of methods, variables, classes, definitions, etc.) according to their popularity ratings which are the essential

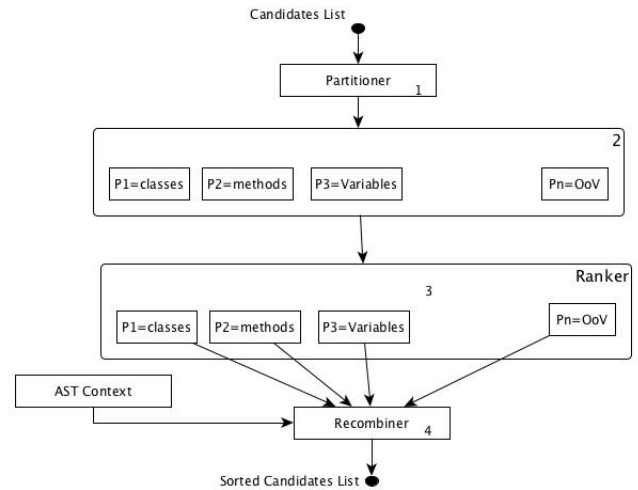

Fig. 1. Overview of RBSS Approach

criteria in referencement. To do this, we contextualize the idea of Google's web page indexing algorithm (PageRank). PageRank is an referencement technique used by the Google search engine to index web pages and provide results that are relevant. The latter, an index used by Google to know the popularity of its index, is noted between 0 and 10. A page is considered very popular if it has a maximum rating or index.

- 1) Partitioning of candidates The first step is to partition the candidates according to the types of elements with the RBSS Partition algorithm as in Fig. 2.

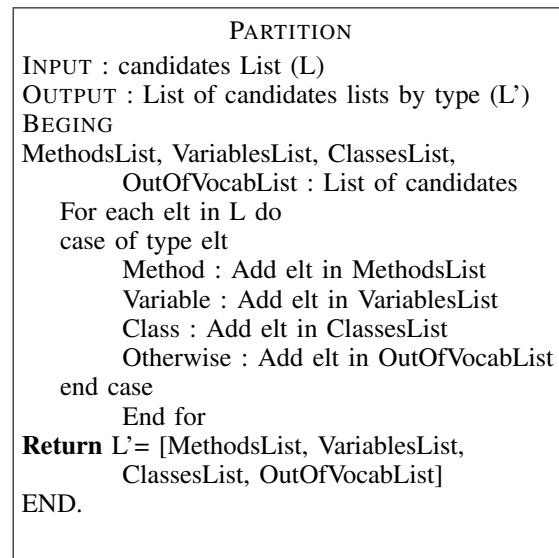

Fig. 2. Algorithm RBSSPartitionner: Partitions a List According to Elements Type

In this step, each item in the list is classified according to:

- Methods For each method in suggestions list, it will be a question of looking at the number of their Senders and their Implementors. The

Senders represent all methods that may use or invoke a given method. The Implementors also work the same way. Instead of returning a list of Senders of a message (or method-envoyeuses), they resolve all classes that implement a method with the same selector. RBSS considers a method popular when many links point to it. Here, a link can represent either a call of the method in question by another method or an implementation of the method in the different classes of the system.

- classes Concerning the case of a class, we will be interested in its references as an attribute for evaluating its popularity. These references are : AllRefInside and AllRefOutside. All-RefInside represents all the references of the other classes of the system which reuse (inheritance, re-implementation,...) the properties of a given class. AllRefOutside does the opposite of AllRefOutside by displaying all the elements of the classes whose attributes a given class uses. Our strategy considers that a class is popular if it has more AllRefInside than AllRefOutside if the size of the AllRefInside list is greater than the size of AllRefOutside.
- variables Regarding the variables, we will consider either the number of methods that use it (outgoingInvocation), or the number of methods that store data in this variable (incomingInvocation). In both cases, the RBSS sorting strategy will consider the size of the list of methods as a criterion for evaluating the popularity of the variable.

- 2) Score attribution by category RBSS then rates the popularity of each item in the suggestion list based on the number of times other objects in the system use it. To assess the popularity score of items in a suggestion list partition, we assign a weight to each link that a given item can have. Thus, the total number of links of an element represents its popularity score, which is one factor that conditions the element's positioning (method, Class, Variable) in the suggestions list. for this, we use the RBSSorter algorithm Fig. 3. This algorithm uses algorithms from Fig. 4 and Fig. 5. The position of an element in the completion list considers the context of the word to be completed. So, we will contextualize the sorting of the list according to the type and the current situation. For example, in the case of a list having methods, variables, classes etc. as a completion proposal, the RBSS strategy after having sorted this list will first consider the context before displaying the result. If we are in a method context, RBSS will place the most popular methods at the top of the list and then complete the list with other popular elements (variable, class, ...) from this list and thus vice versa.
- 3) Recombination of the elements (see Fig. 6) of the partitions into a single list. For this we rely on the following RBSS Recombiner algorithm:

```

                                SORT
INPUT: L, the list of Candidates
RETURN: L', the sorted list of candidates
LOCAL: chg, the list of couple (l,c) where l in L and c
       the computed score
For each l in L
  Chg add (l, score(l))
End for
For i=1 to threshold do
  For each (l,c) in chg
    (l,c) ← (l, (c + SUM Score(l') l' In Neighbor(l) ) /
            1+ (c + SUM Score(l') l' In Neighbor(l) ))
  End For
End for
Sort chg
RETURN first chg
RETURN seq
END.
```

Fig. 3. Algorithm RBSSorter: Sort the List of Candidate According to their Score

```

                                NEIGHBOURG
INPUT: l, a Candidate
RETURN: N, a list of neighbor of l
Case type of l :
  Method : N ← senders(l)
  Class : N ← AllRefInside (l)
  Variable : N ← OutGoingInvocation (l)
End Case
RETURN N
END.
```

III. EXPERIMENTS AND DISCUSSIONS

In a recent study [2] Hellendoorn and others present a case study on 15,000 code completions that were applied by 66 real developers. They find that many aspects of real-world completions are not represented in synthetic benchmarks and tested completion tools were far less accurate on real-world data. Worse, on the few completions that consumed most of the developers' time, prediction accuracy was less than 20% – an effect that is invisible in synthetic benchmarks. For these reasons we choose to test our strategy on real-world system.

```

                                SCORE
INPUT: l, a Candidate
RETURN: c, the score for l
       c ← #Neighbour(l) / 1+ #Neighbour(l)
RETURN c
END.
```

A. Setup

For the evaluation the data used is as follows:

- We tested a large body of 1000 tokens in the pharo 9.0 source code to clearly show the impact. Pharo is a pure object programming language in which everything is object. the criteria that guided this choice are : the length of the object's source code, the type of the object (instance side, class side, ...), for the evaluation. Finally, we compare the score of our model with some basic strategies. The main objective of this evaluation is to empirically answer the research question about RBSS:
- How accurate is the RBSS method? We use this dataset as the basis for our assessments. We use the context and scope of each source code element.

Table 1 shows the data statistics, where LOCs are the line of codes, Files are the number of files, and Total Projects are the number of included projects.

TABLE I. DATA STATISTICS

Packages	Object Types	LOCs	Tokens
Epicea, Collections-Strings, Colors	Instance side	1119	7514
Epicea, Collections-Strings, Colors	Class side	370	2860
Total		1489	10374

We have tried different scope granularities such as class scope, method scope, and block scope. To the test pattern, we used 10,374 Entries names range in length from 3 to 12, with an average of 5. Accuracy assessment measures the difference between the expected result and the result obtained. We are looking for the right word to be placed in top positions at best. Otherwise, it occupies the highest position in the list. For this purpose, we will look at the top2, top 3, top4 and top5. We stop at this level because [1] have shown that beyond position 5 the programmer continues to type. By the way the words are not usually long in Pharo. Experimental result We evaluate the accuracy of our completion models according to standard metrics. We mainly consider top-K accuracies implying that the correct completion was often near the top

of the suggestion list. Meaning that, we evaluated the RBSS strategy according to the position of the expected word in the list of suggestions. We did not dwell on the speed of execution, which will be the subject of another study. For this, we intend to exploit optimization techniques such as indexing and dynamic programming. Table 2 shows the results obtained within the Pharo environments.

Through empirical evaluation of RBSS in both environments, we were capable to show its ability to improve the accuracy of the list of returned candidates. The tests results carried out according to the defined case show that with the RBSS strategy, If we take the first five candidates from the list, in 61,6% of cases, we have the right candidate in the list. From this point of view, the RBSS strategy is improved on auto-completion. In conclusion, we have shown that the sorting strategy based on the popularity of the elements improves the precision of the code completion system, that is, the positioning of the elements in the suggestion list. However, although RBSS performs better, we did not consider the execution speed aspect, which we intend to improve in future studies.

IV. THREATS TO VALIDITY

As any empirical evaluation, the results of our experiments are subject to threats to validity. We identified the following noteworthy threats:

- The studied system might not entirely represent a larger population of systems, either from another application domain or written in another programming language. This is always a complex threat to mitigate as there is little information on what property of a system is essential to ensure representativeness. Replication of the experiment for other systems must be realized. This said, we strongly believe our approach is independent of the programming language and the application domain.
- The way in which we setup our experimentation may introduce bias. We also believe Pharo and visual works are credible, real world, non-trivial, case study. It was medium to big system and it includes a significant number of completion tools and options. However, we firmly believe that our approach is language independent.
- We tried with different type of object (instance side, class side, traits). This was done to eliminate a possible problem with the obviously simple solution working for any kind of object.
- Internal threats to validity are related to the implementation of our approach. It is still possible that our approach implementation contains errors that can affect our results' exactitude. We manually studied a subset of the results to counter this threat and did not find any obvious errors. Bias concerning developer working habits might also occur in our selection of evaluation subjects. We selected various packages from the two studied systems to reduce this risk, all issued from different areas. Thus, we believe the objects represent a heterogeneous enough population of the source code element.

TABLE II. DATA COMPARISON

Token Type	Method			Class			Variable		
	Top3	Top4	Top5	Top3	Top4	Top5	Top3	Top4	Top5
RBSS	56.4%	59.7%	61.6%	50.4%	55.8%	63.4%	38.4%	39.9%	47.6%
Pharo	55.7%	59.6%	61.5%	50.7%	55.5%	63.4%	37.7%	39.8%	47.6%

V. SOME WORK ON CODE COMPLETION

Code completion. With the birth of IDEs, code completion research has received much attention in recent decades. In [8] authors present a largescale study of user interactions with autocompletion. They found that lowerranked auto-completion suggestions receive substantially lower engagement than those higherranked. They note that users are most likely to engage with auto-completion after typing about half of the query, and in particular at word boundaries. They also found that the likelihood of using auto-completion varies with the distance of query characters on the keyboard. In a first study, the traditional models which are based on the formal structure of the programs, that is to say on the syntactic information and the static properties of the code. These syntactic approaches have been the most explored [9], [4], [7]. In the paper [12] we can read: Software engineering and programming languages (SE / PL) should make the same transition as research on natural language processing, assisting traditional methods that only take into account the formal structure of the programs, that is to say the information on the statistical properties of the code, and also exploiting repetitive and predictable elements of the source code. Essentially, three completion techniques are recited, each using the information in the example database differently. It is about : A Frequency Based Code Completion System (FreqCCS) uses the frequency of method calls to decide their suitability and suggests the most frequently used method. An Association Rule Based Code Completion (ArCCS) which is a statistical learning technique for finding interesting associations between elements in data, ArCCS exploits the rules $m \rightarrow n$ which, if the method m is used, the method n is frequently called and suggested. The Best Matching Neighbors code completion (BMN) which is the modification of the K-Nearest-Neighbors machine learning algorithm, BMN adapts the KNN to suggest a variable v . The probabilistic models or statistical language models (Statistic Language Model). Recent work has started to examine linguistic models based on statistical learning [17], [18], [10] aiming to model the source code as statistical language learning models. These approaches offer an exciting new goal of the code completion problem that suggestions can capture the deeper meaning of terms' semantic and idiomatic meaning. These are, among others : N-gram models and Recurrent Neural Networks (RNN). The n-gram models which exploit probabilistic models and predict each token based on the probability of the preceding token. To deal with data scarcity, an N-gram data model estimates the probability of a sentence by modeling language as a Markov chain of order. The probability of the next word in the sentence (phrase) depends only on the previous words [11]. The Recurrent Neural Network outperforms the n-gram and predict each token (node to predict) sequentially. For example [16] proposes an approach that combines RNNs with networks of pointers to complete the code. In [13] authors explore the use of neural network techniques to automatically

learn code completion from a large corpus of dynamically typed JavaScript code. Authors propose a neural network model and believe that neural network techniques can play a transformative role in helping software developers manage the growing complexity of software systems. Performance measurement of these approaches. The following metrics are the most used [15]: precision , recall and F-Measure. Whose formulas are:

$$precision(P) = \frac{Recommendations_{made \cap relevant}}{Recommendations_{made}}$$

$$recall(R) = \frac{Recommendations_{made \cap relevant}}{Recommendations_{relevant}}$$

$$F - measure = \frac{(2 * P * R)}{(P + R)}$$

The measurement F is called the harmonic mean of recall and precision. Usually, it is difficult to achieve optimal results simultaneously for recall and precision. For example, if all words are classified as irrelevant, the resulting recall score will be 100% where the accuracy score will be low. Therefore, measurement F is a compromise between recall and precision. The score range for measure F is 0 to 1 ; the higher score implies a better classification model.

VI. CONCLUSION

In this paper, we have proposed an approach for improving code completion. This approach if used increase the productivity of coders. In addition, this mechanism offers advantages in terms of reducing typing errors and time while increasing the efficiency and productivity of programmers. We have examined our approach with Pharo a dynamic object language. The experimental results have shown that our proposed method surpasses existing methods in terms of effectiveness and efficiency. It turns out that our sorting strategy significantly improves code completion. The accuracy of the list of suggestions (the right candidate is in the top 3 first candidates 59.6% of the time) compared to the Pharo 9.0 completion engine sorting.

Several improvements and perspectives are possible despite achieving an adequate precision sorting strategy. Indeed, the RBSS sorting strategy proposed in this work is limited and has shortcomings. The essential concerns its execution speed : RBSS is slower than the alphabetical sorting strategy, i.e. the strategy takes much longer to display list of suggestions. Thus, the main perspective considered concerns optimizing the RBSS sorting strategy to consume less resources. This optimization requires for example the creation and initialization of an index or of an array in which RBSS will read and that the array is updated automatically at a precise time or at a given

frequency to go fast. And this takes into account the size and the appropriate structure of this table. We also plan to compare the performance of our system with the latest systems proposed in the literature. Another perspective is to evaluate our approach on a large set of developers' community to collect their comments and quantify the pros and cons of our approach. We also wish to extend and test our approach on other languages and environments because currently, our results are valid than Pharo.

Revisiting Polyglot Persistence: From Principles to Practice

Omar Lajam, Salahadin Mohammed
Information and Computer Science Department
King Fahd University of Petroleum and Minerals
Dhahran, Saudi Arabia

Abstract—To cope with the rapid advancements in information technologies, many database systems have been developed in the last decade to satisfy various data storage requirements, such as NoSQL databases. In many cases, using a single database system cannot be an option because of the limitations posed on the functionalities of the software application. Therefore, applications may use multiple distributed storage databases that complement each other to satisfy the conflicting requirements. Such applications that are called polyglot persistent applications. However, the practical implementation of polyglot persistence and its complexities have not been studied enough. In this paper, the most recent studies related to polyglot persistence are reviewed. Database systems are classified based on their data storage model, and their use cases are discussed. The principles of polyglot persistence and its challenges are expounded. The implementation architectures of polyglot persistence applications are categorized into Application-coordinated Polyglot Persistence, Service-oriented Polyglot Persistence, Polyglot- Persistence-as-a-Service, and Multi-models Databases. An analysis of the issues related to each architecture is presented. In light of the study findings, a practical polyglot persistence implantation strategy is proposed. The outcomes of this work can help design future polyglot persistence applications and influence future research on how to resolve the complexity involved in polyglot persistence solutions.

Keywords—Database system; database architecture; relational database; NoSQL; distributed storage; multi-model database; review; classification

I. INTRODUCTION

Data stores have been an integral component of software applications since the emergence of information technology systems, including shopping, accounting, medicine, and games applications. There is a wide range of database systems that are available for storing data, such as MySQL, MongoDB, and Cassandra, to name a few. These database systems are usually classified based on how they model and store the data. Nevertheless, relational databases are the most popular databases used in the industry [1], and they are the default option for typical applications.

Despite their popularity, relational databases have some limitations, such as expensive queries and vertical scalability, that make the selection of non-relational databases vital. As the application gets popular and the database gets burdened with millions of records, there becomes a need for using more flexible databases, such as NoSQL databases, to support features not supported by relational databases. At the same time, the complete abandonment of relational databases cannot be an option in many cases because they also support important

features not supported by other databases, like data consistency and transactions atomicity. To avoid sacrificing any of the different database features, the need for using more than one database system within an application to fulfill the conflicting requirements raises.

When an application uses more than one database system, it is called a polyglot persistence application. Taking this decision of having a polyglot persistence environment is not straightforward because it increases programming complexity and requires developers' knowledge of different database systems. However, successful implementation of polyglot persistence has the great advantage of having the different database systems complement each other and satisfying the conflicting requirements.

In order to ease the development of polyglot persistence applications, several architectures are proposed in the literature on how to design and implement them. Nevertheless, the following problems are identified by this study on those proposals: 1) There is no clear distinction or categorization for the different proposed architectures, which make them irrelevant to each other and difficult to be compared. 2) There is no detailed discussion on the challenges introduced by polyglot persistence architectures, while the focus is mostly on their advantages. 3) Most of the proposed architectures are not abstract in the sense that they cannot be applied on any application domain, and they are mostly targeting specific domains (e.g., e-commerce and healthcare), which makes them, in many cases, lack generalizability.

This review study aims to address these problems and build new knowledge based on the literature findings. The main contributions of this work can be highlighted as follows:

- Review for the most recent studies related to polyglot persistence.
- Classification for database systems with a detailed discussion on their characteristics.
- Description of polyglot persistence and its principles.
- Categorization for the architectures in which polyglot persistence applications can be implemented.
- Analysis of the problems associated with each polyglot persistence architecture.
- A practical strategy for polyglot persistence implementation.

To the best of our knowledge, this is the first work that expounds polyglot persistence comprehensively, from principles to practice. This work opens new opportunities for future research to address polyglot persistence challenges. It guides future polyglot persistence research towards more mindful solutions that consider the theoretical and practical aspects of polyglot persistence. This work can also help practitioners make wiser design decisions when building polyglot persistence applications. In addition, it may serve as a reference for understanding database systems concepts and challenges.

The rest of the paper is organized as follows. Section II discusses the related work. The methodology of this work is explained in Section III. Section IV presents database systems classification. In Section V, an explanation for polyglot persistence principles is given. Section VI describes polyglot persistence architectures and challenges. Section VII outlines the proposed polyglot persistence implementation strategy. And finally, Section VIII concludes the paper.

II. RELATED WORK

Few studies have discussed polyglot persistence concepts, architectures, and challenges. Gessert and Ritter [2] were the first who classified polyglot persistence based on research and industry into three patterns: application-coordinated polyglot persistence, microservices, and polyglot database services. The authors then described them again in [3], where they gave brief details about each pattern without mentioning issues related to each of them.

Another attempt to classify polyglot persistence is given by Khine and Wang [4] based on the polyglot persistence solution orientation. They classify the polyglot persistence solutions into three types: domain-oriented solution, query language-based solution, and other solutions (e.g., frameworks, middleware, and multi-model databases). A main observation on their classification is that it lacks disjointedness and holism.

Wiese [5] discussed polyglot databases architectures and challenges. Three architectures are described: polyglot persistence, lambda architecture, and multi-model databases. However, the lambda architecture is part of polyglot processing, not polyglot databases, as presented in [6].

Jaroslav [7] demonstrated some possible strategies for building an infrastructure that operates on integrated SQL and NoSQL databases. The study provides some approaches to construct such integrated database architectures, mainly by using multi-model databases and multi-level modeling, where interactions occur within and between at least two levels of connected databases.

Clearly, polyglot persistence is not studied enough. In this work, we try to study polyglot persistence principles, architectures, challenges, and implementation, based on the literature findings, as comprehensively as possible.

III. METHODOLOGY

The main objectives of this study are to explore how polyglot persistence applications can be architected and to understand polyglot persistence advantages and challenges. The following methodology is used in order to accomplish the study objectives.

A. Literature Review

This work is mainly a review that surveys the literature to gain knowledge on the topic. Four databases were searched to extract the related studies: IEEEExplore, ACM Digital Library, Web of Science, and Google Scholar. These four databases were chosen because they can capture most related studies. The search string used was 'polyglot persistence'. The inclusion criterion was to include any study that proposes a polyglot persistence architecture, model, or framework. The resulted studies were inspected, and 18 relevant studies were included. The selected studies were then downloaded and fully read. Each study was summarized, and all results were aggregated into an Excel file in a tabular format.

B. Problem Identification

At this stage, several problems were identified in the reviewed studies. First, many different architectures lack a clear distinction or categorization, making them unrelated to each other and difficult to compare. Second, there is no comprehensive treatment of the issues posed by polyglot persistence architectures, with the emphasis being placed mostly on their benefits. Third, most proposed architectures were specific to a few application domains, e.g., e-commerce and healthcare, which make them difficult to be generalized for other domains. In other words, many proposed architectures were developed with specific database requirements in mind.

These three problems are consistent with what Khine and Wang have found [4], where they stated that it has not yet been determined which architectures are best suited for different kinds of applications and how polyglot persistence can be implemented. Additionally, they observed that the benefits and limitations of polyglot persistence are still open research topics for academics and professionals.

C. Classification and Analysis

After identifying the problems, an intensive investigation was carried on to identify polyglot persistence principles, architectures, challenges, and implementation. Search databases were searched again with the same string. The relevant studies were analyzed, and more information was gathered from the literature to build knowledge that addresses the identified problems.

IV. DATABASES CLASSIFICATION

There are different options for storing application data, ranging from simply being stored in a file to being stored in a sophisticated data storage system, depending on the degree of complexity of the application requirements. Database Management Systems (DBMSs) are database systems that manage data storage and retrieval. The implementation of a DBMS specifies how the data will be structured and stored into the disk, how the queries will be processed, how access will be granted, and many other functions. What distinguishes one DBMS from another is its functions and features. DBMSs can be categorized into relational (RDBMS), referred to as SQL databases, and non-relational or NoSQL (Not only SQL) databases.

A. Relational Databases

Relational databases use the relational data model to store the data. It is the most popular model for storing structured data. It was first introduced by E. F. Codd in 1970 [8][9]. It is very mature, stable, trusted, and well researched. In this model, the data is organized as tables, and these tables can have relationships with each other. Examples of relational databases include MySQL, PostgreSQL, and Oracle.

Relational databases support transactions that obey ACID properties (Atomicity, Consistency, Isolation, and Durability) [10]. The atomicity property ensures that all instructions of a transaction will be executed at once, i.e., a transaction is an atomic unit of processing. The consistency property guarantees that the database state is always consistent, and the correct execution of a transaction takes the database from one consistent state to another. The isolation property makes each transaction completely isolated from others, and its effect on the database does not become visible until it is committed. This noninterference transaction execution can be achieved using concurrency control techniques [11]. The durability property, also referred to as permanency, ensures that changes made by a successful transaction will not be lost by subsequent unsuccessful transactions [12].

Relational databases have fixed database schema. They enforce data consistency and integrity. They store the data efficiently with minimal redundancy and maximal space utilization [13]. They have powerful query language. And lastly, they have a great community that provides support and help.

Relational databases manifest some drawbacks under some situations, especially when the number of database users dramatically increases and when the data volume becomes too huge. That is mainly due to the nontrivial processing required for user queries and the difficulty of operating on a distributed architecture. With massive amount of data, the relational database requires powerful machine to operate efficiently. The only option to scale the database system up is to upgrade the machine to a more powerful one. In other words, relational databases are only vertically scalable. Because they usually run on one machine, relational databases are prone to the single point of failure threat.

Relational databases are not suitable for unstructured, semi-structured, and graph data. They are not suitable for applications that store schema-less or schema-free data. They incur a high cost for complex query processing due to the table joins and constraints checking involved. They are less suitable for high-velocity ingestion due to the schema constraints validations. The relational database infrastructure (i.e., server machine) cost is expensive due to the powerful processing and storage space resources it needs, especially when the number of simultaneous users and/or the data volume becomes huge [14].

B. NoSQL Databases

The term "NoSQL" can be interpreted as "not using SQL query language", or can be interpreted as "Not only SQL", where the latter implies either the support of a database system for a query language that is similar to SQL or implies the co-existing of a non-SQL database with a SQL database in a

common polyglot persistence environment. There is no agreed-upon definition of what "NoSQL" is stand for [15].

The main characteristic of NoSQL databases is their ability to operate in a distributed architecture, running on a cluster of commodity hardware. In NoSQL databases, there is almost no referential integrity constraint among data objects. Therefore, processing data residing in many different machines is feasible, and horizontal scalability is enabled by simply adding new processing and storage resources without replacing old ones. In addition, distributed storage architecture enables the migration of processes to data and data to processes, which facilitates big data analysis tasks.

An important problem with SQL databases solved by NoSQL databases is the data structure *impedance mismatch* [16]. The in-memory data can be kept in complex structure (e.g., nested lists), while with SQL databases, the data is always in a simple tabular format. This difference between the two stores (in-memory and database) causes the impedance mismatch and requires translation work upon data writing and reading to and from the database. For object-oriented programming language, it would be more favorable to replicate the data objects stored in memory directly into the database. For SQL databases, this problem is mitigated by the Object-Relational Mappers (ORMs) [17], where they take the responsibility to map data objects to their corresponding underlying database structure. With most NoSQL databases, the in-memory data structure can be stored as-is into the database, and this feature reduces programming overhead and enhances the performance.

NoSQL databases are schema-less, and they do not enforce data integrity constraints. That makes NoSQL databases more efficient because constraints checking and integrity validation upon data insertion are eliminated [18]. The distribution architecture of NoSQL databases makes them fault-tolerant because they are not prone to the single point of failure threat. Data replication across distributed storage nodes in NoSQL databases is easy because there is no obligation to the ACID properties. Alternatively, NoSQL databases adhere to the BASE properties (Basic Availability, Soft state, Eventual consistency) [12]. The basic availability property ensures that every request will get a response. However, consistency among responses is not guaranteed, and multiple users requesting the same data object can get different versions. The soft state property allows the database system to remain inconsistent after query execution. The eventual consistency property promises to propagate the changes to storage nodes until eventually the entire distributed database system becomes on a global consistent state [19].

NoSQL databases are considered "non-relational" databases because their models are divergent from the traditional relational data model and implemented differently. NoSQL data models are categorized into Key-value, Document, Column Family, and Graph data models [20]. The next discussion for each model is mostly inspired from [15] [20], [21], and [22].

1) *Key-Value Model*: This is the simplest data model, where the data object is stored as a pair consisting of a key and a value. The key is a unique alpha-numeric identifier for the value. The value can be a string or complex lists and sets, with no constraints on its content structure. The structure of this

model is very similar to hash tables and dictionaries. In this model, the data can only be searched by key, i.e., the value is not searchable. Examples of key-value databases include Redis and Memcached.

The simplicity of this model makes it scalable and suitable for application that requires fast access to self-contained schema-less data. Examples of these data are user profiles, web sessions, shopping carts, and products information. On the other hand, the key-value model is not suitable if relationships exist between data objects, data is queried by its value, values are updated frequently, or for operating on multi-key transactions.

2) *Document Model*: This model can be considered an expansion to the key-value model, where the value contains semi-structured data and can be fully searched and indexed. Each data object is stored in a document that contains one or more keys. Groups of logically related documents are called collections, which are equivalent to tables in relational databases. To get the flexibility in accessing the data by its value, the database may store metadata that describes the allowable value structure and types. The database can retrieve part of the document based on the user query. The document can be formatted in a standard data exchange format such as XML, YAML, JSON, or BSON (Binary JSON). Examples of document databases include MongoDB and Couchbase.

The design of this model is inspired by a business software called Lotus Notes [23], a document database that enables sharing data across a local network [24]. Document databases use cases include storing and managing large-size collections of text files, such as literal documents, email messages, and XML files. Also, aggregated data objects such as products information or user profiles which are accessed at once together, are another use case for document databases. In general, document databases are best used for searchable data that has no fixed schema and which may add many nulls in an equivalent relational database. Document databases are not the best option for complex application queries or for transactions that require accessing multiple documents at once.

3) *Column Family Model*: Column family (or wide-column) model stores data objects in key-value pairs, where the value points to a second-level of key-value pairs. These second-level keys are called columns, and a subset of them forms a column family. The values can be accessed by any key in the first or second level.

One of the first column databases is BigTable [25], where it was designed to handle big data on a petabyte-scale. Another example of a column-family database is Cassandra [26], with a slightly different design philosophy that supports nested columns.

Column family databases may be the best choice with structured data when the distributed architecture is used, with data batch processing on a large scale, or real-time distributed big-data analysis tools such as MapReduce [27].

4) *Graph Model*: The graph model stores the data object as a graph consisting of nodes and connection edges. The nodes represent data objects while the edges represent relationships between them. Relationships are associated with properties, and two nodes can have one or more relationships. This model

is schema-less, and nodes and edges can be inserted with any content. Examples of graph databases include Neo4j and JanusGraph.

This model is the only NoSQL model that supports relationships and ACID transactions. In fact, this model is closer to the relational model but categorized as NoSQL because of its dissimilarity with the relational model in how the data is structured and queried [28]. A key difference between the graph model and the relational model is in the query cost, where the navigation along the graph network to explore information is cheaper with graph database due to the absence of the expensive join operations. Another obvious difference is that the SQL query language is not supported in graph databases [28].

The graph representation of the data helps extract information that is hard to get with other models. The data of real-world problems that have interconnected entities, such as social networking, maps, products recommendations, pattern detection, network topologies, or any problem that can be represented as a graph, is a good candidate to be stored in a graph database. Nevertheless, graph databases are not good in horizontal scalability and big data processing.

V. POLYGLOT PERSISTENCE PRINCIPLES

Due to the availability of many heterogeneous database systems, the decision of which database system should be used for a given application can be embarrassing. The concepts of polyglot persistence can be utilized in such cases. This section explains the meaning of polyglot persistence and spot the situations in which it is really needed.

A. What is Polyglot Persistence?

The term polyglot persistence was first coined in an online blog by Scott Leberknight in 2008 [29], and it then became famous after the book [15]. Leberknight explained the meaning of polyglot persistence by "*like polyglot programming, is all about choosing the right persistence option for the task at hand*". The term 'polyglot' implies the ability to talk to more than one database system. Polyglot persistence can be defined as *a situation in which different parts of data are stored in the most persistent database system that satisfies the storage requirements*.

Traditionally, relational databases were the default acceptable persistent option for data storage. However, the appearance of non-relational databases has changed the norm since there can be non-relational databases that are more persistent in some cases. The determination of the most persistent database system is totally dependent on the application's storage requirements.

A common example to illustrate the meaning of polyglot persistence is with an e-commerce application. In a typical e-commerce application, queries about clients' shopping data can be easily answered using a key-value NoSQL database. However, if the interest is on what the client's friends have purchased, the problem becomes entirely different. To answer this question, a graph database should be used [15]. Fig. 1 shows an example of a possible implementation for polyglot persistence in an e-commerce application.

Fig. 1. Example of implementation for Polyglot Persistence in E-Commerce Application

Large and well-known applications are found to be employing polyglot persistence. Examples of these applications are Google, Facebook, Amazon, and Twitter. The practical aspects of polyglot persistence are not new for the industry, but they are not studied enough by the research community. There is a shortage of addressing the problems associated with polyglot persistence in the literature, especially with designing, implementing, and maintaining polyglot persistence architectures [3].

B. Why is Polyglot Persistence?

As shown in Section IV, each of SQL and NoSQL databases have their own characteristics and advantages. Polyglot persistence is employed to get the optimal benefits of each different database system. A usual concern is with database scalability, schema flexibility, data consistency, system availability, and performance [3].

In general, polyglot persistence is adopted to resolve conflicting requirements [3] [5]. These conflicts exist due to the limitations of the database systems, where no one database system can satisfy all requirements. With polyglot persistence, all requirements can be satisfied by using as many databases as needed. If there was a one-size-fits-all solution, as promised by NewSQL [30], then polyglot persistence can be overlooked.

Next, examples of three types of conflicting requirements: functional, non-functional, and data requirements, are discussed.

1) *Conflicting Functional Requirements:* The boundaries of database system functions can be determined by the available commands supported by its query language. Examples of these commands in SQL are SELECT and INSERT. The database functional requirements of an application can be determined by listing the commands it needs to perform on its data storage. A conflict in the functional requirements occurs when no single database system supports the entire set of query commands required by an application.

For example, consider a key-value database that only supports GET and PUT commands used by a simple web blog application. If the application added new features that require more complex queries, such as user authentication and online course registration features, then either the database system will be changed, or a new database system will be added

beside the existing one. The latter polyglot persistence solution eliminates the need for a complex data migration process from the legacy database into the new one [31]. Note that the conflict in functional requirements can also be related to the database system security commands, such as the commands related to user authentication and access control [32].

2) *Conflicting Non-Functional Requirements:* The CAP theorem states that three demanding non-functional requirements cannot be satisfied at the same time when designing an application on a distributed architecture: Availability, Consistency, and Partition tolerance [33] [34] [35]. Therefore, there must be a trade-off for these requirements when selecting the database system for a given application. To resolve the conflict, different parts of application data can be stored in different databases.

Many non-functional requirements are subject to the ability of the database system to operate in a distributed architecture on commodity hardware. This ability reduces hardware resource costs, increases fault tolerance and availability, raises processing power, enables data replication, and eases big data analysis [36]. Since NoSQL databases can be deployed in a distributed architecture, they can be used to satisfy the mentioned requirements. On the other hand, other non-functional requirements cannot be accomplished unless the database system runs on a single server. Examples of these requirements are data consistency and integrity.

3) *Conflicting Data Requirements:* The data requirements for an application can also encourage the decision of using more than one database system. For example, a customer profile data (e.g., name, age, job, etc.) may not be designed in a fixed schema since many details can be null-able, and they may be frequently changed along the lifetime of the application development cycle. In addition, it might be impossible sometimes to design a fixed schema because the shape of the data is unknown in advance, as with the case when the data is inserted based on the user preferences. An example of such data object is salary, which contains many data items like basic salary, insurance allowance, transportation allowance, etc. In these cases, the usage of a schema-less non-relational database is recommended.

On the other hand, there are cases where using a relational database is the only possible option. An example of such a case is with money balance data that is used, for example, to purchase products or services within a web application. In this case, ACID transactions must be used to ensure data integrity and avoid race conditions [37].

Another example to illustrate the conflicting data requirements is the speed of data write or read operations. Some data have higher priority for reading speed over writing speed, such as product information, while other data might have higher priority for writing speed over reading speed, such as viewers counter for a product. To satisfy these conflicting requirements, different database systems might be selected for each part of the data.

VI. POLYGLOT PERSISTENCE ARCHITECTURES

To implement polyglot persistence in an application, one can consider more than one architecture. According

to 18 reviewed studies that implement polyglot persistence, these architectures can be categorized into four categories: Application-coordinated Polyglot Persistence, Service-oriented Polyglot Persistence, Polyglot-Persistence-as-a-Service, and Multi-models Databases. Table I shows the four categories, the number of studies implemented each of them, and their references. A description for each of the categories is given in this section.

TABLE I. CATEGORIES OF POLYGLOT PERSISTENCE ARCHITECTURES

Category	Count	Reference
Application-coordinated Polyglot Persistence	6	[38], [21], [39], [40], [41], [42]
Service-oriented Polyglot Persistence	9	[22], [43], [44], [45], [46], [47], [48], [49], [50]
Polyglot-Persistence-as-a-Service	2	[51], [52]
Multi-models Databases	1	[53]

A. Application-Coordinated Polyglot Persistence

With this architecture, the application itself coordinates the polyglot persistence. This coordination requires the application to control the mapping of the data to databases, i.e., to have explicit knowledge about where each part of the data is stored. Typically, if the application is not small, it would be divided into modules [54] (aka packages or components). Each module is responsible for part of the application and has its own logic and functions. If the data managed by a module is specific to it (not shared by any other module), managing polyglot persistence would be simple because each module can have a different exclusive database system. However, usually, data application is shared by more than one module. In this case, many challenges to support polyglot persistence arise. Also, in some cases, a single module may have conflicting requirements that have to be satisfied using more than one database system.

To distinguish between these different cases and ease the discussion of the challenges of each of them, we classify the relationships between modules and databases within an application as follows:

- **One-to-One:** A module has a connection with one exclusive database.
- **One-to-Many:** A module has connections with more than one exclusive databases.
- **Many-to-One:** More than one module have connections with one mutual database.
- **Many-to-Many:** More than one module have connections with more than one mutual databases.

An application can have a combination of these relationships. The four relationships are shown in Figure 2, where 'M' stands for module and 'D' for database. The assumption is that different databases in the figure are of different storage models. Next, each of these relationships is discussed.

1) *One-to-One Relationship:* This is the simplest relationship. The module controls everything related to its data in one sole database. One query language can be used to manipulate the data. Thus, programmers need to learn only one query language. The application development will also

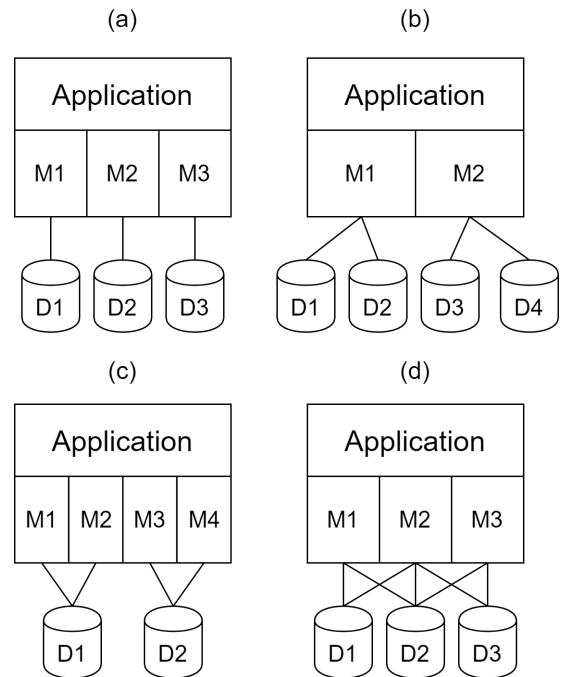

Fig. 2. Polyglot Relationships: (a) One-to-One, (b) One-to-Many, (c) Many-to-One, and (d) Many-to-Many

be easier because different programmers can work separately on different modules with knowledge about only one database system. A failure of one database will affect only part of the application and will not be propagated. Database configurations and security are taken care of by one module. A main concern here is with the design decision that will decide which database system is the best to satisfy the requirements for a given module. However, the approach proposed by [55] can ease the problem, where the functional, non-functional, and data requirements can be analyzed systemically to determine the most persistent database system.

2) *One-to-Many Relationship:* In this relationship, one module controls data stored by more than one database system, and that can cause several problems.

First, there will be a need to use more than one query language, one for each database system, which requires wider knowledge and longer training for developers. In addition, that may make the programming task more confusing. Possible mitigation to this problem can be by using a uniform query language for heterogeneous database systems [56], by a query mediator [57], or by translating SQL queries into NoSQL queries [58].

Second, cross-database consistency of dependent data objects stored in different databases needs to be managed by the module because there are no global referential integrity constraints enforced on the different databases. Consider Fig. 2(b). If dependency exists between a data object X on $D1$ and another data object Y on $D2$, then module $M1$ should maintain consistency across databases $D1$ and $D2$ by reflecting changes of X on Y and vice versa.

Third, running a query across different databases is not straightforward since data need to be processed and integrated

at the module, not at the database system, which may increase the query cost and require complicated data processing logic [59]. For example, a read query for a data object that is scattered on multiple databases may require several different sub-queries, one for each database, and the results of these sub-queries should be integrated and structured by the module. Data integration from different sources is studied in [60].

Forth, data redundancy might be a problem when different parts of the same data object are stored at different databases because common parts of the data object can be unnecessarily duplicated.

Fifth, in case of a failure of one database, this failure might be logically cascaded to other databases that are used by the same module in case a dependency exists between data objects.

3) *Many-to-One Relationship*: In this relationship, two or more modules use one mutual database. A main issue with this relationship is that the database configurations and security depend on more than one module, which may violate the Least Common Mechanism security design principle [61]. More on database security can be found in [62].

If all modules of the application are using the same database, then the polyglot persistence concepts are not applied. If this is not the case, then one can think of the modules that share the same database as one logical module, and the relationship becomes as if it were a one-to-one relationship. To simplify the control of a single database, a data manager (e.g., ORM) can be used as an intermediate layer between the modules and the database. It should control the database queries and configurations and mitigate security threats.

4) *Many-to-Many Relationship*: This relationship is the most complex, where each module uses at least two mutual databases. From the modules side, one can think of this relationship as a one-to-many. On the other hand, from the database side, one can think of this relationship as a many-to-one. Therefore, the same discussion of the two previous relationships can be said again here. However, the consistency problem is expended here because there will be a need to maintain cross-modules consistency for the data objects that are dependent on each other and stored in different databases, and are used by different modules. For example, in Fig. 2 (d), if a data object *X* on D1 is dependent on another data object *Y* on D2, and another data object *Z* on D3 is dependent on the same data object *Y* on D2, then we need to ensure consistency across modules M1 and M3 because they both share a common data object *Y* at D2.

A summary of the four relationships and their issues is given in Table II, where 'm' in the table header stands for 'many'. Note that the discussion here was at the module level, but it can be generalized to a larger programming unit, such as an entire application or even a set of applications, or smaller programming units, such as classes or methods.

B. Service-Oriented Polyglot Persistence

If the database is being used by more than one module or application, then the database can be *decoupled* from the application to reduce the complexity. In this case, only one *mediator* will be able to access and control the database. This mediator is an independent module or a small application that

TABLE II. ISSUES OF POLYGLOT PERSISTENCE RELATIONSHIPS

Issue	1-1	1-m	m-1	m-m
More than one query language might be needed	No	Yes	No	Yes
The module(s) need(s) to control cross-database consistency	No	Yes	No	Yes
Data integration might be required at the application side	No	Yes	No	Yes
The application should control cross-modules consistency	No	No	No	Yes
Data might be unnecessarily redundant	No	Yes	No	Yes
Database failure will be logically cascaded	No	Yes	No	Yes
Database configurations & security are dependent on more than one module	No	No	Yes	Yes

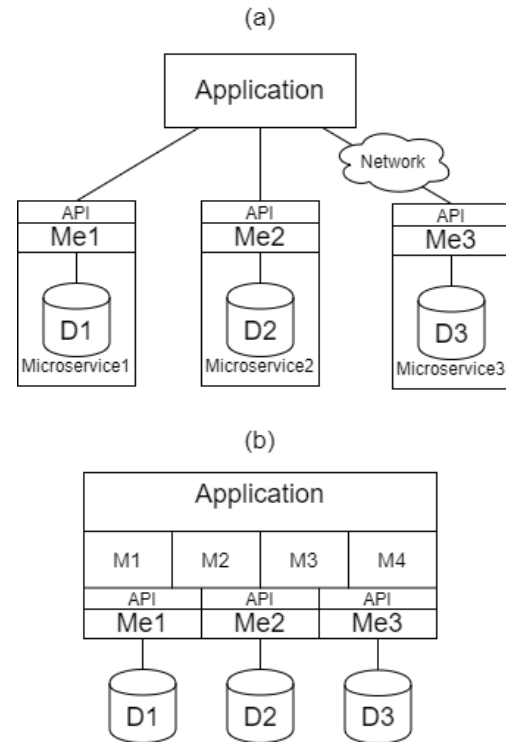

Fig. 3. Service-Oriented Architecture with (a) Microservices and (b) Modular Mediators

offers an API for external users. The degree of decoupling this mediator can have different levels. In one extreme, the mediator will completely be independent from the application and can be deployed in a different machine, and it can even be programmed with a different programming language. The API in this case will be network calls (e.g., REST API [63]). In this extreme, the mediator is part of what is called a *microservice* [64]. In the other extreme, the mediator is part of the application, and it offers an API as public function calls to other modules, or even other applications.

Regardless of the detailed structure of this architecture, it can be seen as service-oriented architecture [65], where the database is wrapped with a software controller (which is called inhere a mediator). Illustrative examples of this architecture are shown in Figure 3, where 'M' stands for module, 'Me' for mediator, and 'D' for database. In Fig. 3(a), the network cloud implies the possibility for the entire microservice to be remotely accessed.

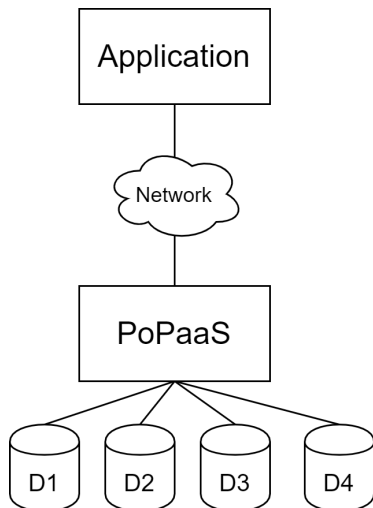

Fig. 4. An Illustrative Example for PoPaaS Architecture

A main advantage of this architecture is that different databases are accessed using similar APIs. The application is completely unaware about the underlying query languages of the databases. However, this architecture puts the load of managing consistency and cross-queries on the application modules. In case the relationships between the application and the databases are many-to-one or many-to-many, the same issues discussed in Section VI-A can be considered here.

Several strategies are proposed in the literature to manage polyglot persistence queries with microservices, and they are presented in [48].

C. Polyglot-Persistence-as-a-Service

In this architecture, the burden of managing polyglot persistence is conveyed to a completely different location, the cloud. The application here only provides the data requirements, and then these requirements should be satisfied by the Polyglot-Persistence-as-a-Service (PoPaaS) provider. The provider should automatically specify the appropriate database system for each segment of the data, based on its requirements, and then provide an API for data access. Such an API design strategy is proposed by [51].

The problem with this architecture is how the client can formulate the requirements in a standard format? Another problem is the selection of the appropriate database system for the given requirements, which should be automated based on quantifiable metrics [3]. A possible solution is to use an automated rule-based data model selection technique, as proposed by [52]. In reality, we do not know an example of such a service. An illustrative example of this architecture is shown in Fig. 4.

D. Multi-Model Databases

Instead of dealing with the complexity of managing multiple databases, one possible solution is to use a database that supports multiple data models, which is called a multi-model database. In this case, the application will manage a single database that fulfills its requirements. Multi-model database

engines can be designed to manage a combined data model that has the features of several data models. OrientDB and ArangoDB are two examples of such databases [66]. They support document, graph, and key-value data models in one database instance. OrientDB has a query language that is very similar to SQL, while ArangoDB has a new language called ArangoDB Query Language (AQL), which is similar to an extent to SQL.

A new paradigm to support more than one model is with the Flexible Schema Data Management (FSDM) [67]. This paradigm integrates the JSON data model into SQL databases. The stored JSON data is storable, indexable, and queryable, without the need for upfront schema definition. This support will reduce the use cases where polyglot persistence is needed because there will be no need to use NoSQL databases to store schema-less data. PostgreSQL and Oracle databases are examples of such database systems that support this feature [68].

Despite the support for multiple data models in those databases, they do not eliminate the demand for polyglot persistence because there are still non-functional requirements that are not satisfied, such as scalability and performance [69]. This emphasizes the fact that satisfying all polyglot persistence requirements in one database system is an engineering challenge [3], and apparently, having a one-size-fits-all solution is not yet feasible.

VII. POLYGLOT PERSISTENCE IMPLEMENTATION STRATEGY

In this section, we propose an implementation strategy that can aid the development of polyglot persistence applications.

A. Step 1: Database Requirements

The first thing to start with is the requirements. The correctness of the requirements should be ensured because the following steps will be dependent on them. Database requirements must be consistent with the application requirements, and they should include functional, non-functional, and data requirements. Database functional requirements should include the queries that will be used to manage application data. Examples of non-functional requirements include consistency, integrity, and availability. One of the most important parts of data requirements is the conceptual data model, which should be created at this step using Unified Modeling Language (UML) [70] or Entity-Relationship (ER) [71] diagrams, for example.

B. Step 2: Database Selection

Based on the gathered requirements, the database system should be selected. At this step, conflicts between database requirements should be identified and resolved by using as many database systems as needed. If there was no conflict, the implementation will normally proceed using one database system without considering polyglot persistence. Otherwise, different database systems should be selected carefully, considering the most persistent database system for each part of application data. A clear mapping between each part of the data and the selected database systems should be preserved. Note that steps 1 and 2 can be accomplished using the systematic approach proposed in [55].

C. Step 3: Database-Specific Data Models

Conceptual data models for each database system should be derived from the general conceptual data model identified in step 1, considering the process proposed by [72]. Since different database systems use different storage models, each of them may require a specific data model to determine database schema. At this step, using a database-independent schema declaration language can be helpful [73].

D. Step 4: Polyglot Persistence Architecture

In this step, the architecture in which the application will be implemented should be designed. The architecture determines how the application will be talking to the different selected databases. The architecture design should consider implementation cost, time, and resources. The discussion on polyglot persistence architectures given in Section VI can guide this step.

E. Step 5: Issues Identification

After selecting the architecture, polyglot persistence issues associated with the selected architecture should be identified. After identifying the architecture issues, a clear plan on how they will be resolved should be made. This plan should include the technical details on how each issue will be addressed. Again, the issues and their resolutions can be inspired by the discussion in Section VI.

F. Step 6: Application Development

This is the last step in which the actual implementation for the application and its infrastructure should start based on the results of the previous steps.

VIII. CONCLUSION

Large applications may require more than one database system to satisfy their requirements. This environment that operates on multiple databases is called a polyglot persistence environment. The polyglot persistence environment is fraught with many challenges and problems. This paper presented classification of database systems with details about their features. Polyglot persistence principles, its possible architectures, and the issues related to each architecture are identified. A polyglot persistence implementation strategy is proposed in light of the study outcomes.

The authors believe that this work has clarified most of the concepts related to polyglot persistence. This work can be a helpful reference for solving polyglot persistence problems.

Future research can further propose solutions to issues introduced by polyglot persistence. A protocol for inter-database negotiations might be devised to support interoperability between different database systems as a means to address issues related to polyglot persistence. Furthermore, future research can study how database functional, non-functional, and data requirements can be reported standardly. In addition, it can study the possibility of having an approach for representing and analyzing database requirements that can automatically determine the needed database systems.

ACKNOWLEDGMENT

The authors would like to thank King Fahd University of Petroleum and Minerals for the support and facilities provided to perform this research.

Computer Vision: The Effectiveness of Deep Learning for Emotion Detection in Marketing Campaigns

Shaldon Wade Naidoo, Nalindren Naicker*, Sulaiman Saleem Patel and Prinavin Govender
Department of Information Systems,
Durban University of Technology,
Durban, South Africa

Abstract—As businesses move towards more customer-centric business models, marketing functions are becoming increasingly interested in gathering natural, unbiased feedback from customers. This has led to increased interest in computer vision studies into emotion recognition from facial features, for application in marketing contexts. This research study was conducted using the publicly-available Facial Emotion Recognition 2013 data-set, published on Kaggle. This article provides a comparative study of four deep learning algorithms for computer vision application in emotion recognition, namely, Convolution Neural Network (CNN), Multilayer Perceptron (MLP), Recurring Neural Network (RNN), Generative Adversarial Networks (GAN) and Long Short-Term Memory (LSTM) models. Comparisons between these models were done quantitatively using the metrics of accuracy, precision, recall and f1-score; as well and qualitatively by determining goodness-of-fit and learning rate from accuracy and loss curves. The results of the study show that the CNN, GAN and MLP models surpassed the data, and the LSTM model failed to learn at all. Only the RNN adequately learnt from the data. The RNN was found to exhibit a low learning rate, and the computational intensiveness of training the model resulted in a premature termination of the training process. However, the model still achieved a test accuracy of up to 72%, the highest of all models studied, and it is possible that this could be increased through further training. The RNN also had the best F1-score (0.70), precision (0.73) and recall (0.73) of all models studied.

Keywords—computer vision; deep learning; emotion detection; generative adversarial networks, marketing campaigns component

I. INTRODUCTION

The evolution of technology has enabled businesses to gain a better understanding of their customers and develop products and services to better accommodate their markets [1]. The growth of customer centric business models has led to a variety of research studies in business and academia. Notably, Zaim et al in [1] have studied different analytical models for measuring customer experience (CX). A common requirement of these analytical models is that subjective opinions on CX are needed. These opinions are typically captured using surveys and similar methods in [2] and [3]. However, these methods are subject to bias due to human elements such as dishonesty and pressure. This has motivated for more technologically driven, automated approaches to soliciting customer feedback which mitigate some of these biases. One such approach is the use of computer vision to recognise human emotion from facial features. In these studies, cameras were used to record the facial expressions of individuals in real-time. The video

footage was then processed to determine emotions based on the facial expressions that were recorded, and hence obtained a more authentic source of CX feedback.

In this work, we evaluate and compare a variety of machine learning algorithms that perform human emotion recognition in the context of marketing campaigns. Our study focuses on the following three: happiness, anger and surprise. In the context of marketing studies, happiness is an emotion that indicates that adverts are received favourably, which strengthens brand reputation [2]. Anger is a powerful emotion that can evoke responses from communities, and can be leveraged in social marketing campaigns around sensitive or political issues [2]. Finally, the emotion of surprise creates a sense of urgency in a marketing campaign, and may result in consumers taking more immediate action (e.g. online popup advertisements that are valid for a limited time) [2]. Emotion recognition is a classification problem, which literature indicates can be solved using the “deep learning” class of machine learning algorithms [4], [5]. Deep learning is a class of machine learning algorithms that mimics the way the human brain functions, and are typically used in solving prediction or classification problems [6]. The review study by Liang et al. in [7] showed that the convolutional neural network (CNN) deep learning algorithm is popular when performing facial expression recognition (FER). In this paper, other deep learning algorithms were explored and compared to the CNN model to perform FER; viz. the Multilayer Perceptron (MLP), Generative Adversarial Networks (GAN), Long-Short term memory (LSTM) and Recurring Neural Network (RNN) models were studied. The performance of these models was evaluated using accuracy, f1-score, precision, and recall as metrics [8].

May 24, 2022

II. LITERATURE REVIEW

In their 2017 study, Siau and Yang in [6] stated that marketing is a field that has been impacted by advanced technology. The pair elaborated that the marketing field is the most vulnerable to be radicalized by the Fourth Industrial Revolution. In the years following the article, there were significant findings that were made in which the above predictions were fulfilled. Articles that prove this are discussed in the literature review that follows.

Ładyżyński, Żbikowski in [9] experimented in 2019 on a system that directs marketing campaigns to targeted customers,

utilising machine learning techniques. This paper proposed the use of several machine learning algorithms such as Random Forest classifiers, Deep Belief Networks and Classification and regression (CART) classifiers. The team made use of a time series approach. In addition, in order to get results, a marketing campaign simulator was used. This simulator mimicked the call centre scenario described in the paper. Metrics such as precision and recall were applied to evaluate the models.

In the year 2020, Koehn, Lessmann in [10] published findings in which predictions were made about the online shopping behaviour from click-stream data using deep learning. In the paper, the data of user sessions were utilised and mined within a time frame of three months. The data was submitted into various classification models such as Multilayer Perceptron, Long Short-Term Memory (LSTM), Gradient Boosting and Gated Recurrent Networks. The results from this model were based on revenue, the amount of revenue each correct prediction brought in and model accuracy.

Cheng and Tsai in [11] published results in 2019, in which three deep learning models were applied for automated sentiment analysis using social media data. The use of WOM (word of mouth data) was supplied into a LSTM, Bidirectional LSTM (BiLSTM) and Gated Recurrent (GRU) model. The methodology consisted of employing a web crawler in order to gain the data. The data underwent pre-processing due to anomalies such as colloquialism and emotions. The data was labelled using tools such as NLTK and MS text block API, embedded through GLoVe and eventually distributed into the three models. The models were equipped to predict sentiment, and were evaluated using metrics such as precision, recall, F-measure and accuracy [11].

Reviewing these four articles and the respective methodologies proved that Siau and Yang's findings in [11] that was published in their article, which suggests technology is taking over the marketing field at an alarming rate. A common topic among these four articles was the use of Deep Learning. Deep learning is the ability to mimic behaviours of the human brain to solve problems using technology. Emotion depicts a person's feelings about a certain situation and is often portrayed by a facial expression. Therefore, if we were to detect a person's facial expression, one can classify how a person ought to feel about certain scenarios. In the next section of our literature re-view, the relevant findings on the use of deep learning in emotion detection are going to be explored further.

Ko in [12] published a brief review of facial emotion recognition methods. This paper stated that there are two types of ways in which facial recognition can be detected using static and dynamic images. Further on into the paper, the process of recognizing these emotions were described. The process flows from the input images, followed by facial detection and landmark detection, feature extraction and lastly emotion classification were discussed. This process is a standard for all facial emotion recognition experiments; however, it may be flawed. Due to the process the raw image itself is not used and only features are extracted. There are many different models in which can be used to detect facial emotion recognition.

The use of a CNN model for Facial emotion recognition (FER) is common. Tümen, Söylemez in [13] used a CNN model in their paper in which had a 57% success rate. The

methodology included using images from the FER 2013 data-set. Subsequently, the images were supplied into a 3-layer CNN model after feature extraction. The draw-back from this experiment was the data split. Tümen, Söylemez in [13] split the FER data-set into an 80% for training 10% for testing and 10% for validation.

An MLP model is a multi-layer perceptron which consists of multiple neural layers. This model, as used by Tarnowski, Kołodziej in [4] in their findings, is the second most common FER model. Tarnowski, Kołodziej in [4] published findings in which real time 3D data was used to classify amongst the MLP model. The input consisted of a data size of 12 men, in which is relatively small and biased. However, the team was able to obtain a model accuracy of 73%. The methodology used included using a Microsoft Kinect camera in which 12 men sat two metres away from each other. Each participant was tasked with mimicking certain facial expressions. The data collected was deposited into the model, which consisted of seven neural layers, and finally a classification was done. The use of live data left room for many flaws. The response time of the participant to mimic expressions, the lighting conditions, The limitations of the Kinect camera and the size and biases of the data-set were a part of several flaws in this title.

GAN models are an interesting topic. Yi, Sun in [5] experimented on image augmentation using a GAN model. Images were used from the FER 2013 data-set in which a GAN model was able to augment some images and used the images normally. In the paper, it was found that a higher accuracy was generated by using the GAN for image augmentation. However, in this paper, a CNN was done to generate these results as opposed to a GAN model. These models do have potential in facial recognition as stated by Luo, Zhu in [14].

Another deep learning model which is overlooked due to CNNs are LSTM-RNN models. Sepas-Moghaddam, Etemad in [15] stated in their paper that the tested method of an LSTM-RNN model proved to be superior to the normal CNN way of image classification. In the publication, the use of a CNN VGG16 model extracted special features and also added an attention mechanism, which enables effective learning, before running the image through a Bi-directional LSTM-RNN model. The experiment used 800 images from the LFFD data-set. In the absence of the attention layer, the normal LSTM model produced an accuracy of 80%. There is room for improvement with this model. A bigger data-set with more expressions is recommended to solidify the results.

The manner in which technology has impacted the marketing field and how deep learning has been used to identify facial expressions and classify it as an emotion has been expressed in aforementioned statements. Reyes in [16] stated in an article that expression can be derived from emotion, and that emotion is a type of universal language, which stands in the gap for verbal communication. This leads us onto the last section of this literature review. The following section will discuss emotion detection in Marketing.

Yolcu et al in [17] published findings about a deep learning face analysis system to monitor customer interest. In their findings they monitored customers head position and facial expression to determine how interested customers are. In the methodology of the article Yolcu et al, used the Viola and

Jones algorithm for feature extraction, in which the image was cropped and only the head pose, and facial expression was extracted. A 3-layer CNN model was used to classify 8040 images for head position and 1206 for facial expression, from the Radboud Face Database. To verify this system the KDEF database was used with 4900 images and seven different emotions. A 90:10 split was done for model training and testing. A 94% accuracy was achieved for emotion accuracy in this article. Yolcu et al, used a mask generation flow in order to achieve such high results. The images were also pre-processed twice, using the Viola and Jones algorithm and also another CNN model. To improve this research, a multimodal approach in which multiple models can be used are suggested.

Ceccacci, Generosi in [3] experimented on a deep learning system which tracked and monitored customer behaviour in store. The system conducted testing in real life, using a Logitech Quickcam 4K camera. This experiment input the images of customers into these cameras which was linked to a CNN model. A total of 30 customers, split equally of gender, were tested. Images of them were distributed into a CNN model that was trained and tested using FER+ and EmotioNet data-sets in which consists of millions of images between the two. Model accuracy was not stated in the article. However, the model was able to predict 66% of emotions in the live experiment. These are two of the articles in which face emotion recognition was processed and completed using deep learning.

In our review of similar work, we have discussed deep learning in marketing, the use of deep learning in emotion detection and emotion detection in marketing. It can be assumed that there are gaps in literature that can add to how one can utilise deep learning in emotion recognition in order to aid marketing strategies.

III. METHODS AND MATERIALS

A. Data Acquisition

This study uses the Facial Emotion Recognition 2013 (FER 2013) data-set, available publicly on Kaggle [16]. The FER 2013 data-set consists of 35 685 greyscale images of size 48x48 pixels, and the provides recommended splits for testing and training image sets.

Fig. 1. Sample Images: Angry

In our study, the original FER 2013 data-set was first divided into two smaller data-sets. This was a result of limited processing power available by the HP i5 4GB RAM that was

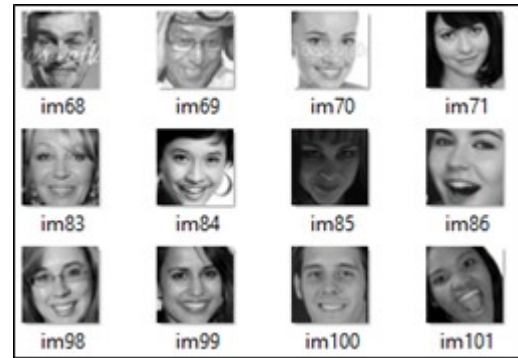

Fig. 2. Sample Images: Happy

Fig. 3. Sample Images: Surprised

used in performing these experiments. Both data-sets were then subdivided into training and testing sets, using an 80:20 ratio. In this research experiment, three emotions from the original FER 2013 data-set were considered (i.e. happy, angry, and surprised). Sample images from the FER 2013 data-set are provided in Fig. 1, 2 and 3, which show sample images of angry, happy and surprised facial expressions, respectively. The motivation for selecting these three emotions for the scope of this study was given in Section I.

The first data-set contained 12 000 images from these three images classes, consisting of 3 000 training images and 1 000 test images per emotion class. A similar structure was used for the second data-set, in order to avoid any type of bias. This data-set consisted of 21 000 images (5 600 training images and 1 400 testing images per emotion class).

B. Data Pre-Processing

There are generally two approaches to performing facial expression recognition (FER) using computer vision. The first is to pre-process images and extract features from them, which form the input to the machine learning algorithm. This has been shown to provide robust machine learning models in some studies, for example the study by Ceccacci et al [3]. The second approach is to use raw pixel data directly, which allow deep learning models to identify features for themselves during the model training process [18]. Exploratory checks performed on the data indicated that quality of images was high, and hence the experiment was designed using raw pixel data with no feature extraction or cleaning. However, model-

TABLE I. EXPERIMENT PROCESS

Step No.	Step Name	Details
1	Imports	Relevant import classes were imported into the experiment. Consistent imports namely would be Tensorflow, Keras, Matplotlib.pyplot, OpenCV and OS.
2	Pre-processing	A method is created in which sorts data according to its label and expression and populates them into an array. Images are also resized in this method
3	Train and Test variable population	The above method created populates the relevant data into their train and test variables.
4	Array Reshape	The array size of each image is reshaped according to the model requirements.
5	Hyper-parameters set	A model is called in which hyper parameters are set. All models consist of the same hyper-parameters, except for layers and epochs. This is due to model requirements.
6	Model compiled	The model is compiled and set to produce model accuracy. Categorical cross-entropy to help us measure the performance of the classification output and tell us the difference between the classifications.
7	Epochs set, model fitted.	Epoch numbers are set and the model is fitted with training and testing data. The output of this step would be the accuracy of the model.
8	Graphs and Table of results.	Graphs are created to measure validation loss and accuracy. Table of results calculated

specific data transformations were necessary (discussed further in subsection 4).

According to [19], data segmentation and data transformation are critical factors in data pre-processing. Consequently, in this experiment, data segmentation was performed first by splitting the training and testing data to ensure we kept the integrity of the 80:20 split. Furthermore, each emotion had been allocated its own files within the testing and training folders. Each image was resized using OpenCV, to ensure the data would meet model requirements. In order to ensure the deep learning model was able to learn properly, each image was converted into an array. In which, the label and feature of each image was stored respectively.

Singh and Singh in [20] stated in their article that normalization of data in deep learning is imperative in order to make a good contribution to each feature. The writers also stated that normalization is a critical success factor in the learning of each algorithm. Therefore, in our experiment, we normalize the data according to the requirement of the algorithm being used.

Concluding our data pre-processing, the use of methods such as data segmentation, data transformation and data normalization ensured that each model that was used has an equal chance at performing its best.

C. Design of Study

The experimental design method was used in the study of the effectiveness of deep learning for emotion detection in marketing campaigns. This type of study proved effective in a number of deep learning articles [4], [21], [22]. The independent variable being the different types of deep learning models such as CNN, GAN, MLP, RNN and LSM. The dependent variable was our metrics such as model accuracy, f1-score, precision and recall. The model accuracies depend on the type of model in order to prove the title of our paper. Experiments carried out on both data-sets followed the same steps and procedures, to prevent biasness in any way. Our experiments were conducted on Jupyter Notebook, using Python 3.0. It consisted of eight steps, as indicated in Table I above.

The steps shown Table I were a general guideline of how we carried out the experiment on how effective deep learning

was used for emotion recognition. The process outlined is consistent with the extant literature, such as in [23].

D. Algorithms

In the study that was conducted, we focused on five deep learning models. Convolutional Neural Network (CNN), Long Short-Term Memory (LSTM), Multilayer Perceptron (MLP), Generative Adversarial Network (GAN) and Recurrent Neural Networks (RNN). In this subset of our paper, we will be discussing in depth, these models and their unique capabilities they bring to the deep learning field. We will also discuss how they have been implemented and define functions used to generate appropriate outputs.

1) *Convolutional Neural Network (CNN)*: CNN classifiers have been getting high amount of recognition in the deep learning world [24]. Most image classification problems use CNN models, due to the high levels of model accuracy, CNN has also proved to be the better and most preferred model amongst most deep learning models for image classification [25]. Convolutional neural networks generally consist of two layers. The first being a convolution layer, also known as a C layer. The second layer being the subsampling layer, known as the S layer. Each S layer follows a C layer as depicted in graph below. Convolutional Neural Networks have an advantage over normal deep learning models, having the ability to accept 2D images without major changes to the array.

Fig. 4. Conventional CNN

The illustration depicted in Fig. 4 is a basic CNN model. Normally CNN models consist of two C1 layers and two S1 layers. However, to explain its structure we will use a single C1 and S1 layer. The input image, usually in the form of an array, would be fed into the first C1 layer. In this layer, feature maps would be formed through the convolutions. These feature maps would be inputted next into the S1 layer. During sampling the

feature map size would be reduced by a pooling method which normally consists of 2×2 . Usually this process is repeated, depending on the number of layers. After the S1 layer the data is rasterized and a classification is formed.

The CNN model that we experimented on consisted of five convolution layers, in which had a kernel size of 3. Five Subsampling layers of pooling size 2×2 . We used the Rectified Linear Unit (ReLU) activation function to output the input only if the output is a positive value. We used batch normalization to improve the speed of our model and finally a dropout of 0.20 is used in order to prevent overfitting. The equation for the ReLU activation function is describe as:

$$f(x) = \max(0, x) \quad (1)$$

2) *Multi-Layer Perceptron (MLP)*: MLP models are binary classifiers in the field of deep learning. General MLP models consist of multilayers however, single layers are also used. MLP models are famously used to state whether an input is something or not. Each Perceptron model consists of three layers. An input layer, a hidden and an output layer. Perceptron has a general rule, it states that the model will learn the best weight coefficients.

Fig. 5. MLP Model

Following from the beginning of the diagram in Fig. 5 the inputs were read in the input layer. In the hidden layer the weights were then calculated and their net input function was determined. After this, their activation function transformed the net input into an output, within the output layer. If any errors occurred, they were caught and sent back to the input layer. The perception activation function is described as:

$$f(x) = \begin{cases} 1 & \text{if } \mathbf{wX} + \mathbf{b} > 0 \\ 0 & \text{otherwise} \end{cases}, \quad (2)$$

where \mathbf{w} is the real weight value matrix, \mathbf{b} is the bias vector and $\mathbf{X} = [x_1 \dots x_k]^T$ is the k -dimensional vector of input data. Note that the boldface in (2) represents matrix variables, rather than scalar variables and that $(\cdot)^T$ represents the matrix transpose.

As stated above, each MLP model consists of three layers. In the research that we have carried out, the MLP model that we used consists of two dense layers. The first dense layer

having 128 neurons and using the ReLU activation function. The second layer consisting of 5 neurons and the softmax activation function

E. Generative Adversarial Network (GAN)

The popularity around GAN models stems around their ability to augment data. GAN models are used famously throughout the deep learning fields to enhance other deep learning algorithms [26]. GANs are generally made up of two smaller deep neural networks. The first being a generator, in which is responsible for generating data. The second being a discriminator, which takes the real and fake images to classify which one is real or fake.

Fig. 6. GAN Model

Fig. 6 depicts the general structure of a GAN model. In the experiment that we have conducted, the GAN model does not consist of a generator, due to the input images already being available. However, the discriminator that we have used consists of a method created. The discriminator consist of two down sample layers consisting of three kernels each and LeakyReLU as an activation function, which was suggested from reviewing the works of Krestinskaya, Choubey in [27]. The activation function for LeakyReLU is described below.

$$f(x) = \max(0.01x, x), \quad (3)$$

where x is the input to the activation function.

Our discriminator also has a flatten feature, followed by a 0.4 dropout layer. The output layer of our GAN model has a softmax activation function. It is understood that GAN models classify whether an image is fake or not. However, in our research we were able to recognize whether an emotion was present or not by using three GAN models developed independently. In this study we utilized the GAN models to independently test for the emotions “happy”, “angry” and “surprised”. The structure of the GAN was based on the work in [28].

F. Recurring Neural Network (RNN)

The operations and structures of RNNs are the same as Fig. 7. RNNs feed the information through their vectors back into their input gates. In the RNN model that we used, the hidden layer consisted of 64 neurons, a dropout layer and a recurrent dropout layer. In the second hidden layer we used the ReLU activation function. For the output layer we use a dropout of 0.5 and the softmax activation function.

G. Long Short-Term Memory (LSTM)

LSTM models are a type of RNN deep learning model. Conventional neural networks have a feed forward tendency. However, the LSTM models have a feedback connection. LSTM neural networks are advancements of the general Recurrent neural network model and are known for modelling chronological sequences [29]. However, they can be used to classify images [30].

Fig. 7. General LSTM Model

The labels $Ct-1$, $ht-1$ and xt represent the input values for the LSTM diagram shown in Fig. 7. The stars represent pointwise operations, and the rectangular boxes are neural networks. Each arrow represents a vector movement. $Ct-1$ to Ct represents the cell state and is the key to any LSTM model. Each pointwise operation is followed by a quadrature which were seen by the sigmoid function. Together the pair is called a gate, and their prime purpose is to allow data to flow through. Each LSTM model consisted of three gates to control the flow of information. The outputs of these gates were either 0 or 1. Which represent to let information through or not, respectively. Information flowed from $ht-1$ and xt through the gates one and two, followed by the hyperbolic tangent operator. Then finally through the third gate and the second hyperbolic tangent operator followed by the output [31].

Our LSTM model has two layers, both of which uses the ReLU activation function, and a kernel optimizer. The model also has a loss and momentum function to prevent over fitting and help with model performance.

H. Performance Metrics

In the experiment that was conducted a total of four metrics were used. The descriptions of the evaluation metrics are [8]:

- **Precision:** Precision is the number of most relevant instances amongst those that were retrieved. It is a metric used in our findings to determine how correct our model is and how many true predictions were made.
- **Recall:** Recall measures the actual number of relevant instances made, without taking those that were retrieved into accord [8]. This metric determines the number of positive predictions made by the model.
- **F1-score:** Also known as the F score, these metrics are used in binary classifiers. They determine how accurate each model is according to the data-set.
- **Model accuracy:** This is the output accuracy taken from the model training. It determines how accurately the model has been trained.

IV. RESULTS AND DISCUSSION

In this section, we present the results of the comparative study that investigated emotion recognition using deep learning algorithms. Five deep learning models were considered (i.e. CNN, MLP, GAN, RNN and LSTM) and compared in terms of four metrics (accuracy, F1-score, precision and recall). The learning rates of each model produced was also discussed. Details on the configuration of each algorithm studied was provided in Section III-D.

The results of the study are summarised in Table II, which gives results broken down by model and data set used. Analysing the results presented in Table II, the following points are noted:

- The LSTM model fails to learn for both data-sets and is not suitable for performing FER. This is intuitively understandable, as the LSTM model is deep learning algorithm that is designed primarily for sequential or chronological data [29]. As such, poor performance was understandable when considering independent, unrelated images such as those used in this study.
- The CNN, MLP and GAN models are overfitted to the respective data-sets and do not produce trained models that can be applied to generalised data. This makes these models unsuitable for performing facial emotion recognition.
- The RNN learns appropriately and achieves a 72% accuracy on the larger of the two data-sets (Data-set 2). The accuracy and loss curves indicate that this accuracy can be improved by further training, but this was not done in this study due to the computational intensiveness of training the model and its low learning rate. The RNN performs best in terms of precision, recall and F1-score.

V. CONCLUSION

In this study, we considered five deep learning algorithms for facial emotion recognition, with the overall objective of utilising deep learning to improve marketing business functions by soliciting more accurate feedback on CX. The algorithms studied were the CNN, MLP, GAN, RNN and LSTM. Although literature often uses the CNN for facial emotion recognition studies, in our study the CNN overfits to training data and the RNN is found to be more suitable. The designed RNN is computationally intensive to train, and training in this study was terminated prematurely. The model achieved a 72% testing accuracy on a 21 000-image subset of the FER 2013 data-set, and indicators are that more training could improve this accuracy. This motivates for more intense studies that design RNN-based computer vision systems for facial emotion recognition. We recommend that future works in this area use cloud computing technologies to overcome the limitations of computational intensiveness. In so doing, a larger and more varied data-set could be evaluated which may influence the performance of the models evaluated. It would also be interesting to consider more emotion classes in future studies to cover a broader spectrum of human reactions.

TABLE II. SUMMARY OF RESULTS

Model	Data-set	Accuracy	Precision	F1-score	Recall	Learning and Fit
CNN	1	0.68	0.73	0.68	0.68	Loss-epoch curve shows evidence of severe overfitting.
	2	0.70	0.70	0.70	0.70	Loss-epoch curve shows evidence of severe overfitting.
MLP	1	0.56	0.66	0.57	0.57	Loss-epoch curve shows evidence of moderate overfitting.
	2	0.57	0.63	0.56	0.56	Loss-epoch curve shows evidence of severe overfitting.
GAN	1	0.68	0.67	0.60	0.60	Loss-epoch curve shows evidence of moderate overfitting.
	2	0.65	0.72	0.66	0.66	Loss-epoch curve shows evidence of severe overfitting.
RNN	1	0.60	0.78	0.71	0.71	Learning rate is slow, further training could improve accuracy.
	2	0.72	0.70	0.73	0.73	Learning rate is slow, further training could improve accuracy.
LSTM	1	0.33	0.50	0.33	0.33	Model does not learn.
	2	0.35	0.30	0.46	0.46	Model does not learn.

FUNDING

All funding to support this research was provided by the Durban University of Technology.

DATA AVAILABILITY STATEMENT

The data on facial emotion recognition 2013 (FER-2013) is available online at <https://www.kaggle.com/ananthu017/emotion-detection-fer>

ACKNOWLEDGMENT

The authors would like to acknowledge Lerissa Gounden (BEd) of the University of Johannesburg for editing and Ghulam Masudh Mohammed (BICTH) of the Durban University of Technology for their respective inputs.

CONFLICTS OF INTEREST

The authors declare that there are no conflicts of interest.

Using Machine Learning Techniques to Predict Bugs in Classes: An Empirical Study

Musaad Alzahrani
Department of Computer Science
Albaha University
Al-Baha 65799, Saudi Arabia

Abstract—Software bug prediction is an important step in the software development life cycle that aims to identify bug-prone software modules. Identification of such modules can reduce the overall cost and effort of the software testing phase. Many approaches have been introduced in the literature that have investigated the performance of machine learning techniques when used in software bug prediction activities. However, in most of these approaches, the empirical investigations were conducted using bug datasets that are small or have erroneous data leading to results with limited generality. Therefore, this study empirically investigates the performance of 8 commonly used machine learning techniques based on the Unified Bug Dataset which is a large and clean bug dataset that was published recently. A set of experiments are conducted to construct bug prediction models using the considered machine learning techniques. Each constructed model is evaluated using three performance metrics: accuracy, area under the curve, and F-measure. The results of the experiments show that logistic regression has better performance for bug prediction compared to other considered techniques.

Keywords—Software bugs; bug prediction; machine learning techniques; software metrics; unified bug dataset

I. INTRODUCTION

Software development is an error-prone process. Mistakes and errors that occur during the development process result in bugs that can ultimately cause software failure [1]. Software testing is one of the most important phases in the software development process which aims to identify bugs and to ensure the overall quality of systems before they are released. However, the testing cost and effort can grow dramatically when the size and complexity of a system increase. It is estimated that the cost of the testing activities constitutes around 25% of the total cost of the software development budget and it can reach to 50% when the size and complexity of the system increase [2], [3]. Therefore, the testing resources should be allocated efficiently in order to minimize the total cost of the overall development process.

Software Bug Prediction (SBP) is one of the most useful techniques that can be used to decrease the testing cost and effort [4]. The main goal of SBP is to identify the modules that are likely to have bugs. Software professionals use SBP models at the beginning of the testing phase to classify the modules of a system into bug-prone modules and non-bug-prone modules based on a set features extracted from the modules. The most commonly used features are software metrics that measures different characteristics of the module such complexity, size, coupling, and cohesion. Fig. 1 shows the basic architecture of a SBP model. Most of the testing cost and effort should be

Fig. 1. Basic Architecture of a SBP Model.

allocated on bug-prone modules in order to use the limited testing resources efficiently.

Many approaches have been introduced into the literature that have shown the success of using machine learning algorithms to construct SBP models (e.g., [5], [6], [7], [8]) based on public available bug datasets such as NASA and Columbus [9]. However, the size and quality of the bug datasets used to train SBP models can have a great impact on the performance of the models and can limit their generality. Ferenc, Rudolf et al. [10] explained several issues in most commonly used bug datasets including the missing of the source code elements associated with data; dissimilarities in terms of granularity, features, and format between the datasets; the missing values in the datasets; and the existence of contrasting bug information. To mitigate these issues, they produced a unified bug dataset at class and file level by analyzing the source code of the reported systems in 5 public bug datasets. The Unified Bug Dataset [10] contains the values of 60 metrics and bug information for 47,618 classes and for 43,744 files and their corresponding source code. Although the Unified Bug Dataset is considered to be a large and clean dataset and has better quality compared to most commonly used bug datasets, it has been used in only a few studies in literature (e.g., [10], [11]) to build machine learning based SBP models.

Therefore, this paper empirically investigates the performance of 8 well-known machine learning techniques, namely, Logistic Regression (LR), Support Vector Machine (SVM), K-Nearest Neighbor (KNN), Naive Bayes(NB), Decision Tree (DT), Bagging, Random Forest (RF), and AdaBoost based on the Unified Bug Dataset. The contribution of the paper is twofold:

- Constructing 8 SBP models based on the Unified Bug Dataset.
- Evaluating and comparing the performance of the constructed SBP models.

The rest of the paper is organized as follows. Related

studies are summarized and discussed in Section II. Section III describes the used methodology. The results and discussion are given in Section IV. The threats to validity are presented in Section V. Section VI concludes the study and provides future work.

II. RELATED WORK

SBP refers to the process of predicting buggy modules in a software system. In the last two decades, many approaches in the literature have introduced SBP models that tried to identify a causal relationship between a set of characteristics or features of a given software module and the existence of bugs in that module based on historical bug datasets. The most commonly used features to predict bugs are software metrics such as McCabe's Cyclomatic Complexity [12], Halstead Metrics [13], and Chidamber and Kemerer object-oriented metrics suite [14].

The majority of SBP models are constructed using machine learning algorithms such as LR (e.g., [5], [6]), SVM (e.g., [7], [8]), and KNN (e.g., [8]). The study by Basili et al. [5] was one of the early studies that used LR to construct a SBP model for the purpose of empirically validating Chidamber and Kemerer object-oriented metrics as quality indicators based data collected from 8 small object-oriented systems. The results of the study showed that the object-oriented metrics are beneficial to some degree to predict bugs in software systems in early phases of their development life cycle. Osman et al. [8] studied the impact of adjusting the parameters of two machine learning algorithms: SVM and KNN to build better SBP models. They conducted a set of experiments on five systems and the results showed that tuning the parameters of the two algorithms can improve their accuracy when compared to the default parameters setting. Researchers in [15] experimentally compared the performance of NB to DT for defect prediction based NASA Datasets [9]. Their results suggested that NB is more accurate and useful in predicting software defects when compared to DT. Singh et al. [16] analyzed the performance of five machine learning algorithms namely Artificial Neural Network, Particle Swarm Optimization, DT, NB, and SVM. They carried out a set of experiments on NASA datasets to compare the accuracy of the considered algorithms when used for software defect prediction. The output of the experiments showed that SVM outperformed the other 4 algorithms. Matloob et al. [17] conducted a systematic literature review on software defect prediction using ensemble learning methods. They considered only studies that were published in the period from 2012 to 2021. The results of their systematic literature review showed that RF, boosting, and bagging are the most frequently proposed methods in the literature during the considered period. In addition, their results showed that most of the proposed ensemble models were built based on PROMISE datasets [9] (which consists of a set of public datasets mostly NASA datasets). In a recently published study [11], the performance of the two ensemble learning methods: AdaBoost and Bagging was investigated. A set of experiments were conducted on the Unified Bug Dataset [10]. The results indicated that AdaBoost with a DT as a base learner outperformed Bagging technique.

A considerable amount of previously published studies have indicated the effectiveness of using machine learning algorithms to build SBP models. However, most of these

studies used bug datasets that are small or have erroneous data such as NASA datasets [18], [11]. Therefore, this study tries to bridge this gap by using a set of well-known machine learning algorithms to construct SBP models based on the Unified Bug Dataset [10], which is a large and clean dataset and which has been used in only a few studies in the literature [11].

III. METHODOLOGY

A. Motivation

Many machine learning algorithms have been used in previous studies to construct SBP models. However, the results of these studies are not always agreeing on the superiority of a machine learning algorithm or technique over others. In addition, most of the previous studies built SBP models based on bug datasets (such as NASA datasets) that have been shown to be noisy and containing erroneous data [19], [18], [11], which can have a significant impact on the performance of these models.

Motivated by the previously mentioned remarks, this study aims to answer the following research question:

- RQ: What is the most effective machine learning technique (in terms of performance metrics) for bug prediction in classes based on the Unified Bug Dataset?

B. Research Framework

The overall research framework of this study is depicted in Fig. 2. The input dataset is first preprocessed. The preprocessing step includes data normalization and feature selection. After the preprocessing of the input dataset, the ten-fold cross-validation is used to train and evaluate the considered machine learning models. The ten-fold cross-validation randomly divides the dataset into 10 equal size subdatasets. For each subdataset, the remaining 9 subdatasets are used to train a model and the subdataset is used to test the performance of the model. Finally, the results of the ten-fold cross-validation for each model are averaged and reported.

C. Dataset

The Unified Bug Dataset [10] is used to construct the SBP models. The dataset contains information for 47,618 classes and for 43,744 files and their corresponding source code. The information includes the values of 60 software metrics (including McCabe's Cyclomatic Complexity [12], Halstead Metrics [13], and Chidamber and Kemerer object-oriented metrics suite [14]) and the number of bugs in each class and file. The values of the software metrics for the classes and files were calculated from their source code using the open-source OpenStaticAnalyzer tool [20]. The bug information of the classes and file were collected from 5 public bug datasets namely: PROMISE [21], Eclipse Bug Dataset [22], Bug Prediction Dataset [23], Bugcatchers Bug Dataset [24], and GitHub Bug Dataset [25].

D. Dependent and Independent Variables

The dependent variable Y in this study is binary (i.e., $Y \in \{0, 1\}$) where 0 means that the class does not have a bug (referred as non-buggy class) and 1 means the class has

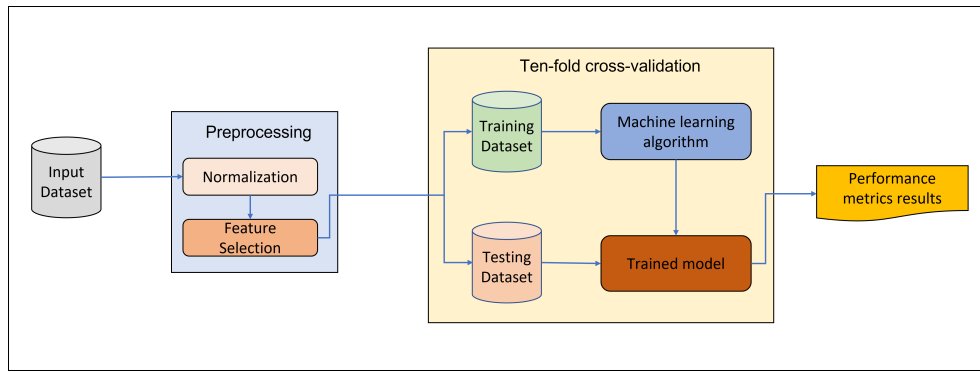

Fig. 2. The Research Framework of this Study.

Fig. 3. The Distribution of Classes in the used Dataset.

at least one bug (referred as buggy class). Figure 3 shows the distribution of buggy and non-buggy classes in the Unified Bug Dataset. It can be seen from Fig. 3 that the Unified Bug Dataset has imbalanced distribution in terms of buggy and non-buggy classes. The non-buggy classes make up to 82% of the total classes in dataset whereas the buggy classes form only 18%. The ultimate goal of a SBP model is to label a class in question with 0 or 1 based on the values of a set of independent variables. The software metrics of the classes reported in the Unified Bug Dataset are used as independent variables in this study. Software metrics of a class are quantitative measurements that indicate the degree to which a class possesses a property or attributes such as class complexity, size, coupling and cohesion.

E. Data Preprocessing

Two common techniques are applied sequentially to preprocess the considered dataset namely: MinMaxScaler [26], and correlation-based filter-subset feature selection with BestFirst search [27].

One issue in the Unified Bug Dataset is that the dataset includes software metrics that are not normalized (i.e., they do not have an upper bound) and they differ in the order of magnitude [4]. This issue can have a negative impact on the accuracy of a prediction model [4]. Normalization is a commonly used technique that is used to address this issue by rescaling of the original values of variables to a specific range. In this paper, the MinMaxScaler [26] technique is applied

in the data preprocessing to transform the original values of all the metrics in the Unified Bug Dataset between the closed interval 0 and 1.

High dimensionality is another issue in the Unified Bug Dataset. The dataset includes 60 software metrics. Fig. 4 shows the Spearman correlation coefficients between each pair of software metrics in the dataset. As it can be seen from Fig. 4, some of these metrics have strong correlations with each other. Building SBP models based on high dimensional redundant dataset takes more time and computational resources and can negatively affect the performance models [4], [28]. Therefore, researchers often apply feature selection techniques to address this problem before constructing prediction models [1], [29], [30], [31]. In this study, the correlation-based filter-subset feature selection with best first search is used. This technique was found to be the best when used in the field of SBP among 30 feature selection techniques that were analyzed in a large-scale study [27].

F. Learners

The learners that are used to build SBP models in this study include: Logistic Regression (LR), Support Vector Machine (SVM), K-Nearest Neighbor (KNN), Naive Bayes (NB), Decision Tree (DT), Bagging, Random Forest (RF), and AdaBoost. The former 5 learners referred in the literature as traditional learners whereas the latter 3 learners referred as ensemble learners. In traditional learning techniques, a single learner (e.g., LR) is used to build a prediction model. On the other hand, a combination of learners are used to build a prediction model in ensemble learning techniques [17]. A brief description of each learner is given in the following.

Logistic Regression (LR): LR is a statistical model used to predict a binary dependent variable based on a set of independent variables using the following equation:

$$\pi(X_1, X_2, \dots, X_n) = \frac{1}{1 + e^{-(C_0 + C_1 X_1 + C_2 X_2 + \dots + C_n X_n)}} \quad (1)$$

where X_1, X_2, \dots, X_n are the independent variables and C_1, C_2, \dots, C_n are estimated regression coefficients. The larger the absolute value of the coefficient, the stronger the impact of the independent variable is on the dependent variable. π is the probability that a the dependent variable is 0 or 1.

Fig. 4. A Heat Map Showing the Spearman Correlation Coefficients between the Software Metrics Existing in the used Dataset.

Support Vector Machine (SVM): SVM is a discriminative classifier algorithm that separates data samples into (generally) two different classes. The data samples are represented on 2-dimensional space and SVM tries to find an optimal hyperplane that divides the 2-dimensional space into two parts such that the data samples of each class reside on one part.

K-Nearest Neighbor (KNN): KNN is simple algorithm that solves the machine leaning classification problems by finding the k nearest neighbours (which has been previously classified) to the data point to be classified. Then KNN classifies the data point to the most frequent class in k nearest neighbours.

Naive Bayes (NB): NB a simple technique that is used to build a probabilistic classifier based on Bayes’ theorem. NB classifiers assume that the input features are statistically independent. Thus, each feature contributes independently to the probability that an instance data belongs to a certain class regardless the correlation between the considered feature and other features.

Decision Tree (DT): DT is a learning technique that constructs a decision tree model for classification problems based on the given dataset. Each internal node in the constructed tree

symbolizes a test condition on a feature, each branch denotes an output of a test condition, and each leaf node denotes a label (or a decision).

Random Forest (RF): RF is an ensemble learning method that uses a set of unpruned decision trees for classification. The decision trees are constructed based samples of the dataset. During the classification of a data sample, the data sample is given to each decision tree and the class label of the instance is determined by taking the mode of the outputs of the decision trees.

Bagging: Bagging (aka Bootstrap aggregating) is an ensemble learning method that aims to improve the accuracy of machine learning algorithms most commonly decision trees. It reduces the variance of a model and helps to avoid the overfitting of data. It creates n subdatasets each of which contains a subset of features and data samples that are randomly selected with replacement from the original training dataset. The n subdatasets are used in parallel to construct n base (or weak) prediction models. The label class predicted by the majority of the base models is chosen to be the output of the bagging classifier.

AdaBoost: AdaBoost (stands for Adaptive Boosting) is an

ensemble learning method that is used to combine multiple weak classifiers into a single strong classifier for the purpose of improving the accuracy and performance of the weak classifiers. The weak classifiers in Adaboost are usually decision stumps which are decision tree with just one node (the root) and two leaves. The weak classifiers are trained sequentially. Samples misclassified by a weak classifier are given more weight in subsequent classifiers. Also each weak classifier is given a weight according to its accuracy. The final output of Adaboost classifier is the weighted sum of the outputs of the weak classifiers.

G. Performance Evaluation

Three performance metrics are used to evaluate the performance of the constructed models including accuracy (ACC), F-measure (F1), and Area under the ROC Curve (AUC). These metrics are widely used in the literature to evaluate SBP models.

Accuracy measures the fraction of the predictions that are classified correctly by a model. The value of accuracy ranges from 0 to 1 where a higher value means better accuracy. It is calculated for a binary classification according to the following equation:

$$ACC = \frac{TP + TN}{TP + TN + FP + FN} \quad (2)$$

where TP = True Positives, TN = True Negatives, FP = False Positives, and FN = False Negatives.

The F-measure is a commonly used performance metric (especially in case of the existence of an imbalanced classification problem) that considers both the precision and recall of a model. It is the harmonic mean of the precision and recall and its value ranges from 0 to 1 where a large value means a better performance. The following equation is used to compute the F-measure:

$$F1 = \frac{2 * Precision * Recall}{Precision + Recall} \quad (3)$$

where the Precision and Recall are calculated as follows:

$$Precision = \frac{TP}{TP + FP} \quad (4)$$

$$Recall = \frac{TP}{TP + FN} \quad (5)$$

AUC is a performance metric for classification problems across all the various classification thresholds. The value of AUC lies between the closed interval [0, 1] where a larger value of AUC means better performance for a classifier. AUC is calculated based on the following equation:

$$AUC = \frac{\sum rank(All\ Positive\ Samples) - \frac{X(X+1)}{2}}{P * N} \quad (6)$$

Where P and N represent the number of positive and negative samples, respectively.

H. Tools

All the experiments in this study are implemented using the open source scikit-learn tools [26]. They are simple and efficient tools used to implement machine learning techniques in Python.

IV. RESULTS AND DISCUSSION

Following the research framework shown in Fig. 2, eight SBP models were constructed using the considered machine learning techniques and the used bug dataset. Out of the 60 features (Software metrics), 25 features were selected to construct the models after the application of the correlation-based filter-subset feature selection with best first search. The results of the considered performance metrics for each constructed model are given in Fig. 5.

The highest accuracy value is 0.82 which is achieved by LR, SVM, and RF classifiers. The accuracy values of NB, Adaboost, and KNN are 0.81, 0.8, and 0.79, respectively. The Bagging classifier has an accuracy of 0.76. DT has the lowest accuracy value which is 0.7.

LR, SVM, and RF classifiers attained the highest AUC value (0.77). NB achieved the second largest value of AUC (0.76). Adaboost has a value of 0.73 for AUC. The values of AUC for KNN, Bagging, and DT are 0.67, 0.62, and 0.53, respectively, which are relatively low compared to the values of AUC for other classifiers.

For the F1 values, LR and NB have the highest value (0.77). SVM, RF, and Adaboost attained the second largest value of F1 (0.76). KNN, Bagging, and DT have F1 values of 0.75, 0.73, and 0.7, respectively.

Answering RQ: From the results depicted in Fig. 5, it can be said that LR is the most effective machine learning technique (in terms of performance metrics) for bug prediction in classes based on the Unified Bug Dataset as it achieved the highest values of accuracy, AUC, and F1 measure. However, the performance of LR is not significantly better than the performance of the other considered techniques. In fact, some of the other classifiers have exactly the same performance of LR (for some of the used performance metrics) such as SVM and RF for the accuracy and AUC metrics and NB for the F1 metric.

V. THREATS TO VALIDITY

There are several issues that may impact the results of this study and limit their generality.

The quality of the bug dataset used to build the SBP models was not evaluated in this paper. The values of the software metrics and the bug information were used in all the experiments conducted in this study without verification or validation. However, the dataset was extensively evaluated and validated in [10] and it has been used in other studies in the literature (e.g. [11])

Software metrics included in the used dataset are not the only factors that can have impact on software bug proneness. Other factors such as the experience of software engineers involved in the development process of a software unit (e.g., class) and development environment can also make a software

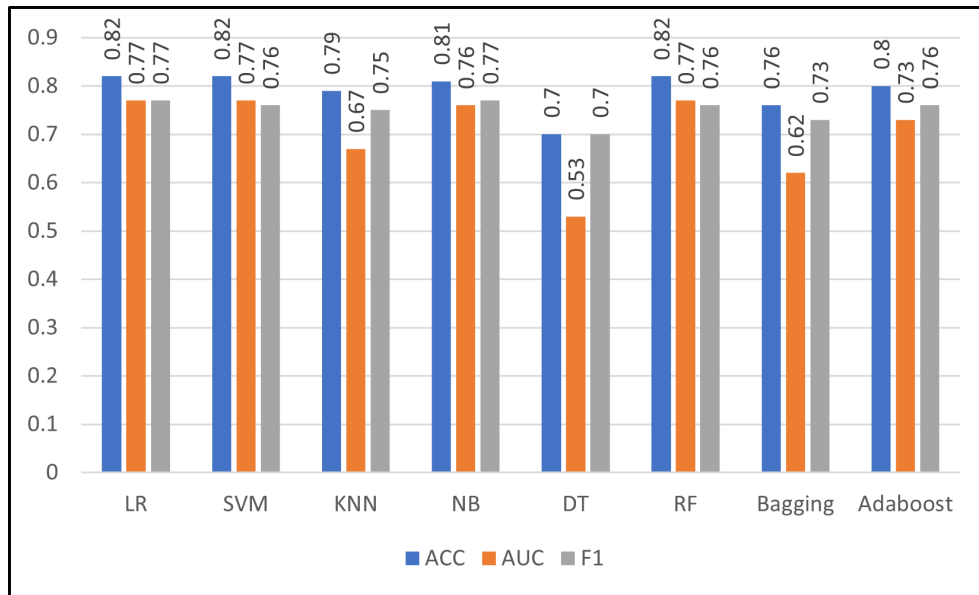

Fig. 5. The Average Results of the used Performance Metrics for the Constructed Models.

unit to be bug prone. However, these factors are out of the scope of this study and the aim of the study is to compare the performance of well-known machine learning techniques based on the used bug dataset which only includes software metrics and bug information.

The performance of the SBP models constructed in this study were evaluated based on only accuracy, F-1, and AUC. There are several other well-known performance metrics which were not used in this study such as Precision, Recall, Balance, and G-mean. However, there is no previous study on SBP that has used all the existing performance metrics to evaluate SBP models. In this study, the accuracy was used because it is one of the most commonly used metric to evaluate the performance of prediction models. In addition, the F-1 and AUC metrics were used in this study because the considered dataset is greatly imbalanced and these two metrics are good performance metrics for evaluating models constructed based on a biased dataset.

VI. CONCLUSION AND FUTURE WORK

In this study, the performance of 8 widely used machine learning techniques were investigated. A set of experiments were conducted using the Unified Bug Dataset which includes bug information for 47,618 classes. LR was found to be the most effective technique for predicting buggy classes. It attained 0.82, 0.77, and 0.77 for the accuracy, AUC, and F1, respectively.

The correlation-based filter-subset with best first search was the only feature selection technique applied in this study. There are many other feature selection and transformation techniques that have been introduced in the literature. A future work can extend this study by comparing the performance the considered 8 machine learning techniques when applying different feature selection and transformation techniques.

Abstract—Transformer neural networks have increasingly become the neural network design of choice, having recently been shown to outperform state-of-the-art end-to-end (E2E) recurrent neural networks (RNNs). Transformers utilize a self-attention mechanism to relate input frames and extract more expressive sequence representations. Transformers also provide parallelism computation and the ability to capture long dependencies in contexts over RNNs. This work introduces a transformer-based model for the online handwriting recognition (OnHWR) task. As the transformer follows encoder-decoder architecture, we investigated the self-attention encoder (SAE) with two different decoders: a self-attention decoder (SAD) and a connectionist temporal classification (CTC) decoder. The proposed models can recognize complete sentences without the need to integrate with external language modules. We tested our proposed models against two Arabic online handwriting datasets: Online-KHATT and CHAW. On evaluation, SAE-SAD architecture performed better than SAE-CTC architecture. The SAE-SAD model achieved a 5% character error rate (CER) and an 18% word error rate (WER) against the CHAW dataset, and a 22% CER and a 56% WER against the Online-KHATT dataset. The SAE-SAD model showed significant improvements over existing models of the Arabic OnHWR.

Keywords—Self attention; Transformer; deep Learning; connectionist temporal classification; convolutional neural networks; Arabic online handwriting recognition

I. INTRODUCTION

OnHWR is essentially a task of converting digital input handwriting into digital text. Handwriting recognition can be classified into two main categories based upon input data: online and offline handwriting recognition. In online handwriting, data is represented as a series of points with the precision of other information, such as timestamps, dependent upon the capabilities of the input device. In offline handwriting recognition, data is represented as images scanned from documents.

In recent years, OnHWR has attained increased importance concomitant with rapid developments in related hardware and software. Most current communication software supports notetaking and writing on boards using online handwriting as both a communication media and a vehicle of computer-aided education. In the rising markets, greater access to computing devices has allowed ever-increasing populations to connect across the internet, with many depending solely on mobile devices with touchscreens. Handheld devices with styluses are becoming more widely available and used in many domains.

Concomitantly, there have been tremendous advances in prime technologies of deep learning and natural language processing (NLP) algorithms. Such advances have led, in turn, to considerable progress in the field of OnHWR. The Arabic language is spoken by around half a billion people around the world. A number of other languages, including, Urdu, Persian, Kurdish, and Pashto adopted and use Arabic script. Arabic is a 'right to left' language in its written form. It consists of 28 letters, 10 digits as well as a number of punctuation marks. Each Arabic letter has four contextual forms, depending upon its position in a word: isolated, beginning, middle, and end position forms, as shown in Fig. 1. Arabic OnHWR is a challenging problem for multiple reasons. One reason is the existence of a wide range of variations in handwriting styles, in part due to the existence of multiple calligraphies in Arabic. There are eight basic calligraphies in Arabic script [1]. The tendency is to use a combination of these calligraphies when writing in Arabic. This further compounds the variations in styles of writing, thus adding to the challenges that would face the developer of an Arabic script recognition system. Compared to Latin and Chinese and other scripts, published work in the Arabic OnHWR field has to date been fairly limited.

OnHWR is a sequence-to-sequence (S2S) classification task. Input frames are ingested into the S2S model which in turn generates text. Recent advances in S2S models have shown their reliability solve complex NLP tasks such as translation [2] and automatic speech recognition (ASR) [3]. Additionally, the performance of OnHWR systems has improved with the advent of deep learning models including convolutional neural network (CNN) [4] and long short-term memory (LSTM) [5], [6].

Recently, E2E OnHWR systems have achieved remarkable performance, with input handwriting features being mapped directly to an output sequence of letters or tokens. In E2E systems, all components are trained and optimized jointly, thus reducing the complexity of the system and minimizing error propagation between components compared to conventional hybrid systems. Using CTC, E2E modeling has been utilized for handwriting recognition tasks as well as attention-based encoder-decoder systems designed for mathematical expression recognition tasks [7], [8]. Moreover, E2E has been incorporated with external language models (LM), effectively boosting performance [5]. In general, the competitive performance obtained by E2E models and their simplicity facilitate the building of state-of-the-art OnHWR systems. In this work, we explore building an E2E OnHWR system based on self-

attention models.

RNNs have been adopted for sequence modeling and have provided remarkable accuracy in multiple NLP tasks [9], [2], [10]. RNNs have been extensively utilized in OnHWR, including in the build-up of LSTM and gated recurrent units (GRU). In RNN, each hidden state depends on the previous one which makes parallelizing computations of RNNs difficult. Additionally, the hidden states are condensed into a fixed-length vector which introduces a 'bottleneck' making capturing long dependencies difficult as well [10].

As alternatives to RNNs, transformer-based models [11] have recently yielded outstanding results, achieving state-of-the-art performance in a variety of NLP tasks, including text and image-related tasks, and ASR [12], [11], [13]. Transformers rely on a self-attention mechanism, which extracts a more representative sequence by relating all position pairs of an input sequence. The self-attention mechanism offers two

attractive features compared with RNNs: (1) computations can be parallelized and carried out efficiently through batched tensor operations, and (2) self-attention allows direct connection for long-range and short-range dependencies without propagating contextual information between intermediate hidden states (as in case of RNNs) [11]. In addition to self-attention, the transformer model utilizes multi-head attention (MHA) in order to learn different representations in one instant. As with RNNs attention-based models, transformers are architecturally designed as encoder-decoder models, with both the encoder and decoder containing stacked self-attention networks (SANs) on top of each other. The cross-attention mechanism is used to bridge between the encoder and the decoder. The successes of transformer models have inspired this work in which self-attention was applied to an OnHWR task.

In this paper, we introduce transformer-based models OnHWR for Arabic script. The proposed models can transform a full-sentence handwriting input sequence into the corresponding letter sequence. Basically, we applied CNN layers to subsample input sequence features (via convolution strides) and process local relationships between handwriting frames of the input sequence. The output is added to positional embedding output to maintain input orders and then fed into the self-attention encoder (SAE). For the decoder, we employed two decoders: the self-attention decoder (SAD) and the CTC decoder. The proposed models were trained and evaluated against two datasets: Online-KHATT dataset [14] and CHWA dataset [15]. To the best of our knowledge, there has been no prior work on OnHWR that has proposed or applied self-attention models. As far as we are aware, this is the first attempt to apply the transformer model to an OnHWR task. Our results show that our proposed SAE-SED model can outperform existing RNNs models.

The main contributions can be summarized as follow:

- We introduce a new self-attention-based non-recurrent neural network models for OnHWR task.
- Two architectures have been developed in the decoding stage for the transformer: a SAD decoder and a CTC decoder.
- The proposed models have been evaluated against a full sentence (OnKHATT) [14] and a word-based (CHAW) Arabic dataset [15]. Results were compared with existing models, with our model evidently outperforming these models.

The rest of this paper is structured as follows: Section II details related work previously conducted on OnHWR. In Section III we layout the architecture of the transformer we designed for the OnHWR task. Then, experimental results are presented in Section IV. Lastly, Section V details our conclusions and recommendations for possible future work.

II. RELATED WORK

OnHWR data have a temporal structure and can be represented as a sequence of geometrical features vectors over time. OnHWR relies on sequence modeling, including statistical modeling. Previously, hidden Markov models (HMMs) have been reportedly utilized to model online handwriting in multiple published works. In [16], the HMM was designed

to model stroke segments as handwriting model units. In their model, letter models are subsequently formed by concatenating model units as defined in a pronunciation dictionary. Letter models are integrated as word sequence probabilities to form a stochastic language model. In [17], The researchers integrated Gaussian mixture models (GMMs) with the HMMs as continuous HMMs, using the GMMs to estimate observation probability distributions emitted by HMM states. Hybrid HMMs with feed-forward neural networks (NNs) were also part of their design [18]. Authors in [19] integrated a time-delay neural network (TDNN) with an HMMs into a single architecture, combining the recognition and segmentation phases into a single hybrid architecture. In their model, this hybrid architecture was intended to utilize the power of TDNN in the recognition and power of HMMs in the segmentation.

Traditional approaches involve multiple components that are separately trained and optimized, introducing suboptimality. On the other hand, deep learning models work on feature representation by learning discriminative representation from the raw data, thus providing an E2E solution for concomitant training of OnHWR system components jointly. One of the first works used implicit segmentation that was to be trained jointly with the recognition phase in [20]. In [20], the connectionist temporal classification (CTC) loss was introduced as an objective to map input frames into letters and optimize recognition jointly with LSTM.

Deep CNN was also utilized by [21]. In this study, the authors integrated CNN with domain-specific technologies to form an integrated network to improve performance. The efficacy of a combination of a CNN, RNN, and CTC was also investigated by [22]. They placed CNN layers at the front in order to support features representation. Next, they added LSTM to model the sequence of OnHWR along with a CTC to optimize the integrated network in an E2E manner. Authors investigated handcraft features and raw data ingested to CNN and reported that the proposed model had performed better with handcraft features. Furthermore, in [1], CNN-BiLSTM-CTC architecture was used to design an Arabic OnHWR model.

Recent work by Google investigated a model consisting of bidirectional LSTM (BiLSTM) with CTC [5]. In this work, the authors utilized a BiLSTM encoder trained using CTC loss. In decoding, they used different scoring LMs to incorporate prior knowledge about the underlying language and decode the output of the RNN encoder. GRU was employed in S2S with attention architecture and used in recognition tasks of online handwriting data of mathematical expression [8], [23], which was originally used in neural machine translation (NMT) by [24]. In [25], authors utilized attention encoder-decoder to recognize unconstrained Vietnamese Handwriting. The encoder was fronted with a CNN to extract invariant features and a BiLSTM to encode the output of CNN. The decoder was composed of BiLSTM layers with attention incorporated with encoders in order to generate text output. In [26], an edge graph attention network (EGAT) was proposed as a model that would perform stroke recognition. Stroke classification was formulated as node classification in a graph neural network (GNN).

In Arabic OnHWR, the line of work simply flows the Latin OnHWR workflow [27], [28]. As with traditional OnHWR sys-

tems, HMMs was utilized in many works for Arabic OnHWR [29], [30], [31], [32], [33]. Hybrid NN/HMMs were investigated in [34] and a DNN/HMMs model was tested by [15]. CTC based models were employed in several works for Arabic OnHWR [35], [36], [37], [1]. Most of the aforementioned studies targeting Arabic OnHWR tested their models against word-based datasets, with the exception of our previous work [35], [1] in which we tested our models against both sentence-based and word-based datasets. In our previous work [35], we proposed an E2E BiLSTM-CTC model and incorporated LM with outputs of RNNs to boost the performance of the system. More recently, we developed a writer adaptation method that utilized an E2E CNN-BiLSTM-CTC model [1]. In the current work, we did not integrate with any external module, and we evaluated our work against the CHWA and Online-KHATT datasets.

Variations can be reduced by normalization preprocessing steps. Normalization acts by reducing geometric variants in order to facilitate extracting features that are relevant to recognition. In the literature on OnHWR, multiple normalization methods, including slant correction, smoothing using a Gaussian filter, and resampling, have been proposed and tested against OnHWR data. The most comprehensive preprocessing steps were detailed by [38].

Features extraction refers to the process of extracting a meaningful set of features from raw data to be ingested and eased in the recognition phase. In OnHWR, traditional features can be classified into local features per point and global features per stroke or character [38]. Recently, as deep learning helped perfect features representation, the need for handcraft features with learnable features representation was eliminated in such areas as NLP [39], ASR [3], and computer vision [40]. Two recent works in which the authors used deep learning for features representation are [5], [21]. Despite its advantages, deep learning needs large-scale datasets to learn features representation and OnHWR datasets are rare and limited in size.

To summarize, state-of-the-art OnHWR models based on deep recurrent networks have begun to achieve remarkable recognition results, although training is computationally expensive and takes a long time to converge. Furthermore, the problem with pure RNN methods is that information may be forgotten during the encoding process, thus degrading overall model performance. In this work, we propose the usage of transformer-based models for the OnHWR task for the first time with no-recurrent design. A single, unified E2E architecture capable of recognizing full sentences from input online handwriting without the need for predetermined lexicons or language models.

III. TRANSFORMER FOR ONHWR

Typically, the OnHWR is an S2S task in which the lengths of input and output can differ. In our framework, the architecture of the transformer is based on an encoder-decoder structure. Given the handwriting input sequence $X = (x_1, x_2, \dots, x_{T^{in}})$, $x_i \in R^{d_{in}}$ where T^{in} is the length of input sequence and d_{in} is the number of features. Before feeding the input into the encoder, we prepended the encoder with CNN layers to extract better representative handwriting features and

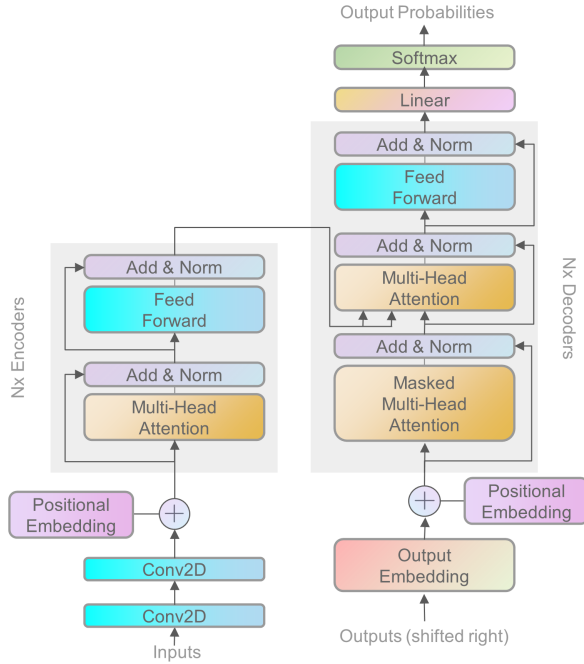

Fig. 2. The Architecture of OnHWR Transformer.

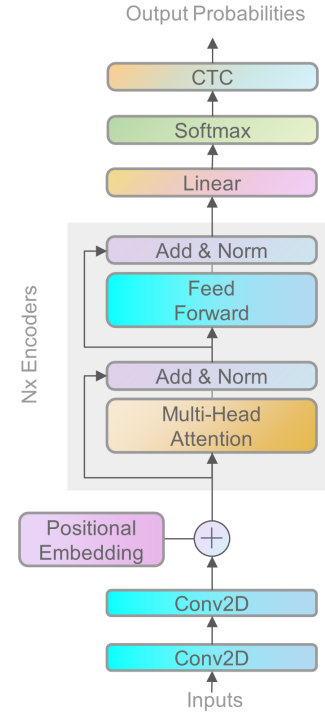

Fig. 3. Self Attention Encoder (SAE) with CTC.

perform subsampling on the input handwriting frames. Then, we applied positional embedding to the output of CNN layers $X = (x_1, x_2, \dots, x_T), x_i \in R^{d_{model}}$, where $T = |X|$ after subsampling. Positional embedding affords the input sequence a perception of order. The encoder was designed to encode the input sequence $X = (x_1, \dots, x_T), x_i \in R^{d_{model}}$ and generate intermediate updated representation using a self-attention mechanism $h = (h_1, h_2, \dots, h_T), h_i \in R^{d_{model}}$. The decoder transduces the output sequence using autoregressive approach. Given h representation and previously emitted characters of the decoder outputs to that point $y_{i-1} = (y_1, \dots, y_{i-1})$, the decoder computes the next character y_i . This procedure is repeated until the end of the sentence token is emitted as shown in Figure 2.

We also examined using a CTC decoder instead of the transformer decoder in which h representation would be ingested directly into the linear output layer. The output $y = (y_1, \dots, y_L)$ with length L is emitted by CTC decoder at once as shown in Fig. 3.

A. Self-Attention

The transformer-based models are built on a new concept of self-attention as an extension of attention introduced in S2S [24], [2]. Self-attention is a mechanism to compute updated representations for each sequence element in parallel. The attention mechanism would allow each representation to differentially consider the representations in every other position in a sense, and the communication paths would have the same length for all pairs of elements. The attention mechanism consists of a query matrix Q , a key matrix K , and a value V matrix. The basic idea is that a query vector would be compared to a set of key vectors to determine their

rapport. Each key vector comes paired with a value vector. The greater the rapport of a given key with the query the greater influence the corresponding value would have on the output of the attention mechanism. Transformer employs **scaled dot product attention** to map a query with a series of key-value pairs to output using the following equation:

$$\text{Attention}(Q, K, V) = \text{softmax}\left(\frac{QK^T}{\sqrt{d_k}}\right)V \quad (1)$$

where $Q \in R^{M \times d_k}$ and $K, V \in R^{N \times d_k}$ denote queries, keys and values in the matrix form, M and N are the number of queries and key-value pairs, and d_k is the dimension of representation. Scaling by factor $\sqrt{d_k}$ is done to prevent extremely small gradients.

B. Multi Head Attention (MHA)

Using a single attention head, the linear combination of value vectors leads to an averaging outcome that restricts the resolution of the learned representations. Therefore, the authors propose using multiple attention heads that can simultaneously learn different representations to alleviate this. MHA is computed as follows:

$$\begin{aligned} \text{MultiHead}(Q, K, V) &= \text{Concat}(\text{head}_1, \dots, \text{head}_h)W^O \\ \text{where } \text{head}_i &= \text{Attention}(QW_i^Q, KW_i^K, VW_i^V) \\ W_i^Q &\in R^{d_{model} \times d_k}, \\ W_i^K &\in R^{d_{model} \times d_k}, \\ W_i^V &\in R^{d_{model} \times d_v}, \\ W_i^O &\in R^{hd_v \times d_{model}} \end{aligned} \quad (2)$$

First, the inputs: query matrix Q , key matrix K and value matrix V are linearly projected using W^Q , W^K and W^V . The projected query QW^Q , key KW^K and value VW^V are split into h heads. Scaled dot-product attention is computed for each head i . The independent attention head computed are then concatenated and linearly projected using W^O .

C. Self-Attention Encoder (SAE)

Instead of positional encoding proposed in the original paper, we adopted learnable positional embedding [41]. The positional embedding has the same dimensionality as the input embedding, and we summed them together before feeding them to the encoder. MHA is the first of two sub-layers of an encoder layer. After each sublayer, both residual connection and layer normalization were applied. The residual connection adds a copy of the input to the output, which means the input representations before an MHA block are added to the output representations. Then layer normalization takes the input vectors and essentially normalizes each one individually to have zero mean and variance. This is done to assure training stability. The second sub-layer is a **position-wise feed-forward network**, composed of a simple network of two fully connected layers with value activation between them to each input representation as follows:

$$FFN(x) = \max(0, xW_1 + b_1)W_2 + b_2 \quad (3)$$

After the second sub-layer, we again applied a residual connection and layer normalization, thus completing one encoder layer. The aforementioned layers can then be stacked up N times to form the full encoder.

D. Self Attention Decoder (SAD)

The design of the self-attention decoder mimicked that of the aforementioned encoder architecture, except that it is composed of two MHA layers. The first MHA layer applies attention to outputs generated by the decoder up to a point. The first layer is masked to avoid attending to future positions, while the second MHA layer applies attention to the encoder outputs.

E. The CTC Decoder

CTC objective loss was described by [7], [20]. CTC directly estimates prediction labels in E2E models without the need for explicit segmentation or alignment between input frames and output labels. As with the RNN encoder [35], the encoder (SAE) outputs sequences with the same length of input sequence frame length of the input. CTC manages this condition by introducing an additional blank label b symbol to the target labels and allowing repetition of labels or by adding banks across frames to match the lengths of input frames. Given input handwriting frames $\mathbf{x} = (x_1, \dots, x_T)$, where $T = |\mathbf{x}|$ and $x_t \in R^{\text{d}_{\text{model}}}$ and output sequence labels $\mathbf{y} = (y_1, \dots, y_L)$, where $L = |\mathbf{y}|$ and $y_l \in Z$ and Z denote the (finite) label alphabet, the encoder (SAE) generates posteriors $P(\mathbf{y}|\mathbf{x})$ as follows:

$$P(\mathbf{y}|\mathbf{x}) = \sum_{\hat{\mathbf{y}} \in H_{CTC}(\mathbf{x}, \mathbf{y})} \prod_{t=1}^T P(\hat{y}_t | x_1, \dots, x_T)$$

where $\hat{\mathbf{y}} = (\hat{y}_1, \dots, \hat{y}_T) \in H_{CTC}(\mathbf{x}, \mathbf{y}) \subset \{Z \cup b\}^T$ harmonizes to any possible paths under the condition that $\hat{\mathbf{y}}$ yields \mathbf{y} after dropping the blank symbols b and repeated successive symbols of $\hat{\mathbf{y}}$. The CTC loss assumes that each label in the output sequence is conditionally independent given the input handwriting sequence.

IV. EXPERIMENTS AND RESULTS

A. Datasets

We tested our models against two open vocabulary datasets, the Online-KHATT and CHAW. The Online-KHATT dataset is an open vocabulary dataset collected by KFUPM [14]. It is comprised of 10,040 sentences of Arabic text written by 623 writers using Windows and Android run devices. Writers that contributed to the Online-KHATT dataset represent different ages, education levels, nationalities, genders, and handedness. This dataset consists of natural and unrestricted handwriting styles. The Online Arabic handwriting Cairo University dataset (CHAW) [15] is a word-level collection of Arabic writing. CHAW was collected using Android Samsung tablets. It consists of 18k of distinct words within a total of 192k samples. These samples are split into a training set, consisting of 17k unique words within a total of 180k samples, and a testing set, consisting of 500 unique words within 12k samples. A total of 1250 writers had contributed to this dataset. These writers are of varied ages, genders, and handedness.

B. Model Description

For input features, all preprocessing steps and features described in [17], [20] are used except delayed strokes representation features. The input sequence consists of a vector of 20 features per point. We normalized the input samples using z-score normalization before samples are fed into the models. For output, we adopted 160-character units, including 28 Arabic characters and their variations at different positions within a word, numbers, blank, punctuations, a start of sentence label (SOS) and end of sentence label (EOS).

We placed 2 CNN layers for the purposes of handwriting feature embedding. To stabilize training, we applied batch normalization (BN) [10] after each CNN layer, followed by ReLU activation. In our models, CNN layers perform subsampling by time reduction of the input frame handwriting sequence and retaining more representative features.

For the SAE-SAD model shown in Fig. 2, we stacked 6 SAE encoders and only one SAD decoder layer. In addition, we used $h_{\text{heads}} = 4$ for MHA. A total of 256 units comprised the feed-forward sub-layers. For the SAE-CTC model shown in Fig. 3, we mimicked the structure of the SAE-SAD model, replacing the SAD layer with a CTC as described in Section III-E.

In the training phase, we used an Adam optimizer with a learning rate scheduling [11]. In cross-entropy loss, which is used to optimize the SAE-SAD model, we applied label smoothing with a plenty factor of 0.1 [42]. SAE-CTC model optimized, the entire model using CTC loss. To avoid overfitting during training, dropout, at a rate of 0.3, is used [43]. In the end, we averaged the parameters of models of the last five epochs [44].

TABLE I. THE CERs COMPARISONS OF DIFFERENT HYPERPARAMETERS COMBINATIONS FOR SAE-SAD MODEL.

# of encoders	# of decoder	h_{heads}	d_{ff}	CER [%]
4	4	2	128	34.77 %
4	4	4	256	28.64 %
6	4	4	256	23.16 %
6	2	4	256	21.35 %
6	1	4	256	20.03 %
6	1	4	512	25.88 %
8	1	4	256	23.47 %

TABLE II. COMPARING OUR MODELS TO OTHER HYBRID AND E2E SYSTEMS REPORTING ON ONLINE-KHATT AND CHAW.

Models	CHAW dataset		Online-KHATT dataset	
	CER [%]	WER [%]	CER [%]	WER [%]
DNN/HMMs [15]	-	25%	-	-
BiLSTM-CTC-LM [35]	4.08%	14.65%	12.24%	28.35%
CNN-BiLSTM-CTC [1]	9.43%	34.48%	18.49%	59.94%
SAE-CTC	10.83%	40.68%	23.89%	78.17%
SAE-SAD	5.70%	18.45%	22.88%	56.48%

C. Results

We used the standard matrices word error rate (WER) and character error rate (CER) to evaluate our experiment results. WER is calculated by summing up insertions, substitutions, and deletions present in recognized words divided by the length of words in the target sentence. CER is calculated in a similar fashion, this time focusing on characters instead of words.

To select the best hyperparameters for our proposed mod-

els, we ran multiple experiments of different hyperparameter combinations, varying the number of blocks in encoders, feed-forward units in the sub-layers of each block, number of heads h_{heads} for the encoder and number of blocks of the decoder in SAE-SAD. For the subsampling CNN module, we followed the architecture and hyperparameters in [1]. Table I shows different configurations we had tried for SAE and SAD with the CER on the validation set.

We trained the SAE-SAD model for 228 epochs and SAE-CTC model for 60 epochs. Training stopped when models started overfitting. We then selected the best model with the lowest CER on the validation set. Fig. 4, shows a comparison of validation loss and training loss for both SAE-SAD and SAE-CTC models, respectively. We also compared CER and WER on the validation dataset for both the SAE-SAD and SAE-CTC models. We trained all models using a GeForce GTX 1080 Ti, and we conducted all experiments using a Tensorflow [45]. At this scale, 228 epochs of SAE-SAD model run over 112 hours, whilst SAD-CTC model took over 30 hours. In Fig. 4, we see that the SAE-CTC model converges faster than the SAE-SAD model. However, the SAE-SAE model took more epochs to converge, and its WER was superior to that of the SAE-CTC model. We also found that CER was closer to WER in the case of the SAE-SAD model than in the case of the SAE-CTC model, indicating the SAE-SAE model to be capable of capturing words more accurately at a higher rate than the SAE-CTC model.

The online-KHATT dataset is challenging and contains sentence-based samples and a subset of segmented characters. All previous works, [46], [47], [48], [35], [1] conducted their experiments against the character set in Online- KHATT except

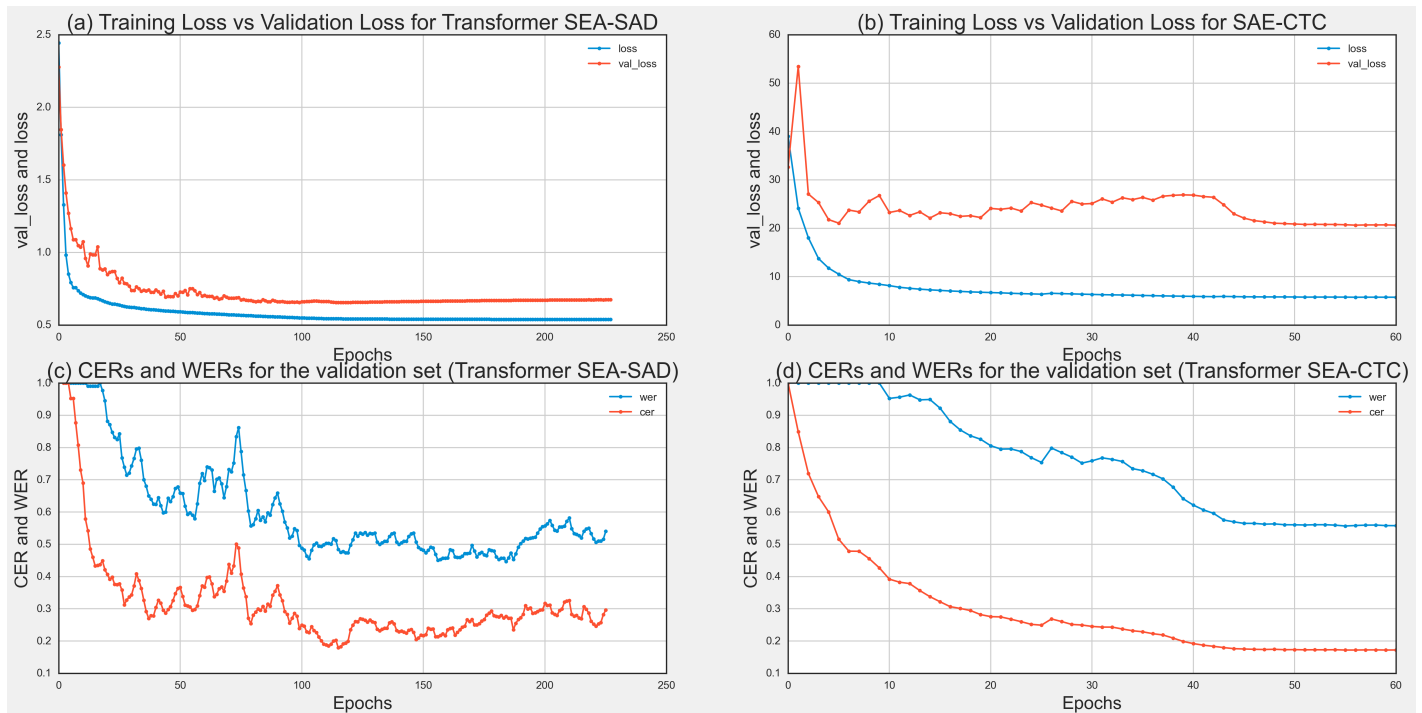

Fig. 4. (a) Training and Validation Losses for (a) SEA-SAD Model (b) SEA-CTC Model and CERs and WERs on Validation Dataset (c) SEA-SAD Model (d) SEA-CTC Model

[1], [35]. In our work, we compared our proposed models to existing systems that had tested their models against the full sentence-based set in the Online-KHATT dataset.

Table II shows the evaluation results on Online-KHATT and CHAW datasets. For the hybrid DNN/HMM-based approach in [15], the authors evaluated their work on the CHAW dataset, which is a word-based dataset. Furthermore, they integrated a dictionary with the model output to improve the results of the proposed approach. For the E2E system in our previous work [35], we incorporated n-gram LM to boost the result of the proposed approach, and we evaluated the proposed method on both Online-KHATT and CHAW datasets. Naturally, LMs boost the result of DNN models, and in this work, we have not incorporated any external LM or dictionary. Thus, this approach is not comparable to this work. The bottom row in Table II compares our previous CNN-BiLSTM-CTC [1] model with the proposed models since it does not integrate any external module. We compared our results with [1] results of the writer independent model as this result was achieved on the whole test dataset. The results show that SAE-SAD model outperforms our prior CNN-BiLSTM-CTC model [1]. Also, SAE-SAD outperforms SAE-CTC models. In addition, our proposed SAE-SAD performs better than the hybrid DNN/HMM model [15].

D. Discussion

Deep learning models learn to model discriminative features representation. As shown in Table I, deeper encoders perform better as we increase encoder layers. This is because each layer learns at a different level of abstraction for a given set of features. Multiple encoder layers are capable of generalization because each layer learns a different intermediate representation of raw data which helps at the classification level.

E2E CTC-based models are typically trained jointly using the loss CTC function. However, CTC-based models assume that relationships among produced labels from the CTC-based model are conditionally independent. Thus, such models cannot implicitly learn the LM from the training data. On the other hand, transformer-based models with a SAD decoder generate with each time step a label that is conditionally dependent on the previously generated ones. Consequently, they are capable of capturing the LM directly from training data. This would explain why the SAE-SAD model outperformed the SAE-CTC model, as shown in Table II. Also, we believe that SAE-SAD models could outperform traditional models that are integrated with external LMs in the presence of sufficient data. However, one advantage of the SAE-CTC model compared with the SAE-SAD model is its ability to generate the output labels in parallel at inference time.

CNN networks are widely used in transformer-based ASR models for down-sampling as well as providing positional encoding [13]. However, in the case of our OnHWR models, CNNs did not provide sufficient order information to the models other than that contributed through subsampling. Thus, we utilized positional embedding to add order sense to CNN outputs before feeding them into the encoder. The inability of CNN to provide sufficient order information may be due to the nature of handwriting data which contains delayed strokes, and

the limited nature of Arabic handwriting datasets. We found that adding learnable positional embedding made the model converge faster.

V. CONCLUSION

In this work, we have introduced self-attention based Arabic OnHWR models. We trained and evaluated the proposed models against sentence-based and word-based datasets. We utilized different strategies and structures to improve the performance of models. Our transformer-based models are actual E2E models following the S2S architecture with a self-attention encoder (SAE) and two decoders, a self-attention decoder (SAD), and a CTC decoder. Despite we did not incorporate any external modules such as an LM nor a dictionary into our architecture design, the proposed models are capable of recognizing complete sentences and words. Compared to state-of-the-art models, our transformer models have outperformed RNN models, which do not use LMs. Our best SAE-SAD model achieved a 5% CER and 18% WER against the CHAW dataset and 22% CER and 56% WER against the Online-KHATT dataset. Planned future work will involve investigating other features and expanding datasets by synthesizing new samples. We also plan to incorporate LM with transformer-based models to boost the performance.

Abstract—Android apps have security risks due to rapid development in android devices. In the Android ecosystem, there are many challenges to detecting Android malware. Traditional techniques such as static, dynamic, and hybrid approach, most of the existing approaches require a high rate of human intervention to detect Android malware. Most of the current techniques have the most significant security challenges to detect Android malware, the inspection of Android Package Kit(APK) file structures, increased complexity, high processing power, more storage space, and much human intervention. This paper proposed Machine Learning(ML)based algorithms to detect Android malware apps through feature extraction and classification of grayscale images. In our proposed approach, convert most of the files of APK such multiDex, resources, certificate, and manifest transform into a grayscale image, using the image algorithm to extract the local feature of the image. In the paper used different ML models to classify the local features with the help of multiple images of malware families. This approach deals with the obfuscation attack. It can hide in any files of APK. The proposed approach enhanced accuracy reached up to 96.86%, and computation time did not increase more than the existing techniques. The quality of that proposed worked; it has a high classification accuracy and less complexity validation loss.

Keywords—Android malware; obfuscation attack machine learning; android application package (APK); android malware app; grayscale images

I. INTRODUCTION

Android operating system (OS) is the most popular OS in the smart device ecosystem. Due to intelligence devices, every android user is very close to and dependent on Android Application Package (APK). In the present scenario, the android users sharing sensitive information, banking operation, e-shopping, locations information, the identity of the users, and privacy of data are also involved. In Android, device security is the biggest challenge and severe issue. A survey report of GDATA in 2019 [1] showed that 1,852,170 Android malware samples were detected in the first half of 2019. Here, data showed an android malware is detected every 8 seconds. The statistical report represents eight mobile infected by malicious out of ten Android devices [2]. One more research report, Google detected 86% of the total Android devices market in 2017. The most popular GlobalStats website showed that 73% of Android-based devices counted sales of total devices of Android in 2019 [3]. Due to the popularity of Android

devices, Android app becomes more targeting apps compared to other kinds of apps. As per one evolution report of mobile malware, 5,321,142 apps were installed on devices, 151,359 mobile apps were detected as Trojans, 60,176 were detected as mobile ransomware by Kaspersky 2018 [4].

Android users threaten by different types of malware families; some are distributed by Google Play stores, some type apps such as downloader, banker, and hidden ads [5]. Most of the extensive attacks pointing the Android OS. The hackers mainly focused on attacking games, banking, academics, e-shopping domain. However, this domain published many malicious apps, which have gaps between the app development and the number of works. Third-party stores have untrusted apps; most gaming apps have adware due to the repackaging technique [6]; with the help of repackaging tools, reassemble the original app and add the malicious code with the original code and then assemble again, upload on third party store. Here, the main challenging task to identify malicious apps is the most severe issue. Most existing techniques are static and dynamic; most techniques used behavior and signature base to identify the android malware.

Static techniques do not require running apps; they disassemble the code and extract the feature of apps to identify. The dynamic approach always needs to run the application and identify the android malware through behavior and signature base. These techniques have significant drawbacks; it requires more computing power, resources, and space [7]. The dynamic analysis was evaded by some powerful and intelligent malware [8]. Moreover, existing dynamic and static techniques used the manual intervention of humans. It also needs domain expertise to identify reverse engineering [9]. The existing approach used single classes.dex file, but in the current scenario, we have multiclass files, or multiDex files [10], which have not been converted into a grayscale image to detect malware.

Our proposed work takes care of all essential files such as multiDex (MD), resources.ARSC(RS), Manifest.xml(MX), and certificate (CR) files of APK to detect Android malware. The existing approaches need human intervention to separate the dex, manifest.xml resource.ARSC(RS) and certificate files convert into the grayscale image [11-12].

META-INF: This file very essential in Android apps, which the information about the signature and information

Fig. 1. Proposed Methodology to Detect the Android Malware

about the resource list.

Lib: lib file is used to run the specific device architectures of the native library, such as armeabi-v7a and x86.

Res: to Keep the resources such as images. Which is not compiled with resources.arsc

Assets: Raw information about resources

AndroidManifest.xml: Meta information about the apps such as version, content, and name of APK files.

Multiple classes.dex: Main and necessary file of apps, which run java class methods on the devices.

Resources.arsc: Compiled all resources on the devices which is used by the apps.

Android apps development using java.class files. By the DX tools convert multiple java.class into the DEX files. DEX and manifest are essential files in APK, and DEX consists of the data structure; the interpreter used the different data types that belong to the data structure. All static reverse engineering tools used the DEX files to reassemble the apps for reengineering. Multiple methods are proposed to protect the DEX files. Our Proposed approach does not require any human intervention, does not require separate files, and does not need reverse engineering to find different types of files. Our proposed approach takes less computation power to detect the android malware because it takes less time complexity because it worked without any reverse engineering operation. Our proposed approach used DEBIAN and AMD datasets containing 10560 apps (5000 benign and 5560 malicious apps). The grayscale image datasets, each containing 10560 samples (5000, 5560 benign, malicious samples, respectively), were constructed based on diverse files from the contents of the APK

collections. Firstly, all the benign and malicious APK convert into Grayscale images, a block diagram depicted in Fig. 2. Secondly, extract the local features from images using image-based feature extraction techniques such as SIFT, SURF, and ORB. Thirdly, apply the BOVW approach to convert multiple local feature descriptor vectors into a single feature vector to feed into ML classifiers. Finally, extract the global and local features and apply the different ML classifier techniques such as AdaBoost K-Nearest Neighbors(KNN), Support Vector Machine(SVM), and Random Forest(RF). The Proposed approach worked on the raw bytes of grayscale images; the main advantage of this approach does not require any reengineering operation and making different types of datasets. The existing approaches have the main disadvantage, approaches that require human intervention. Our approach proposed safe from human intervention and reengineering operation. Many ML algorithms are developed for the detection of malware apps. The most common challenge in Android malware detection is obfuscation attacks. Malicious code can be hidden in any files of APK, which is very dangerous to android malware app detection. Our proposed works have a novelty that now no needs to do reverse engineering to obtain all files of APK. Directly conversion of Entire APK files structure converts into a grayscale image. Most of the existing techniques used separate files to transform into grayscale scale images to analyze the image-based android malware detection. All existing methods do not care about multiple DEX, Share Object (SO), Meta-Inf, lib files, etc., just observation of manifest, single DEX files, resource files only. In the meantime, the author should explain the functions of multiDEX (MD). Resources, ARSC (RS), Manifest.xml (MX), and certificate (CR) files of APK separately because they are used to detect Android malware. Then, the proposed methodology to detect the android malware

is well represented in Fig. 1.

II. RELATED WORK

Many researchers worked in the domain of Android malware detection; some are listed below in this section. An approach designed to analyze the suspicious behaviors and detection of resources abuse [13]. The major drawback of this approach is the need to decompile the app and embedded hook code; this approach used runtime events to track and monitor the logging. The SafeDroid static framework approached, which statically analyzed the DEX (Dalvik Executable). By this approach, extract the binary feature vectors to train various ML classifiers [14]. Moreover, the multiple features are system calls, app permission, system events [15]. Those features train RF classifiers to analyze whether Apps are affected by malicious or not. Some approaches differentiate whether the app is a malicious or normal app based on patterns permission [16], the required permissions extracted statically. Most popular permissions are registered into class [17] to define whether the permission is benign or malicious. The permissions of a class determine the benign and malicious app. Moreover, a data mining technique made the constructive pattern of permission to determine whether the android app is malicious or benign. Here, the authors applied the bi-clustering method to used permissions. Also, the authors used the information of the Android app package and permissions to train of KNN, Linear Discrimination(LD) function, and Radial Basis Function (RBF) network. Moreover, Application Programming Interface(API) system calls integrated with permissions [18] are used as features to train the RF classifier of android's apps classification. It is a very lightweight method for detecting Android malware through ML and dataflow-related API system calls used in this approach [19]. In [20], the proposed approach used the n-gram series to extract the features from the opcode of malicious and benign apps. This approach used a limited number of features to train RF and Support Vector Machines (SVM) classifiers. The proposed approach [21] installed the Android application(APK) on Android devices to extract dynamic features such as networks behavior, memory consumption, computation power, time-space, battery, and binder; these features are used to classify malware. This dynamic approach [22] captured network traffic behaviors of running Android applications(APK) from different android devices. This traffic correlates with malware URLs and with DNS service network traffic for the detection of malware. An approach [23] used to fog computing reduces the load and dynamically enhances the computation power to detect Android malware. Another approach [24] used the API system calls and network behaviors, collectively applied to detect Android malware. In [25] this paper, the authors showed the multiple network behavior and emulator-based dynamic experiments to analyze android malware. Android operating system embedded by an extension kit has been proposed [26] to deals with confused delegate attacks [a genuine APK is manipulated for communicating with the trusted application for Inter-Process Communication(IPC)]. To enhance permissions-based policy [27]at runtime tracking and communication link analysis by pre-defined policy to prevent malicious behavior. Moreover, the signature set is constructed by network log and correlated with the permissions-based methods [28] for android apps classification. The recent approach [29] uses

reverse engineering techniques to decompile the APK, extract the source code, and convert it into a grayscale image. The constructed dataset of images is used to train a convolutional neural network (CNN) to detect the malicious app. API system calls and semantic information is used to train the Short-Term Long Memory (LSTM)[30] model to classify the android malware. Moreover, a hybrid approach includes CNN and deep autoencoder (DAE) [31] to detect Android malware. In [32], this proposed approach used the hybrid scheme; it extracts dynamic and static behavior features used to train the deep learning model. Also, in [33] approach extracted the four features, such as permissions, rate of permission, system events, APIs system calls used to train the collective RF classifier. DREBIN [34] is a static analysis approach; this approach used similar malicious apps as per experiment works (5,560 malicious apps). This method used as many possible features of apps and was added with joint vector space. Due maximum number of features and determination increased the complexity level. This paper [35] proposed the classification of the dependency graph. The features extracted from the dependency graph make the semantic feature set from the weighted contextual API of the graph. The metric of the homogeneous app determines same the application behaviors. The sensitive and important API call allocated the weight according to the Android malware family [36]. Every app implemented the function call graph (FCG), and each FCG construct the sensitive API call-related graph (SARG). The SARG has the parent and sensitive API call nodes. Here, train multiple machine learning approaches to classify the common behavior of the malware family. Moreover, from source code is extracted from hexadecimal representation and converted into RGB images [37]. The color RGB dataset is used to train a CNN classifier to classify Android malware. Furthermore, the Android (APK) application converted to grayscale images, then extract the feature of grayscale images for training the RF classifier for classification in [38]. Also, in [39], extracted the feature from 2D of Opcode Sequences and assigned the weight based on their occurrence. The weight value is converted into grayscale images. The image detection approach is very limited to detecting Android malware domains. Local and global feature extraction of the entire APK is more effective than existing approaches. Our paper has mainly converted the image into grayscale without any reverse engineering tools. It does not require separating the files of APK such as resource, Multidex, manifest, and certificate. Moreover, it does not require human intervention; most existing techniques have a common issue of human intervention and extracting the source code from reverse engineering tools.

III. METHODOLOGY

This section discussed the full detail of the proposed model. The first subsection briefly describes constructed dataset, the other section described the brief details of extracted features, and the last section briefly describes the training Machine Learning (ML) classification.

1) *Dataset*: this dataset. Our experiment setup used the 5560 files of android malware and 5000 benign apps from AMD, which have 179 different Android malware families. In the investigation of research of android malware from 2012 to 2020, most of the researchers used the DREBIN dataset. The DREBIN dataset has the most famous malware such as

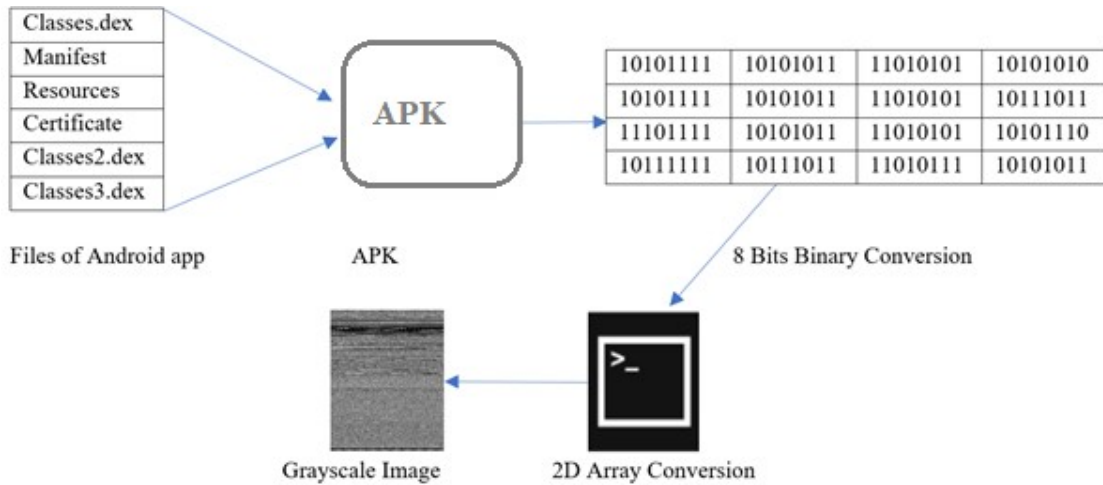

Fig. 2. APK to Image Conversion Process

DroidKungFu, GingerMaster, GoldDream, and Fake Installer. The primary objective of our proposed approach is to detect Android malware. The DREBIN dataset has the most famous malware such as DroidKungFu, GingerMaster, GoldDream, and Fake Installer. The primary objective of our proposed approach is to detect Android malware. Many researchers used the DREBIN dataset to analyze the android malware, and various institutions utilized this dataset to investigate Android malware. Our Proposed models used the DREBIN dataset because it has 179 different android malware families, appropriate for any investigation dataset.

A. Transformation APK into Grayscale Images

The Android APK files convert into grayscale images [40]. In this proposed article, the authors construct the malware images using files of the Android app from malware APK. The APK is transformed into 8-bit vectors, and then the 8-bit vector transforms into a grayscale image. Every substring has an 8-bit value as a pixel converted into a decimal value between 0-255, shown in Fig. 2. Any digital file on the memory device is stored as a stream of a bit of '0' and '1'. In the model read every APK file as a binary stream, group every eight bits, and store them in a new file with the image file extension.

B. Local Features Extraction

The local feature is a defined image object (basically, in the image, a cluster of pixels or small blobs) [41]. The local feature of images is the most stimulating point in the image, which defines the image descriptor vectors(DV) or feature vectors. The set of feature vectors is described by different types of algorithms. Our proposed approach used the four different algorithm types to extract the local features as Scale invariant feature transform(SIFT), Speeded up robust features (SURF), Oriented FAST, and Rotated BRIEF(ORB). Those methods are very famous in the malware domain for better accuracy.

1) *SIFT*: The Scale invariant feature transform (SIFT) method is applied to extract the local feature key points. This method computes the Laplacian of Gaussian on the multiple

scale level to provide a better result. This SIFT algorithm obtains the local minima and local maxima of stimulating points with the help of LoG at different scale levels. The several Laplacian of Gaussian on different scale levels (ρ), by the scale, obtain the local maxima, minima of every single pixel in the image. The Laplacian of Gaussian (LoG) calculation is costly for feature points to more or less extent. The Laplacian of Gaussian(LoG) approximately is determined by Eq.1.

$$\rho \nabla^2 L = \frac{\partial L}{\partial \rho} = \frac{L(x, y, k\rho) - L(x, y, \rho)}{k\rho - \rho} \quad (1)$$

where $L(x,y,\rho)$ is the Laplacian Gaussian on the position (x, y) at scale ρ . $L(x,y,k\rho)$ is the Laplacian of Gaussian(LoG) on the position (x, y) at scale $k\rho$, and the $k\rho$ is a scale a little more than ρ . The SIFT methods identified the stimulating points at the level of 128-bit descriptors in Eq.1. The extracted feature from the input images through the SIFT matched each feature of k nearest neighbors. The main objective of SIFT is to object recognition techniques to panorama stitching. As a result, the system is insensitive to the images' ordering, positioning, scale, and illumination. Two-Dimension isotropic measure by the Laplacian to the second spatial derivative of an image. The Laplacian Gaussian approach highlights areas of speedy intensity change and is often used for zero-crossing edge detectors. In our system, the Gaussian smoothing filter reduces its sensitivity to noise for smoothing with something approximating.

2) *SURF*: The algorithm that Speeds up robust features(SURF) [42] is the faster algorithm, and it can be the replacement for SIFT. This algorithm is faster and more robust for similarity comparison and similarity invariant of images. SURF algorithm plays a vital role in the real type of tracking and recognition of the object. The main merit of this algorithm is box filters approximation and calculation of the integral images. Additionally, it has the location and scale-based determinant of the Hessian matrix. The Hessian matrix has good performance to obtain the image key points, and it has good accuracy. In the SURF algorithm filtered by Gaussian

kernel, with location $X=(x,y)$, and scale ρ in Eq.2.

$$H(x, y) = \begin{pmatrix} S_{xx}(x, \rho) & S_{xy}(x, \rho) \\ S_{xy}(x, \rho) & S_{yy}(x, \rho) \end{pmatrix} \quad (2)$$

where, $S_{xx}(x, \rho)$ has a Gaussian kernel derivative on the point of x in the image, and similarly for $S_{xy}(x, \rho)$ and $S_{yy}(x, \rho)$. Haar-wavelet responses determine horizontal and vertical paths to the neighborhood of size six and used the 64 Bit Descriptor. Within interest point neighborhood, distribution of Haar-wavelet responses obtained from descriptor description. We used integral images to speed up the system. Additionally, using the 64 Bit Descriptor dimensions to improve the system's performance for feature computation increases robustness and matching. In the invariant to rotation, we recognized the reproducible orientation for the interest points. For this reason, we obtained the Haar-wavelet responses in the vertical and horizontal directions. The circular neighborhood of radius 6s around the interest points, with s the scale that the interesting point detected. Therefore, our proposed approach uses integral images for fast filtering again. Only six actions are needed to SURF: Speeded Up Robust Features, the seventh determines the feedback in the vertical and horizontal directions at any scale.

3) *ORB*: The feature vector Oriented FAST and rotated BRIEF (ORB) is a high-speed keypoint detector [43]; in BRIEF, descriptors have much modification to improve the algorithm performance. The ORB algorithm detects the keypoint in images by using the FAST algorithm. Also used the Harris corner to detect the key point. Moreover, it used the multiscale feature with 32 bits BRIEF-based descriptor

$$(S;x, y) = \begin{cases} 1 : S(x) < S(y) \\ 0 : S(x) \geq S(y) \end{cases} \quad (3)$$

where S is the flattened spot in the image, and $S(x)$ is the intensity in Eq. 3. In the implementation of the FAST algorithm, we extract the kernel windows from single line buffers. In the approach, the center pixel is subtracted from each circle pixels. The result is measured with the minContrast value whenever the obligatory number of consecutive pixels exceeds the threshold level; the center is marked as the corner. For the circle region, evaluate the sum-of-absolute-difference (SAD) metric. Only the differences that exceed the minimum contrast threshold level are involved in the metric. This calculation means that the algorithm detects a light center pixel surrounded by dark pixels or a dark center pixel surrounded by light pixels as corners with high metrics. The Harris algorithm used five image filters, and three circular windows and evaluated the two gradients. The design of the calculation of the eigenvalue of the Harris matrix practices three multipliers and three adders and is pipelined to optimize performance.

C. Machine Learning (ML) Classification

Our proposed models used four types of Machine Learning models such as Adaboost, K-Nearest Neighbors(KNN), Support Vector Machine(SVM), and Random Forest(RF) to classify the extracted local features from Grayscale images.

1) *K-Nearest Neighbors (KNN)*: K-Nearest Neighbors(KNN) is a supervised ML models, which is used for the classification of input data. It recognizes data points classified into multiple classes and calculates the class label for the new input data point. This method is famous for classifying the object into the train closest feature space. The nearest neighbors are signified by K in KNN, and the maximum unknown data points classify near to K neighbors. The primary benefit of the KNN algorithm uses the minimum distance to search the nearest neighbors. The selection of the number of nearest neighbors is essential to obtain the augmented KNN model. The selection of the number of nearest neighbors is essential to get the augmented KNN model.

2) *Support Vector Machine (SVM)*: Support Vector Machine(SVM) also is a supervised ML algorithm. In this model, take the past input data and predict the feature output. The primary purpose of SVM is classification, but it is also used for regression statements. The SVM algorithm chooses the support vectors in the dataset at the extreme points. It selects the maximum distance between the support vector and hyperplane as much as possible. A class in support vectors has the maximum distance from the hyperplane. The distance margin defines as the distance between different support vector classes. The sum of $D+$ and $D-$ is calculated as distance margin, where $D-$, hyperplane has the minimum distance from the closest negative point and $D+$, hyperplane has the minimum distance from the closest positive point. The main aim of SVM is to find the maximum distance margin, which gives the optimal hyperplane. The optimal hyperplane always gives excellent classification. In the case of non-linear, which produces low and no distance margin, SVM showed misclassification. In that scenario, SVM used the kernel functions to convert the non-linear data into 2D or 3 D dimension arrays. The minor dimensional feature is converted into high dimensional feature space by the kernel functions.

3) *Random Forest (RF)*: Random Forest (RF) is one of the most common and powerful supervised ML algorithms. RF executes efficiently massive datasets and predicts accurate results. This algorithm support both types of functionality, such as classification and regression—the decision tree support RF to enhance the accuracy and flexibility. In general, with more trees in the forest, the output would be more predictable. The more trees in the RF reduce the risk of when a statistical model fits exactly against its training data. RF can obtain good accuracy in case of missing a large proportion. According to attributes, the new object classifies, and the decision tree gives the classification output per the ruleset.

4) *AdaBoost*: The first boosting algorithm is AdaBoost, which solved multiple problems. The AdaBoost constructs a robust classifier from multiple weak classifiers. This algorithm keeps a single split of the decisions tree with the weak stump, known as the decision stump. AdaBoost always keeps more load on tough to classify, easy to handle the problem, and do less. This algorithm has solved both types of problems, such as classification and regression. Multiple APK's are repackaged, which steal code by reverse engineering methods and reassemble with another name by adding adware or small scripts of malicious code into repacked APK. Here the APK has very slightly changed, so the dataset has slight noise in

data We found that in the case of less noisy data, only a few hyperparameters need to be tuned to improve the Adaboost performance. In the case of the small number of input variables, KNN models provide excellent performance. Whenever we increase more number of input variables, the performance of KNN degrades. In our dataset, we used multiple DEX files based on APKs. All files structure of APK were converted into grayscale images, which increased the number of input variables and memory size and complexity of the KNN model.

IV. PROPOSED MODELS

In our work, we proposed an image-based detection of android malware using machine learning classification. In this process, Android APK converts into a grayscale image, extracts the image feature using image processing techniques, and trains the machine learning classification to detect malicious or benign apps depicted in Fig. 1. The novelty of this approach the entire files of APK transforms into images to deal with the obfuscation attack. Most of the existing techniques used only three files of APK to transform into the image. The main disadvantage of the other techniques requires decompiling the APK and separating the files such as DEX (MD), ARSC(RS), Manifest.xml(MX), and certificate files. Moreover, the disadvantage is that it does not take care of the mutliDEX files. If APK has more than 6500 methods in the app, it needs to create the multiDex files [40]. If the malicious code is embedded with second or third classes.dex files, no existing algorithm detects the Android malware app from multiDex class files. The primary source of the malicious code is embedded into classes.dex files. Our models used three algorithms (SURF, ORB, and SIFT) to extract local features (LF) descriptors from the grayscale image dataset. One by one, local features (Extracted from each image) train to multiple machine learning algorithms (RF, KNN, DT, and AdaBoost). The multiple descriptors represent an image. Above mentioned machine learning algorithm gave the multiple vectors as outputs, which cannot be direct as inputs for any machine learning algorithm. This model used the Bag of Visual Words(BOVW) to create one feature vector with multiple local feature descriptors [41]. The BOVW uses any clustering techniques to fragment the extracted descriptors vectors into multiple clusters. Then the cluster is predicted by the clustering algorithm.

A. Accuracy Assessment

The accuracy metrics for multiple Machine Learning models were determined based on the precision, recall, f1-score, and accuracy in Eq. 4, 5, 6, 7 respectively, and precision in fraction of data entries of malicious activity are categorized as truly Android malware.

$$\text{Precision} = \frac{\text{True Possitive}}{\text{True Possitive} + \text{False Possitive}} \quad (4)$$

The recall is the fraction of malicious apps data of correctly classified malicious families.

$$\text{Recall} = \frac{\text{True Possitive}}{\text{True Possitive} + \text{False Negative}} \quad (5)$$

TABLE I. OBTAINED ACCURACY, PRECISION, RECALL AND F1-SCORE FROM MULTIPLE MACHINE LEARNING MODELS USING MULTIPLE LOCAL FEATURES EXTRACTOR METHODS

Performance Evaluator	Feature Vectors Methods	Machine Learning Methods			
		K-Nearest Neighbors	Support Vector Machine	Random Forest	AdaBoost
Accuracy	SIFT	92.42%	94.06%	94.65%	93.16%
	SURF	94.69%	95.37%	96.33%	96.86%
	ORB	89.41%	89.83%	91.42%	92.83%
Precision	SIFT	94.48%	91.00%	95.11%	95.71%
	SURF	95.79%	94.63%	97.44%	97.41%
	ORB	90.46%	89.13%	92.48%	93.36%
Recall	SIFT	91.31%	94.97%	93.42%	92.66%
	SURF	93.47%	96.29%	95.09%	96.35%
	ORB	88.33%	90.70%	90.24%	92.34%
F1-Score	SIFT	92.40%	94.14%	94.57%	93.18%
	SURF	94.71%	95.45%	96.25%	96.88%
	ORB	89.39%	89.91%	91.34%	92.85%

f1- score is the harmonic mean between sensitivity and precision.

$$f1 - score = 2 * \frac{\text{Precision} * \text{Recall}}{\text{Precision} + \text{Recall}} \quad (6)$$

The accuracy or complete classification accuracy is the portion of all suitably classified negative and positive records with the losses.

$$\text{Accuracy} = \frac{TN + TP}{TN + FN + TP + FP} \quad (7)$$

$$\text{Cross-EntropyLoss} = -\frac{1}{N} \sum_{o=1}^n \log p_{model}(y_o \in C y_o) \quad (8)$$

V. EXPERIMENT

The experiment has been designed on Intel core™ i-7 10700 CPU @ 3.8 GHz with 16 GB RAM. The experiment used the BOVW algorithm, which needs a size 120 codewords vocabulary. The K-means technique collected all key points from created datasets, and it has the codeword vocabulary size 120. Moreover, the proposed model used Opencv, Sklearn python libraries for the implementation of laboratory works.

The performance of different Machine Learning models has been achieved in terms of the whole percentage of true positive, true negative, false positive, and false-negative decisions. Our local features extractor models, such as SIFT, SURF, and ORB, extract key points from the image dataset. The extracted local feature passed to train four renowned machine learning models, i.e., K-Nearest Neighbors(KNN), Support Vector Machine (SVM), Random forest, and AdaBoost. The complete result with multiple ML models and local feature extractor models is presented in Table I and shown in Fig. 3. The validation set of the accuracy and losses in our proposed works proves that the results are correct, not overfitting problems depicted in Fig. 4. The high accuracies, precision, recall, and Fi-score from different machine learning models are displayed in Table II and Fig. 3. if the losses decrement and accuracy developments of both groups are like the same, then the process aborted changed the modeling parameters to remove the overfitting problem. Last, the AdaBoost model accuracy touched 96.86%. The traditional machine-learning algorithm shows the performance of each algorithm in Table III and is

depicted in Fig. 4. The accuracy value maximum 96.88% in the AdaBoost model, with losses, using SURF local feature extraction models in Fig. 4. In our work, computation time is scanned in each step of all ML models, inclusive of the feature extraction process, training, and testing of the model. The computation time from different ML models, the feature extraction process, training, and validation are presented in Table IV and Fig. 6.

VI. CONCLUSION

Our proposed model uses an image-based framework to classify the android app, whether malicious or benign app. Most image-based detection techniques do not care about the multiDex files of APK, using only a single class.DEX file for image conversion. In existing techniques of image-based malware detection found [11-12,23,36,37] the maximum detection probability of malware in classes.DEX file, not in another file such as Resources.ARSC, Manifest.xml, certificate files, if the hackers hide malicious code into second or third classes.DEX files, there is no chance to detect the malware in previous approaches. In our experimental works, transform

TABLE IV. THE EXECUTION TIME OF THE PROPOSED MODEL

Feature Vectors Methods	Machine Learning Models			
	K-Nearest Neighbors	Support Vector Machine	Random Forest	AdaBoost
SIFT	941.63	945.87	941.03	943.91
SURF	827.00	830.64	826.72	828.91
ORB	43.36	44.87	44.10	266.43

all classes.DEX APK file's contents into grayscale images. We used the image processing techniques to extract the local feature of images, including SIFT, SURF, and ORB models. The Local features are classified using machine learning models (KNN, SVM, RF, and AdaBoost) to detect Android malware. The achieved results exhibited that the proposed approach overtakes the existing techniques in classification accuracy and computational time. Our work showed that the AdaBoost detection rate reached up to 96.86 %, shown in Fig. 5, and run time did not exceed 0.0195 s on average for each sample. In the future, we will try to use the local and global features of images on multiDEX files to classify the Android malware to improve accuracy.

ACKNOWLEDGMENT

Mohd Abdul Rahim Khan would like to thank the Deanship of Scientific Research at Majmaah University for supporting this work under Project No. R-2022-162

Abstract—This paper addresses an industrial case of the two-agent scheduling problem with a global objective function. Each agent manages one or several projects and competes with another agent for the use of common multi-skilled employees. There is a pool of employees, each of which can perform a set of skills with heterogeneous performance levels. The objectives of the two agents are both to minimize the total weighted tardiness of its tasks. Furthermore, We assume that some constraints (soft constraints) can be violated when there is no feasible schedule for the problem. Thus, the global objective function minimizes the constraint violations by reducing the undesirable deviations in the soft constraints from their respective goals. The overall objective is to find a schedule that minimizes both agents objective functions (local objectives) and the global objective function. We provide a mixed-integer goal programming (MIGP) formulation for the problem. In addition, we present a hybrid algorithm combining an exact procedure, a greedy heuristic, and a genetic algorithm to find an approximate Pareto solution set. We compare the performance of the hybrid algorithm against the corresponding MIGP formulation with simulated instances derived from real-world instances.

Keywords—Two agents; multi-skilled employees; multi-project scheduling; hybrid genetic algorithm; MIGP

I. INTRODUCTION

In the last decade, multi-project scheduling studies have introduced a new environment where different agents (local decision makers) are involved in the scheduling process. This is very common in some real-life situations, where tasks to be processed belong to different subsets and are subject to different performance measures. Such a situation can be encountered in an organization that deals with multiple projects for which the customers do not have the same requirements. For instance, some customers may be more demanding on delay, some on cost, and others on both at the same time, etc. To deal with these different requirements, new extensions of multi-project scheduling problems have been introduced, in which at least one performance measure is applied on some

tasks and not on the whole set. In addition, subsets of tasks compete for the use of common processing resources, which can create conflicts. These kinds of problems are called multi-agent scheduling problems [1].

The authors in [2] and [1] were pioneers who introduce the multi-agent concept into scheduling problems. Particularly in the two-agent scheduling model, two agents want to perform their respective tasks on common processing resources. Each agent has its own subset of tasks, which is entirely distinct from the subset of the other agent, and wants to optimize some scheduling criterion that depends on its tasks only. The goal is to determine the best compromise solutions that satisfy the agents' criteria.

This paper studies, to our knowledge for the first time, a model integrating the concept of the two-agent scheduling and multi-skill project scheduling. The two agents compete on the usage of common multi-skilled employees. Each agent manages one or more software projects that must be carried out simultaneously and completed within a fixed horizon (consecutive weeks). Each project consists of a set of independent, preemptive tasks; and each task belongs to one of the agents.

Each task is associated with a release date, a due date, and a penalty value must be paid for each week of delay. These release and due dates are negotiated with the final client and are contractually fixed. Thus, the non-respect of one of these due dates may lead to the payment of penalties. Our aim is to reduce these penalties. We consider that each task needs exactly one skill and must be performed by one employee who possesses the corresponding skill with an efficiency level. Furthermore, each task has a nominal load which corresponds to a theoretical time needed to perform this task. The nominal load for each task may be compressed according to the efficiency level of the employee in charge of that task.

There is a pool of multi-skilled employees with known weekly availability. Each employee may be involved in more

than one project at the same time with a maximum quota (percentage of time) allotted to each project. These quotas are considered here as variables and need to be calculated by the procedure of scheduling.

Furthermore, we consider that some constraints (soft constraints) can be violated when there is no feasible schedule for the problem. The global objective function seeks to minimize these constraint violations by reducing the undesirable deviations in the soft constraints from their respective goals. The objectives of the two agents are both to minimize the total weighted tardiness of its tasks.

The problem under study is a general instance of the uniform parallel machines scheduling problem with preemptions and release dates $Qm | r_j, pmtn | \sum w_j T_j$, which is known to be \mathcal{NP} -hard ([3]). However, we focus here on the case with more than one agent with different objective functions and resources with heterogeneous skills, which obviously increases the difficulty of solving an instance considerably. Our goal in this paper is to design effective heuristics that are able to generate a good approximation of the Pareto set.

The rest of the paper is organized as follows. The next section reviews the relevant literature on the two-agent scheduling problem. Section III describes the addressed problem in more detail. Sections IV and V present a mixed-integer goal programming (MIGP) formulation and heuristic approaches, respectively. Afterward, section VI-B5 presents the results of experiments conducted to analyze the performance of the proposed methods, and then Section VII concludes and presents future works.

II. LITERATURE REVIEW

This section presents the literature related to two scheduling topics that have been addressed so far separately: the multi-skill resource-constrained project scheduling problem (MS-RCPSP) and the multi-agent scheduling problem. In Section II-A, we discuss multi-skill project scheduling studies that focused on the multi-project environment. In Section II-B, we discuss multi-agent scheduling studies that specifically interested in the case of two agents competing on parallel machines. A synthesis of the reviewed literature is given in Section II-C.

A. Multi-Project Multi-Skill Resources-Constrained Project Scheduling Problems

The multi-skill Resources-Constrained Project Scheduling problem (MS-RCPSP) is an extension of the well-known Resource-Constrained Project Scheduling Problem (RCPSP), whereby multi-skilled resources (human resources or multipurpose machines) are involved. This multi-skill RCPSP extension focuses more on the particularities of human resources, such as the skills they master and sometimes the level of effectiveness in exercising those skills.

The author in [4] were the pioneers who introduced multi-skill resources into the project-scheduling field. Since then, many researchers have focused their studies on this problem considering many properties and optimizing various objectives. Particularly, most of the studies focused on MS-RCPSP merely assume that all tasks to be scheduled belong to the same

project. In this review, we focus on a multi-project setting, the reader interested in the mono-project case is referred to the papers by [5], [6].

The MS-RCPSP has been considered in a multi-project environment. The author in [7] consider a multi-project setting with heterogeneous skill resources and learning effect. The concept of learning effect means that the efficiency of resources will increase by doing more. The objective function in their study minimizes outsourcing costs. The authors in [8] and [9] considered resources with heterogeneous skills that influence the speed of work of resources. The author in [8] subdivided projects into work packages, with earliest and latest start periods associated with projects. However, [9] considered earliest and latest start periods for tasks. Thus, each task has exactly one predecessor task linked with it by maximum and minimum start-to-start time lags. The objective functions in both studies minimize the costs associated with internal and external resource usage. The author in [10] extended the same model by considering a stochastic setting. The author in [11] considered heterogeneous skills and assumed that the efficiency levels of skills may increase or decrease task duration. The objective is to assign to each project a subset of resources (team), with each team member can be assigned to several projects at a time. The author in [12] focused on a multi-objective version for project selection and scheduling problem, that includes heterogeneous skills, variable capacities over time, learning and forgetting effects. The joint problem of project selection and scheduling consists in selecting then scheduling an optimal portfolio of projects among several available projects. The objectives of the authors are the maximization of the economic gains of the selected projects and the maximization of the efficiency increase of the resources due to learning effects. The author in [13] developed a similar model for multi-project scheduling and multi-skilled staff assignment for IT product development. The objective functions they considered consist of maximizing the efficiency gain and minimizing the product development cycle time and costs. The author in [14] investigated a roughly similar model with uncertainty and learning effect. They assumed that each task requires several skills with a minimum level per skill and its processing time is related to resource efficiency. The book of [15] covers three versions for multi-project scheduling, namely project selection and scheduling, workforce assignment, and resource leveling. In the recent paper of [16], an integrated model of multi-mode and multi-skill project scheduling problem is considered. The multi-skilled resources have different skill levels, resulting in different processing times for the same task. The author focused on the minimization of the total makespan of projects.

B. Two-Agent Scheduling Problems

To better position our work more clearly in the multi-agent scheduling literature, we decide to limit our review to the related literature, which topics may be classified into (1) two-agent single-machine scheduling problems and (2) two-agent scheduling problems in a parallel machine environment.

1) *Two-Agent Single-Machine Scheduling Problems*: There is an enormous amount of literature investigating two-agent single-machine scheduling problems. Because of the large amount of literature, we only discuss in this section those

including due date-based objective functions. Agnetis et al ([1]) studied several scenarios for different combinations of objective functions of the two agents involving a single machine. The problems addressed consist in minimizing the value of one agent, while maintaining the objective value of the other agent below or at a fixed level. The objective functions they considered include the maximum of regular functions (f_{max}), number of late jobs ($\sum U_j$), and total weighted completion times ($\sum w_j C_j$). The author in [17] deal with a similar model with the goal to minimize the total completion time ($\sum C_j$) of one agent with the restriction that the number of tardy jobs ($\sum U_j$) of the other agent cannot exceed a given number. The author in [18] addressed several two-agent single-machine problems consisting in minimizing the total weighted completion time of one agent, subject to an upper bound on the value of the other agent, which may be: total weighted completion time, maximum lateness, and maximum completion time. More recently, [19] considered a similar model with an objective to minimize the weighted number of tardy tasks ($\sum w_j U_j$) of the first agent, subject to an upper bound on the weighted number of tardy jobs of the second agent. The author in [20] proposed a model similar to the models above with the objective to minimize the total weighted late tasks of one agent, while keeping the value of the total completion time of the other agent lower than or equal to a given value. The authors of [21] addressed a two-agent single-machine scheduling problem with learning effects where the objective is to minimize the total tardiness ($\sum T_j$) of the first agent, subject to an upper bound on the maximum tardiness (T_{max}) of the second agent. The author in [22] extended the model of [17] to the case with learning effect. The objective was the minimization of the total weighted completion time of the first agent with the restriction that no tardy job is allowed for the second agent. The author in [23] considered a two-agent single-machine scheduling problem with assignable due dates. The goal is to assign a due date from a given set of due dates and a position in the sequence to each task so that the weighted sum of the objectives of both agents is minimized. The authors considered several combinations of the objectives, which include the maximum lateness, total (weighted) tardiness, and total (weighted) number of tardy tasks. In [24], the author extended the same model by minimizing the objective of the first agent with an upper bound on the value of the objective of the second agent. The author in [25] considered unit processing time tasks and a common due date (see Section II-B2). The author in [26] tackled a two-agent single-machine scheduling model that considers setup times between agent tasks. The authors considered several combinations of the objectives: the maximum lateness, the total (weighted) completion time, and the (weighted) number of tardy tasks. The author in [27] considered the same setting with the objective to minimize the total weighted completion time of the first agent subject to an upper bound on the makespan of the second agent. The author in [28] assumed that tardy a task incurs a tardiness penalty cost which can be avoided by compressing the processing time of some tasks, which includes an additional cost. The objective of each agent is to minimize the total tardiness penalty cost plus the total compression cost. The authors considered two single-machine scheduling problems. The first problem is to minimize the weighted sum of the objectives of the two agents. The second problem is to minimize the objective of one agent with a constraint on the value of the objective of the other

agent.

2) *Two-Agent Scheduling on Several Machines*: Considering the above literature, it can be seen that studies including a parallel-machine environment are relatively limited. More precisely, most of the studies on the two-agent parallel-machine scheduling problem focused on identical parallel machine environment. The author in [29] were the first to consider this setting, where the objective of one agent is to minimize the makespan and that of the other is to minimize the total completion time. The author in [30] studied two models of two-agent scheduling on identical machines where the goal is to minimize the makespan and the total completion time of one agent respectively, subject to an upper bound on the makespan of the other agent. The author in [31] interested in a similar model with the goal to minimize the total weighted completion time of the first agent, subject to an upper bound on the value of the makespan of the second agent. The author in [32] tackled also a similar model with the goal to minimize the makespan of the first agent, subject to an upper bound on the makespan of the second agent. The author in [33] studied several two-agent scheduling problems for identical parallel machines with preemption and release dates for either one set or both sets of tasks. The objective functions they considered are the total (weighted) completion time, the number of tardy tasks, the total tardiness, the maximum lateness, and a regular function of type f_{max} . The author in [34] considered a two-agent setting with a single machine or two identical machines in parallel. The processing times of the tasks of one agent are compressible at an additional cost. The authors considered several different objective functions: the regular function f_{max} , the total completion time plus compression cost, the maximum tardiness plus compression cost, the maximum lateness plus compression cost, and the total compression cost subject to deadline constraints. The author in [35] studied a two-agent parallel-machine scheduling model with the assumption that a task can be rejected, which incurs a penalty. The objective is to minimize the sum of the scheduling cost of the accepted tasks and the total rejection penalty of the rejected tasks. The authors considered several combinations of objectives: the makespan, the total completion time, the maximum lateness, and the weighted number of tardy tasks. The author in [36] studied a two agent scheduling problem with deteriorating effect on bounded parallel batching machines. The objective is to minimize the makespan of one agent with the constraint that the makespan of the other agent is no more than a given threshold. The author in [37] study a scheduling problem for concurrent jobs on identical parallel machines. It deals with an interfering multi-agent scheduling problem. New complexity results have been developed when the jobs are of identical durations. Some problems are shown to be polynomial where exact solution algorithms are developed and others are shown to be \mathcal{NP} -hard.

To the best of our knowledge, very few studies focused on a setting of two agents competing on uniform parallel machines. The author in [38] considered identical processing time tasks where the goal is to minimize at the same time a general cost function associated with the first agent and the makespan of the other agent. In [39], the author addressed the same model with the goal to minimize two maximum functions associated with the two agents. The author in [25] developed a single machine, and parallel (both identical and uniform) machine

settings. They discussed the case where the tasks have identical processing times and a common due date. They focused on minimizing the total weighted earliness–tardiness of the first agent, subject to an upper bound on the maximum weighted deviation from the common due date of the tasks of the second agent.

There exist at least two studies that tackled the case of two competing agents on unrelated parallel machines. The author in [40] considered a Just-in-Time setting where the objective of the first agent is to maximize the weighted number of its just-in-time tasks, while the objective of the second agent is either to maximize its maximum gain from its just-in-time jobs or to maximize the weighted number of its just-in-time jobs. The author in [41] focused on the objective of minimizing the total completion time of the tasks of one agent, while keeping the weighted number of tardy tasks of the other agent within a given limit.

C. Synthesis

In this paper, we study an integrated multi-agent scheduling and multi-skill project scheduling problem with many particularities. To the best of our knowledge, this problem has never been studied in the literature. The novelty of our model is related also to several particularities stem from the preferences of the managers. For instance, we consider minimum and maximum loads associated with each task. Also, we consider that each employee, should not exceed a fixed number of different tasks over a given week. We consider a preemptive MS-RCPSp problem with a multi-project setting and heterogeneous skill levels. In light of the existing literature on multi-project multi-skill RCPSp, it is noticed that the studies including those two features are very limited.

Table I presents a synthesis of the studies reviewed above. The first column indicates the paper. The second column provides the characteristics of mutli-skilling: “#SK” indicates the number of skills required by the task, “HS” for heterogeneous skills and “ML” indicates if a minimum level of skill is required to perform the task. The third column indicates some multi-agent features presented according to several sub-columns. Sub-column “M” indicates the number of machines. Sub-column ‘E’ describes the parallel machine environment (“Pm” for identical machines (Qm” for uniform machines “Rm” for unrelated machines). Sub-column “O” indicates that the objective value of one agent is constrained under an upper bound. Sub-column “C” means that the objective function is a combination of the agent’s objectives functions. Sub-column “P” means that the goal is to enumerate the entire Pareto frontier. The fourth column “Objective” shows the objective function. Followed by the last column, which indicates if the paper considers other specific characteristics.

For each paper in Table I, we use the following abbreviations to indicate the objective considered. OC: outsourcing costs; EC: External cost; ATS: average team size; SEG: skill efficiency gain; PDCT: product development cycle time and costs; $w_j E$: weighted numbers of just-in-time tasks, G : gain from just-in-time tasks; $w_j C_j$: weighted total completion time; C_{max} : project duration (makespan); f_{max} : maximum of regular functions; L_{max} : maximum lateness; $w_j U_j$: weighted number of tardy tasks.

III. PROBLEM DEFINITION AND NOTATIONS

There is a set $K = \{k_1, \dots, k_L\}$ of L projects that must be completed before a common due date (horizon). There are two competing project managers (agents), called A and B , each has a disjoint subset of projects. Each project k_l is broken down into a set of independent, preemptive tasks; and each task belongs to one agent. As explained earlier, we do not consider precedence constraints either between projects or between tasks. As the tasks are independent, we suppose that all the tasks are numbered from 0 to $J + 1$, where the 0th and the $n + 1$ th tasks are dummy indicating the start and end of projects, respectively. The subset of tasks of agents A and B are denoted by $N_A = \{n_1, \dots, n_{J_A}\}$ and $N_B = \{n_{J_A+1}, \dots, n_J\}$, respectively. The time unit is the half-day.

For each task n_j , there is a nominal load c_j (expressed in man-days), a release date r_j (given in weeks), and a minimum load denoted c_j^{\min} (expressed in half-days) to quantify the minimum degree of realization of this task per week. The minimum load of tasks per week allows modeling some tasks that cannot be interrupted during more than one week. In the case where the employee assigned to a task n_j works on that task during a given week, he or she should perform at least its minimum load c_j^{\min} . Furthermore, In each week, the employee assigned to task n_j must not exceed its maximum load c_j^{\max} . We want to avoid loss of time due to changing context of employees, which is required when changing from one task to another. Thus, during each week, the number of different tasks on which an employee is working is less than a given value b (fixed for all the projects and all the employees).

Let $E = \{e_1, \dots, e_I\}$ be a set of I multi-skilled employees working in the company. Every employee has an availability per week (a working time known in advance) ranging from 0 to 10 half-days. We refer by $D_{i,s}$ the availability of employee e_i during week h_s , where $h_s \in H$. Employees are allocated to different projects with maximum percentages of time (quotas). As mentioned earlier, these quotas must be determined by the scheduling procedure. Once determined, they must be respected during each week of the horizon. In other words, during each week h_s , any employee e_i assigned to project k_l cannot spend on this project more than $D_{i,s} \times Q_{i,l}$, where $Q_{i,l}$ is the quota of employee e_i on project k_l . Each employee can work on only one task at a given time frame.

In our model, once a task is assigned to an employee with the required skill, it remains so until its accomplishment. The capabilities of performing tasks by resources are represented by a binary skill matrix denoted by m , where $m_{j,i} = 1$ if employee e_i masters task n_j , and $m_{j,i} = 0$ otherwise. It means not every employee can be assigned to a task. Furthermore, we assume that several employees may have different levels of efficiency for the same skill. Since each task requires only one skill, the skill level of the employee is directly associated with the task. The manager estimates the employees’ efficiency level according to the standard classification of expertise level: junior, middle and senior. Based on these estimations, we assign an efficiency coefficient equal to 0, 0.5, and 1 to a junior, middle and senior, respectively. This coefficient is a ratio of an employee’s actual processing time to perform the task against the theoretical processing time (nominal load) needed to complete the corresponding task. Thus, to consider

the employee's efficiency level in the processing time of task calculation, a simple linear formula is assumed between the task nominal load and the employee assigned to it. We apply this formula to convert the task nominal load (c_j) to duration (processing time, $p_{j,i}$) according to the efficiency level ($v_{j,i}$) of the employee: $p_{j,i} = (2 - v_{j,i})c_j$. Since the nominal load of the task is given in number of days, we multiply it by 2 to convert it into half-days. For example, a task that requires a java developer and 2 days to be performed, it can be done by a senior developer in 2 half-days (i.e. half of the time), and by a junior developer in 4 half-days (the actual time).

The constraints on the minimum load of tasks per week and on the number of different tasks on which an employee is working are soft constraints imposed by the manager to increase the productivity of the employees.

For an effective schedule, these soft constraints should be taken into account. However, the manager allows the soft constraints to be violated when there is no feasible schedule for the problem. The solution approach must minimize these constraint violations by reducing the undesirable deviations in the soft constraints from their respective goals. We introduce a global objective function to penalize these constraint violations. All the other constraints (also called hard constraints) must be respected by the proposed solution.

The objective functions considered here are as follows. Let f^A and f^B be the objective functions of agents A and B , respectively. Each of the agents wants to minimize the total weighted tardiness of its tasks denoted by $f^X = \sum_{j \in N_X} w_j T_j$, where $X \in \{A, B\}$, T_j is the number of weeks of task n_j tardiness and w_j is the penalty cost for this task. Note that if task n_j takes at least one half-day of week ($d_j + 1$) before its completion time, it is late by one week ($T_j = 1$). Furthermore, the soft constraints are addressed as goals to be reached, and the global objective is to get as close as possible to these goals. We consider a global objective function that

consists to minimize the violations of these constraints. This objective function is defined by $f^G = \sum_{j=1}^J \sum_{s=r_j}^H \alpha u_{j,s}^- + \sum_{i=1}^I \sum_{s=1}^H \beta o_{i,s}^+$, where $u_{j,s}^-$ is the deviation below c_j^{\min} , $o_{i,s}^+$ is the deviation above b , and α and β are problem parameters stem from the preferences of project managers on soft constraints. Between the two soft constraints, the minimum load constraint is slightly more important than the other soft constraint. Hence, α is slightly higher than β . The problem is to find a schedule that minimizes at the same time the objective functions of both agents as well as the global objective function.

Following the conventional three-field notation introduced by [42] and extended by [43], this problem may be denoted by: $Qm \mid CO - GA, r_j, pmtn \mid f^G, f^A, f^B$, where $CO - GA$ denotes a problem of disjoint subsets competing with a global objective.

A solution consists of two parts: the first is to specify a suitable allocation of employees to projects, and the second is to determine a schedule of tasks for each employee to complete within the planning horizon H . Note that a schedule is defining by a suitable assignment of employees to task and the load (i.e. the number of half-days) that each employee has to perform of each of its tasks during each week. We are interested in determining a good approximation of the Pareto frontier.

Table II presents the notation of the problem parameters used throughout this paper.

TABLE II. NOTATIONS AND PARAMETERS OF THE PROBLEM

General data	
H	project planning horizon
X	index of agent X , $X \in A, B$
K	set of projects, $K = \{k_1, \dots, k_L\}$, $ K =L$
E	set of employees, $E = \{e_1, \dots, e_i\}$, $ E =I$
N	set of tasks, $N = \{n_1, \dots, n_j\}$, $ N =J$
N_X	set of agent X 's tasks, $ N_X = J_X$ and $J = J_A + J_B$
N_l	set of tasks of project k_l
WL_l^k	nominal load of project k_l in skill
$Z_l^k = \{z_k \ k \in \{1, \dots, K\}\}$	required skills to complete k_l project
Tasks data	
c_j	nominal load of task n_j (measured in man-day)
r_j	release date of task n_j (given in number of weeks)
d_j	due date of task n_j (given in number of weeks)
c_j^{\max}	maximum load of task n_j (given in half-day)
c_j^{\min}	minimum load of task n_j (given in half-day)
w_j	penalty cost of task n_j per week
F_j	completion date of task n_j (given in number of weeks)
T_j	tardiness of task n_j (given in number of weeks)
E_k	set of employees mastering skill z_k
Employees data	
$D_{i,s}$	availability of employee e_i during week h_s (given in half-days)
b	number of different tasks on which every employee can work during each week
$M_{i,k}$	1 if employee e_i masters skill z_k required by project k_l , and 0 otherwise
Data on tasks and employees	
$v_{j,i}$	employee e_i 's efficiency level for task n_j
$p_{j,i}$	processing time of task n_j according to the efficiency level of employee e_i (in half-days)
$m_{j,i}$	equal to 1 if employee e_i masters task n_j , and 0 otherwise
v_j	average efficiency of employees mastering task n_j

IV. MIXED-INTEGER GOAL PROGRAMMING FORMULATION

A. Variables

- 1) $x_{j,i}$ –a binary variable equals 1 if employee e_i is assigned to task n_j and equals 0 otherwise.
- 2) $y_{j,i,s}$ –an integer variable (ranging from 0 to 10) equal to the number of half-days performed of task n_j by employee e_i during week h_s .
- 3) $z_{j,i,s}$ –a binary variable equal to 1 if $y_{j,i,s}$ is greater than 0, and equal to 0 otherwise.
- 4) F_j –the completion time of task n_j .
- 5) T_j –the tardiness of task n_j .
- 6) $u_{j,s}^+$ –deviation variable above c_j^{\min} associated to task n_j and week h_s .
- 7) $u_{j,s}^-$ –deviation variable below c_j^{\min} associated to task n_j and week h_s .
- 8) $o_{i,s}^+$ –deviation variable above b associated to employee e_i and week h_s .
- 9) $o_{i,s}^-$ –deviation variable below b associated to employee e_i and week h_s .
- 10) $Q_{i,l}$ –maximum quota of employee e_i on project k_l (percentage of time).

[]

B. Constraints

$$\sum_{i=1}^I x_{j,i} = 1, \quad j = 1, \dots, J \quad (1)$$

$$x_{j,i} \leq m_{j,i}, \quad j = 1, \dots, J; \quad i = 1, \dots, I \quad (2)$$

$$\sum_{s=r_j}^H y_{j,i,s} = p_{j,i} \cdot x_{j,i} \quad j = 1, \dots, J; \quad i = 1, \dots, I \quad (3)$$

$$\sum_{i=1}^I y_{j,i,s} \leq \sum_{i=1}^I c_j^{\max} \cdot x_{j,i}, \quad j = 1, \dots, J; \quad s = r_j, \dots, H \quad (4)$$

$$\sum_{i=1}^I z_{j,i,s} \leq \sum_{i=1}^I x_{j,i} \quad j = 1, \dots, J; \quad s = r_j, \dots, H \quad (5)$$

$$\sum_{i=1}^I 10 \cdot z_{j,i,s} \geq \sum_{i=1}^I y_{j,i,s}, \quad j = 1, \dots, J; \quad s = r_j, \dots, H \quad (6)$$

$$\sum_{j=1}^J y_{j,i,s} \leq D_{i,s}, \quad i = 1, \dots, I; \quad s = 1, \dots, H \quad (7)$$

$$\sum_{j \in N_l} y_{j,i,s} \leq Q_{i,l} \cdot D_{i,s}, \quad i = 1, \dots, I; \quad s = 1, \dots, H; \quad l = 1, \dots, L \quad (8)$$

$$\sum_{i=1}^I y_{j,i,s} \geq \sum_{i=1}^I c_j^{\min} * z_{j,i,s}, \quad j = 1, \dots, J; \quad s = r_j, \dots, H \quad (9)$$

$$\sum_{j=1}^J z_{j,i,s} \leq b, \quad i = 1, \dots, I; \quad s = 1, \dots, H \quad (10)$$

$$F_j \geq \sum_{i=1}^I s \cdot z_{j,i,s}, \quad j = 1, \dots, J; \quad s = r_j, \dots, H; \quad (11)$$

$$F_j - T_j \leq d_j, \quad i \quad F_j, T_j \geq 0 \quad (12)$$

C. Soft Constraints

According to the problem description, constraints (9) and (10) are soft constraints that can be violated when it is not possible to obtain a feasible schedule. Therefore, we incorporate the possibility of relaxing these soft constraints by adding deviation variables in the formulation. Meanwhile, these deviation variables are calculated and added to the objective function as penalties. After adding the deviation variables, the soft constraints in equations (9) and (10) became, respectively:

$$\sum_{i=1}^I y_{j,i,s} - u_{j,s}^+ + u_{j,s}^- = \sum_{i=1}^I c_j^{\min} * z_{j,i,s}, \quad j = 1, \dots, J; \quad s = r_j, \dots, H \quad (13)$$

$$\sum_{j=1}^J z_{j,i,s} - o_{i,s}^+ + o_{i,s}^- = b, \quad i = 1, \dots, I; \quad s = 1, \dots, H \quad (14)$$

D. Objective Functions

The three different objective functions are listed as follows.

Global Objective: the goal associated to constraint (13) is to avoid as much as possible that, on a given week, the employee assigned to a task perform of this task less than its minimum load. Because of that, only the negative deviation from this goal is minimized in the following equation.

$$\text{Min} \sum_{j=1}^J \sum_{s=r_j}^H u_{j,s}^- \quad (15)$$

The goal associated to constraint (14) is to limit the loss of employee time due to switching between tasks. To this end, no employee should work on more than the maximum number of tasks per week. Therefore, only the positive deviation from this goal is minimized in the following objective function.

$$\text{Min} \sum_{i=1}^I \sum_{s=1}^H o_{i,s}^+ \quad (16)$$

After incorporating these goals, the achieving global objective function can be written as follows.

$$\text{Min} \sum_{j=1}^J \sum_{s=r_j}^H \alpha u_{j,s}^- + \sum_{i=1}^I \sum_{s=1}^H \beta o_{i,s}^+ \quad (17)$$

Local Objectives the agents' objective functions in equations 18 and 19 seek to minimize the total weighted tardiness of their tasks.

$$\text{Minimize} \sum_{j=1}^{J_A} w_j T_j \quad (18)$$

$$\text{Minimize} \sum_{j=J_A+1}^J w_j T_j \quad (19)$$

V. HEURISTIC ALGORITHMS

Due to its complexity, an exact resolution of the problem is very difficult within a reasonable computation time. Therefore, we propose a hybrid algorithm combining an exact procedure, a greedy heuristic, and a genetic algorithm to find an approximate Pareto solution set. The main steps of this hybrid algorithm are as follows:

- Use a mixed integer-linear program (MILP) to set maximum quotas of employees' time on projects.
- Use a greedy heuristic to determine initial solutions.
- Apply a genetic algorithm of type NSGA-II to determine a good approximation of the Pareto frontier.

In the next sections, we detail each of the steps of the hybrid algorithm.

A. Generating Maximum Quotas

This procedure, denoted by PGQ_{exact} , is used to allocate to each project the set of employees with the necessary skills for its realization. Furthermore, it specifies the working time that each employee must not exceed per week on each of its projects. We use a simplified MILP model, which considers only the constraints on the weekly availability of employees and the workload of projects to be carried out. This MILP model uses time-indexed decision variables.

1) *Variables:* We define the integer variable $Y_{i,l,s,k}$ (ranging from 0 to 10) equal to the effective working time of employee e_i on project k_l during week h_s on skill z_k . The integer variable $Q_{i,l}$ (ranging from 0 to 10) equal to the maximum quota of employee e_i assigned to the project k_l . The integer variable $d_{i,s}^-$ (ranging from 0 to $D_{i,s}$) equal to the unused availability of employee e_i during week h_s .

2) *General Formulation:* The general formulation is given in the following.

$$\text{Minimize} \sum_{i=1}^I \sum_{s=1}^H d_{i,s}^- \quad (20)$$

s.c.

$$Y_{i,l,s,k} \leq 10 \cdot M_{i,k} \quad i = 1, \dots, I; \quad s = 1, \dots, H; \\ k = 1, \dots, K; \quad l = 1, \dots, L; \quad (21)$$

$$\sum_{k=1}^K Y_{i,l,s,k} \leq D_{i,s} \cdot Q_{i,l}, \quad i = 1, \dots, I; \quad s = 1, \dots, H; \\ l = 1, \dots, L \quad (22)$$

$$\sum_{l=1}^L \sum_{k=1}^K Y_{i,l,s,k} + d_{i,s}^- = D_{i,s}, \quad i = 1, \dots, I; \quad s = 1, \dots, H \quad (23)$$

$$\sum_{i=1}^I \sum_{s=1}^H Y_{i,l,s,k} = WL_l^k, \quad l = 1, \dots, L \quad (24)$$

The objective function (20) minimizes the sum of the unused working time (idle time), by avoiding that employees work, during each week, less than their availability. Constraint (21) guarantees that an employee must not work on a project that he or she does not master any of the skills required by that project. Constraint (22) ensures that, on any given week, no employee must exceed his or her quota on each project. Constraint (23) guarantees that an employee must not exceed his availability each week. Constraint (24) imposes that the nominal load of each project in each skill must be executed until completeness.

B. Greedy Heuristic

This algorithm employs simple priority rules and a simple heuristic to construct good initial solutions. This step is very important because a suitable assignment may help the hybrid algorithm to find an approximate Pareto solution set rapidly and effectively. This greedy heuristic returns all solutions obtained after a computation time-limited to AG_{max} .

Each initial solution is generated through two steps. The first step defines the order in which the tasks will be selected, the next step chooses, for each task, the employee who will be in charge of it among the employees mastering that task. We detail below the three steps of the greedy heuristic.

The procedure of the first step returns the list of tasks ordered in non-decreasing order of the number of employees mastering each task. For example, a task mastered by one employee should be assigned before another task mastered by two employees. This ensures that the most critical employees are not overloaded by other tasks that have multiple assignment options. In the case where two tasks are mastered by the same number of employees, the first task to be assigned is chosen according to the weighted earliest due date (WEDD) priority rule.

The procedure of the second step assigns tasks to employees. To perform this step, we proceed as follows. First, for each task n_j in the order of the list of tasks, we get the list of employees E_j mastering that task and allocated to project k_l (task n_j is part of project k_l). For each employee $e_i \in E_j$, we get $\tau_{j,l}^{tot}$ which corresponds to the total availability of employee e_i on project k_l . Then, the employee with the highest total availability will be assigned to task n_j . We note that before selecting this employee we subtract from his total availability the processing time ($p_{j,i}$) of task n_j , which ensure that he has sufficient availability to perform this task. Otherwise, if the employee does not have the required availability, the second employee in the list will be selected and so on. Finally, we update the availability of the selected employee. This means that the choice of the employee for the next task is influenced by the workload that has already been assigned.

The first and second steps of the GA generate a single solution. The remaining solutions are generated iteratively by performing simple mutation operations on the list of tasks, then repeating the second step. Algorithm (1) describes the procedure of the greedy heuristic.

C. Adaptation of the NSGA-II

NSGA-II (for Non-dominated Sorting Genetic Algorithm II) is a genetic algorithm well known as one of the most efficient and popular algorithms for solving multi-criteria optimization problems. NSGA-II method is originally proposed by [44] on the basis of NSGA proposed in [45]. We recall in the following the main ideas of this method. For more details, the reader can refer to [44]. First, individuals (solutions) are classified into a number of dominance ranks at each generation using a fast non-dominated sorting method with low computational complexity. Second, a parameter-independent partitioning method was defined by evaluating the crowding distance of individuals in the same dominance rank. Third, a selection operator was designed based on the values of

Algorithm 1 Overview of the Greedy Algorithm

```

1: Inputs:  $N$  the set of all tasks ordered in ascending order of the number of employees mastering each task;  $\tau^{tot}$  the total availability of employees on projects
2: Output:  $\sigma$  the assignment of employees to tasks
3: for each Task  $n_j \in N$  do
4:    $k_l$  : the project to which  $n_j$  belongs
5:    $E_j$  : the list of employees mastering  $n_j$ 
6:    $BinomiaList = \phi$ 
7:   for each Employee  $e_i \in E_j$  do
8:     Add  $(e_i, \tau_{i,l}^{tot})$  to  $BinomiaList$ 
9:   end for
10:  Short  $BinomiaList$  in decreasing order of  $\tau^{tot}$ 
11:   $NotAffected = true, count = 0$ 
12:  while  $NotAffected$  do
13:    if  $BinomiaList[count][1] - p_{j,i} \geq 0$  then
14:      Assign employee  $BinomiaList[count][0]$  to task  $n_j$ 
15:       $NotAffected = false$

21: end for
22: return  $\sigma$ 

```

dominance rank and crowding distance of individuals. Finally, an elitism strategy was used to improve the convergence performance of the algorithm.

Our implementation of NSGA-II is based on the following elements. (i) the coding scheme to represent an individual, (ii) the genetic operators to generate and modify new individuals, (iii) the parameters of the algorithm (i.e. population size P_{max} , number of crossover points P_c and mutation points P_m , termination criterion G_{max}).

1) *Coding Scheme:* A chromosome (or an individual or a solution) contains a given number of genes and is divided into one or more segments. In our NSGA-II, an individual is represented by an assignment of employees to tasks, a gene corresponds to a task, a segment corresponds to the set of tasks assigned to an employee, and the length of the segment corresponds to the number of tasks in this segment. Thus, a separator (0) is used in the coding scheme of an individual to indicate the beginning and the end of each segment.

In order to understand the coding scheme, let's consider the case of two agents A and B , each of which is in charge of a single project. The projects consist of 8 tasks (n_1, \dots, n_8) to be scheduled over a two-week horizon. Three employees (e_1, e_2, e_3) can be assigned to different tasks. Each agent wants to minimize the sum of the weighted delays of its tasks. Table III shows for each task, the employee with the skill required to perform it. The gray columns represent the tasks of agent B , while the white columns represent the tasks of agent A .

TABLE III. SUITABLE EMPLOYEE ASSIGNMENTS TO TASKS

	n_1	n_2	n_3	n_4	n_5	n_6	n_7	n_8
c_j	3	5	2	6	4	4	5	3
$m_{j,1}$	1	0	0	1	1	0	0	1
$m_{j,2}$	1	1	1	1	0	0	1	1
$m_{j,3}$	0	0	1	0	1	1	1	1

Fig. 1 shows a solution coding for the previous example. In this solution, tasks n_4, n_5 are assigned to employee e_1 ; tasks n_1, n_2, n_7 are assigned to employee e_2 ; and tasks n_3, n_6, n_8 are assigned to employee e_3 . The 0 is used to separate two assignments.

2) *Initial Solutions:* Initial solutions are generated using the greedy heuristic described in Section V-B. Note that the

n_4	n_5	0	n_1	n_2	n_7	0	n_3	n_6	n_8
-------	-------	---	-------	-------	-------	---	-------	-------	-------

Fig. 1. Representation of a Solution.

number of generated solutions can be smaller than the initial population size P_{max} (P_{max} is a parameter of the NSGA-II method). In this case, we apply simple mutation operations on the elitist individuals to complete the initial population.

3) *Genetic Operators*: These operators comprise several key elements: selection, crossover, mutation, and population sorting.

Selection: it chooses among the solutions of the parent population, those that will reproduce and generate the new population (offspring) for the following iteration. To this end, we use the binary tournament method, which is one of the most common selection operators. This method randomly selects a pair of parents from the population and compares their fitness functions. If both parents are on the same front, then we compare their crowding distances, and the one with the largest crowding distance is kept. Otherwise, if the two parents are on different fronts, the solution with the best Pareto front (i.e. the one with the best value of the objective function) is kept. Both solutions of a couple are unique, but a solution can be part of several couples.

Crossover: once the selection process is done, the entire selected parents move on to the breeding stage. This is where all the parents recombine in some way to create a new population that will be used in the next genetic step (mutation). The process of combining two parents is what is often called crossover.

We adopt the two crossover operators PBX (position-based crossover) and OBX (order-based crossover) proposed by [46]. The choice of these crossover operators is made based on the study published in [47]. The authors compared the performances of 11 crossover operators with the goal to minimize the total weighted tardiness on a single machine. Their experimental results has shown the efficiency of OBX and PBX crossover operators, compared to other operators, to solve this type of scheduling problem. We detail below the different steps of these two crossover operators. Also, two corresponding examples are shown in Fig. 2 and 3.

• **OBX Operator**

- Select randomly several genes (tasks) from a parent ($P1$ for example).
- Place the selected tasks in the new solution, respecting the exact positions that they occupy in the other parent ($P2$).
- Delete the tasks that are already selected in the other parent ($P2$) to avoid repeating these tasks in the offspring ($O1$).
- Insert the remaining tasks into in the offspring, from left to right, in the order that they appear in the parent ($P2$).
- Place the remaining tasks in the offspring, from left to right, in the order that they appear in the parent ($P2$).

- By changing the roles of the parents, the same procedure can be applied to generate the offspring $O2$.
- **PBX operator**
 - Select randomly a set of tasks from a parent ($P1$ for example).
 - Place the selected tasks in the offspring ($O1$, respecting their exact positions in the parent ($P1$)).
 - Delete the tasks that are already selected in the second parent $P2$. The sequence of remaining tasks in $P2$ contains only those tasks that the offspring ($O1$) needs.
 - Place the remaining tasks in $O1$, from left to right, in the order they appear in the parent $P2$.
 - By changing the parent roles, the same procedure can be applied to generate the second offspring ($O2$).

Fig. 2. OBX Crossover Example

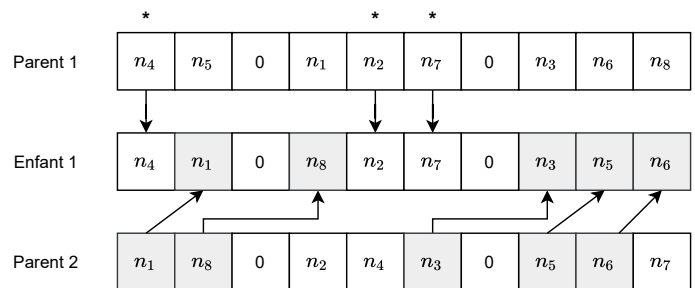

Fig. 3. PBX Crossover Example

The similarity between parent and offspring populations depends on the number of crossover points. This number (denoted by P_c) represents the number of tasks selected to put into the offspring. Preliminary tests show that a large value of P_c gives a higher probability of building solutions similar to their parents. However, a small value of P_c allows the selection of more distant solutions.

Mutation: We apply this operator at the last stage of the population generation procedure. It maintains the diversity between individuals, and therefore, avoids a premature convergence to a local optimum. The mutation operator is applied to each new solution after the crossover stage. It consists in randomly selecting two employees (e_1 and e_2 , for example) who have at least one common skill. Then, each task initially assigned to e_1 and demanding a skill mastered by e_2 will be assigned to the latter. The opposite is also applied to tasks initially assigned to e_2 . These two operations are performed P_m times, where P_m (ranging between 2 and 10.) is a parameter of the NSGA-II method.

Population Sorting: This procedure follows the same dominance sorting procedure proposed by [44]. The crowding distance is also applied.

VI. COMPUTATIONAL EXPERIMENTS

This section outlines the characteristics of the instances and the computational results of the proposed methods. Our experiments consist of three parts. In the first part, we seek to determine the size of problem instances that can be solved by the MIGP within a reasonable computation time. In the second part, we want to determine the best parameterization for the NSGA-II method. Finally, in the last part, we evaluate the performance of the heuristic methods.

Our experiments were performed on an Intel® core™ i7-1.9 GHz with 16 GB of RAM under Windows 10. All algorithms were written in Python. The CPLEX 12.8.0 solver associated with Python API was used for solving the MIGP model, using the default parameters except for the time parameter.

A. Instance Characteristics

The methods proposed in this section are experimentally validated on instances derived from real instances. AS mentioned in the introductory section, our study comes from a real scheduling case raised in an IT company. However, to perform our experiments, we could not get enough real data for confidentiality reasons. So, based on the description of the problem and the few real data given by our partner company, we generated 8 sets of instances ($T1, \dots, T8$) with 40 instances per set.

Table IV describes the characteristics of some general parameters per instance set. From left to right, the columns indicate the instance set, the project planning horizon, the number of projects, the number of employees, and the last column is the number of tasks. For each group of instances, the number of tasks per agent is chosen between $0.4xJ$; $0.5xJ$; $0.6xJ$, with J being the number of tasks. The total number of skills required to perform the tasks is ranging between 3 and 10; and each employee masters 2 to 5 skills. Each task requires one skill with a nominal load of up to 15. The release dates of 30% of tasks (randomly chosen) range between $0.5xH$ and $0.75xH$, equal to 0 for the other tasks. The due dates of 50% of tasks (also randomly chosen) are between $0.5xH$ and $0.75xH$, equal to H for the other tasks. For 30% of tasks (randomly chosen), the values of the maximum loads (resp. the minimum loads) are between 2 and the nominal loads (resp. 2 and the maximum loads). For 80% of employees, we set the availability at 10 during each week of the planning horizon. The availability of the remaining employees is between 2 and 7.

B. NSGA-II Algorithm Evaluation

We present in this section the computational results of the NSGA-II method. First, we conduct some experiments to adjust the NSGA-II parameters. Then, we perform a second test campaign to compare the performances of the two crossover operators (OBX and PBX). Finally, we conduct our last experiments to measure how much the genetic algorithm improved the results of the greedy heuristic.

TABLE IV. GENERAL PARAMETER VALUES PER INSTANCE SET

Instance set	H	L	I	J
T1	4	2	3	15
T2	4	2	3	20
T3	6	2	5	25
T4	8	2	10	50
T5	10	4	15	100
T6	14	4	20	150
T7	18	4	25	200
T8	24	4	30	250

To evaluate the quality of the returned solutions, we apply three performance metrics widely used for multi-criteria optimization problems. These metrics are the hypervolume (HV)(originally proposed by [48]), the generational distance (GD) (originally proposed by [49]), and the Pareto front size (PFS). Note that in this part of the experiments, we used 10 instances on each set of the dataset. The maximum quotas of employees on projects are initially computed by the MILP presented in Section V-A.

1) *Parameters Setting:* The NSGA-II has the following parameters to define: the population size P_{max} , number of iterations G_{max} , number of crossover points P_c , and number of mutation points P_m . The NSGA-II algorithm was run 5 times with each combination of parameters and the best values obtained are presented in Table V. To maintain test consistency, for each run, we start the genetic algorithm from the same initial solutions generated by the GH . In order to fix the number of crossover points, we performed the tests with both crossover operators. We noticed reassuringly that the best values obtained are often the same with the two operators.

TABLE V. THE VALUES OF PARAMETERS USED BY THE NSGA-II

Parameter	Range	Value
P_{max}	[100,300]	200
G_{max}	[200,3000]	1000
P_c	[1,10]	8
P_m	[1,10]	7

TABLE VI. MILP RESULTS FOR A COMPUTATION TIME LIMITED TO 5 MIN

Instance set	Number of feasible instances	Number of instances solved to optimality	Avg. time to the optimality	Avg. GAP from the optimal
T1	40	40	72.8	0%
T2	40	40	122.2	0%
T3	40	40	150.7	0
T4	40	40	194.6	0%
T5	40	38	256.8	2.5%
T6	40	35	299.2	4.5%
T7	40	32	316.5	76.7%
T8	40	29	396.9	7.6%

2) *Comparison of Crossover Operators:* Using the parameter values presented in Table V, and from the same initial solutions, we ran the NSGA-II algorithm 5 times using the OBX and PBX crossover operators. The average values of the results were calculated.

Fig. 4 shows the computed generational distances between the exact Pareto and the approximated Pareto fronts obtained with each operator. Note that, we obtain the exact Pareto fronts

TABLE VII. COMPARISON OF METHODS NSGA-II AND GH

Instance set	GPNE		NSGA-II				AG		
	PFS*	CPU*(s)	PFS	HV	GD	CPU(s)	PFS	HV	GD
T1	3.42	746.22	2.82	0.82	3.51	177.12	1.81	0.47	8.91
T2	2.91	961.86	2.13	0.76	4.43	182.72	1.54	0.43	9.32
T3	2.52	1021.98	1.89	0.73	3.87	202.98	1.95	0.38	8.12
T4	2.23	1746.78	1.63	0.68	4.43	256.10	1.42	0.35	7.25
T5	1.85	3189.21	1.51	0.64	5.14	301.45	0.26	0.28	7.89
T6	0.78	6976.81	1.51	0.62	5.14	389.95	0.42	0.18	6.91
T7	0.12	8819.11	1.41	0.68	5.14	412.34	0	0.11	6.89
T8	0	-	1.12	0.59	5.14	671.73	0	0.18	7.12

by running the MIGP model without a time limit until the exact Pareto front was returned.

Fig. 4. Results of Crossover Operators

3) *Results of Quotas Calculation Procedure:* In this section, we present the experimental results of the MILP presented in Section V-A. Recall that, this mathematical model is used by the hybrid method to calculate an allocation (maximum quotas) of employees on projects. This allocation becomes the starting point for generating an approximate Pareto front using the NSGA-II method.

The MILP model was tested on the different sets of instances. Table VI shows the computational results obtained after a time limit of 5 minutes per instance. In this table, from left to right, the columns refer to the type of instance, the number of feasible instances, the number of solutions that are proven to be the optimal solutions, the average time required to prove optimality, and the average deviations from optimal for instances that are not optimally solved.

4) *NSGA-II and Greedy Heuristic Comparison:* The objective of the experiments presented in this section is to evaluate the improvement provided by the NSGA-II over the initial solutions obtained by the GH. To this end, we compare the results of both methods with those obtained by the MIGP. Note that, we use the best combination of NSGA-II parameters presented in Table V. The solutions returned by the GH are collected after a computation time (AG_{max}) limited to 5 minutes. We run both methods 10 times and the average values are calculated. For each run of the genetic algorithm, we used the same initial solutions generated by the GH, in order to ensure the consistency of the tests.

Table VII compares the experimental results of the NSGA-II and greedy heuristic with those obtained with the GPNE model. We used four different performance indicators: the average Pareto front size (PFS), the average hypervolume (HV), the average generational distance (GD), and the average computation time in seconds (in the CPU column).

5) *Experimental Analysis:* The comparison results in Fig. 4 show that the OBX operator has a better performance compared to the other PBX operator. In fact, the genetic algorithm has a better and faster convergence with the OBX genetic operator. Moreover, reassuringly it was found that computation time for both crossover operations is almost the same for each problem size.

The experiments in Table VI prove the performance of the MILP model in terms of feasibility and optimality. The model finds a feasible solution for each instance on a set. Moreover, all the solutions obtained for the instances on sets $T1, \dots, T4$ are optimal solutions. The model finds only 2, 5, 8 non-optimal solutions (among 40) for the sets of instances $T5, T6, T7$, respectively. For $T8$ instances, a large number of instances (11) are not solved to the optimum. However, the deviation from the optimum is very acceptable (8).

Finally, the results presented in Table VII allow us to clearly conclude that the NSGA-II algorithm significantly improves the solutions obtained by the greedy algorithm. All the metrics used show that the quality of the solutions is always better for all types of instances. Thus, we can also see that the computation time is very acceptable for a heuristic.

VII. CONCLUSION

We studied herein a two-agent multi-skill resource-constrained scheduling problem with a global objective. Motivated by a real scheduling case, we considered that each agent manages one or more projects and wants to minimize the total weighted tardiness of its tasks. We consider a pool of employees in which each one can perform a set of skills with heterogeneous performance levels. We assumed that there are some constraints that can be violated when there is no feasible schedule for the problem. Thus, the global objective function seeks to minimize the constraint violations by reducing the undesirable deviations in the soft constraints from their respective goals. The overall objective is to find a schedule that minimizes at the same time both agents objective functions and the global objective function. We provided a mixed-integer goal programming (MIGP) formulation for the problem. Furthermore, we provided a hybrid algorithm combining an exact procedure, a greedy heuristic, and a genetic algorithm to find

an approximate Pareto solution set. The performance of the heuristics is evaluated on a set of simulated instances. The results show that the NSGA-II algorithm is the best performing method.

Finally, in future research, we will also focus on other types of two-agent multi-skilled resources scheduling problems. Such as the constrained optimization problem, where the goal is to minimize the global function, subject to the constraints that the objective values of the other do not exceed a given threshold.

Abstract—Coherence evaluation is a problem related to the area of natural language processing whose complexity lies mainly in the analysis of the semantics and context of the words in the text. Fortunately, the Bidirectional Encoder Representation from Transformers (BERT) architecture can capture the aforementioned variables and represent them as embeddings to perform Fine-tunings. The present study proposes a Second Fine-Tuned model based on BERT to detect inconsistent sentences (coherence evaluation) in scientific abstracts written in English/Spanish. For this purpose, 2 formal methods for the generation of inconsistent abstracts have been proposed: Random Manipulation (RM) and K-means Random Manipulation (KRM). Six experiments were performed; showing that performing Second Fine-Tuned improves the detection of inconsistent sentences with an accuracy of 71%. This happens even if the new retraining data are of different language or different domain. It was also shown that using several methods for generating inconsistent abstracts and mixing them when performing Second Fine-Tuned does not provide better results than using a single technique.

Keywords—Coherence evaluation; inconsistent sentences detection; BERT; second fine-tuned

I. INTRODUCTION

Natural language processing (NLP) is a subarea of artificial intelligence that involves tasks related to the analysis of text information using computational means. These tasks are: text generation, automatic text summarization, speech analysis and information extraction. Textual coherence modeling belongs to this class of tasks described; it consists of distinguishing coherent documents from incoherent ones [1]. Coherence in NLP is very relevant nowadays, because it is implicitly involved in several applications such as speech generation, text summarization generation, translations etc. The models proposed in text generation must ensure that the results are coherent texts. The automatic evaluation of coherence contributes to the generation of these texts with quality.

According to Charolles [2], coherence operates through the thematic progression which implies that all the ideas of a coherent text must be connected to each other. Each sentence provides a piece of information that ensures thematic continuity. A coherent text must also present consistency of ideas; this implies that no idea in a text should contradict another and neither should it be incongruent with the universe of the text to which it belongs.

Coherence also implies the type of informational and semantic connectivity that a text possesses [3]. A text is

considered coherent if it is semantically consistent and provides cognitive integrity [4], therefore, a coherent document is easier to understand than an incoherent document. Coherence is more important when analyzing scientific papers, as it must communicate information effectively to reviewers and researchers. Incoherence in scientific writing directly affects both the reading experience and the comprehensibility of scientific papers [27]. Let us consider the sentence-divided scientific papers in Fig. 1 and 2.

In the left column of Fig. 1, the scientific abstract reports on the effects of candy advertising and consumption reactions of certain additives in children under 12 years old, while in the right column, the third sentence reports on project-based learning that expresses an idea different from the other sentences, evidencing the incoherence of the text, due to the fact that the thematic progression and consistency of ideas have not been met. This phenomenon occurs in the same way in the right column of Fig. 2. The abstract deals with machine learning and data representation, while the sixth sentence reports on image processing.

As we have seen, the incoherence that occurs during scientific writing creates difficulties in transmitting and disseminating the authors ideas [27]. This happens because the sentences produced are not strongly interconnected, but are isolated, managing to label the scientific paper as "poorly written" or "difficult to follow" [28]. This kind of problem can be intentional or unintentional. Unfortunately, most of the existing systems that check for errors in scientific papers [29] lack advanced features for coherence quality control.

Given the above consideration, identifying incoherent sentences in a scientific paper becomes a problem of high rigor when evaluating scientific abstracts. The abstract is the only part of the article that is usually published in conference proceedings, and that readers usually review when searching through electronic databases; Likewise, it is a section that a potential referee gives a reading to when they are invited by an editor to review a manuscript [5]. It often contains the following structure: context, methodology, results and conclusions, each of which should provide relevant and semantically consistent information.

The evaluation of coherence requires a thorough analysis of the parts of the text at the structural and semantic level, since being a natural language it does not follow a set of rules like formal languages [4]. It is too abstract a concept [6]; however, it is a problem that has been given attention in different studies

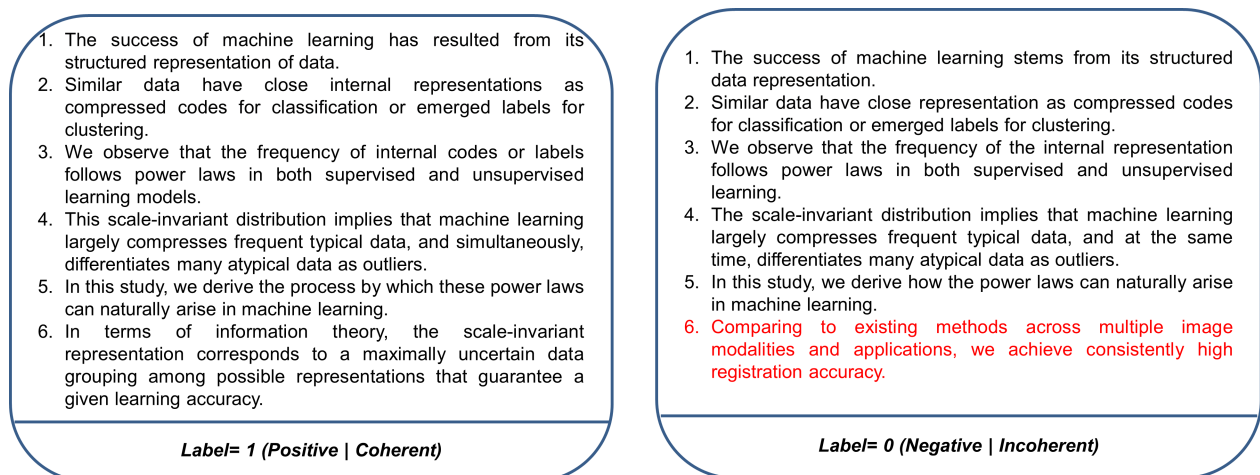

Fig. 2. Coherent and Incoherent Scientific Abstract in English.

and/or solutions since the twentieth century, as mentioned in the following paragraphs.

Foltz in 1998 [7] proposed the first coherence evaluation method using machine. This method is based on the study of latent semantic analysis (LSA), a method that compares units of textual information and determines their semantic relationship. In the following years, several coherence analysis methods were proposed by various researchers; however, no method has proved to be perfect [8].

Relational models such as the "Rhetorical Structure Theory" [9] define relationships that hierarchically structure texts. Thus, in the work of Barzila and Lapata (2008) a model called Entity Grid [10] was proposed to evaluate local cohesion. This approach was based on the centering theory [11], which models a text as a set of segments and utterances that produce centers of attention.

Unlike the Entity Grid model [10], which is a method for evaluating coherence at the local level, in the work of Guinaudeau and Strube (2013) a graphical model called Entity Graph [12] was proposed to measure text coherence at the global level. This bipartite graph allows relating non-adjacent

sentences of a text.

In the work of Li and Hovy (2014) it has been shown that recurrent and recursive neural networks are designed to estimate the coherence of a text [13]. Recurrent neural networks simulate the processing of a text according to a reading process: word by word; while in the recursive neural network the processing is represented through a binary tree.

Li and Jurafsky (2016) developed a discriminative neural model that can distinguish coherent and incoherent text. They also created 2 generative models that produce coherent text, one is based on SEQ2SEQ and the other is a Markovian model. These models capture the latent discourse dependencies of a given text [14]

Based on the foundations of the Entity Graph model [12], a semantic similarity graph model was proposed in the work of Putra and Tokunaga (2017) to address coherence from a cohesion perspective [15]. They argue that the coherence of a text is built by the cohesion between its sentences. This method employs an unsupervised learning approach.

In the work of Baiyun Cui *et al.* (2017) a deep coherence

model (DCM) was proposed making use of a convolutional neural network architecture to capture text coherence [6]. The model captures the interactions between sentences by calculating the similarities of their distributional representations.

In the work of Mesgar and Strube [21], a local coherence model was developed using a unidirectional standardized LSTM architecture to encode the context of an input sequence of words, then the relationships between adjacent sentences were encoded using LSTM. Finally, a vector representing the coherence of the text was produced.

The use of Recurrent or Recursive Neural Networks allows a vector representation of an input sequence. Based on this, a series of dense (linear) layers can be applied to classify whether the input sequence is coherent or incoherent. Thus, in the work of Moon *et al.* [22], the Bidirectional LSTM (BiLSTM) sentence encoder was applied to capture the grammar of each sentence. Given the numerical representations of the sentences, the local coherence model and the global coherence model extract the respective features.

Bao *et al.* [23] used Recurrent Neural Networks (RNN) for the model to semantically represent a text. For this purpose, they used bidirectional closed recurrent units (BiGRU) in conjunction with the pretrained language model Word2Vec to represent this semantics. The results show that a complete analysis of the coherence of a text can be represented, which favors the task of binary text classification.

The creation of a dataset for training, validation and testing is also indispensable for the evaluation of coherence. Because of this, the work of Mohammadi *et al.* [24] proposes different techniques for generating incoherent or negative documents to be added to the coherent documents in order to train a Convolutional Neural Network. Their results indicate that artificially generating incoherent documents does not guarantee "sufficiently incoherent" documents, which negatively influences the accuracy of the model.

As seen, RNN, LSTM, gated recurrent neural network (GRNN) and BiLSTM are some of the sequence models for NLP tasks such as natural language modeling [17]. In 2017, the Google research team presented the Transformer architecture that replaces the complex RNN and CNN (Convolutional Neural Network) architectures because of its better results: parallel training capability with several GPUs and self-attention mechanism, which allows to "remember" the information in the long term [18]. Fig. 3 shows the architecture of the Transformer and the Bidirectional Encoder Representations from Transformers model. In the Transformer architecture, the encoder maps an input sequence of symbols $(x_1, x_2, \dots, x_{n-1}, x_n)$ to a sequence of continuous representations $z = (z_1, z_2, \dots, z_{n-1}, z_n)$. Given z , the decoder generates a sequence of output symbols $(y_1, y_2, \dots, y_{m-1}, y_m)$, considering one element at a time. The general architecture of Transformer comprises the self-attention mechanism, the encoder and decoder, which are fully connected.

BERT is a model of the pretrained open source language introduced in 2018 [19]. It is based on Google's Transformer architecture. Also, it is designed to pre-train text representations in a bidirectional (left-to-right) manner from unlabeled texts [20]. BERT has two pre-trained models: BERT Base and BERT Large. The first model consists of 12 encoders

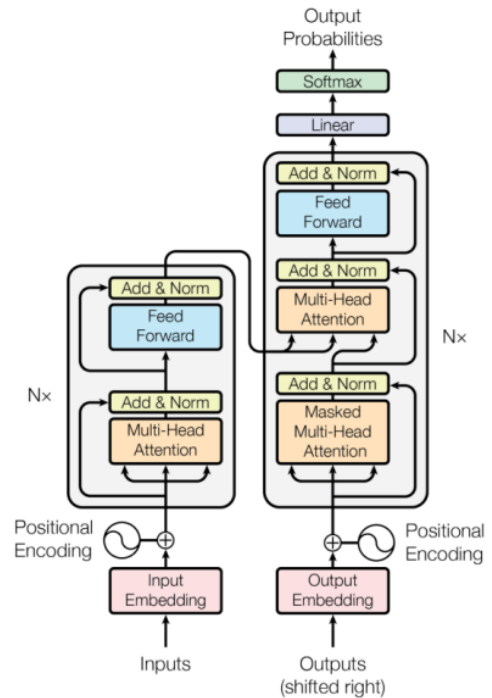

Fig. 3. The Transformer Model Architecture [18].

and a bidirectional self-attention mechanism; while the second model consists of 24 encoders and 16 bidirectional heads. The BERT model is pre-trained with 800 million words from BooksCorpus and unlabeled text from English Wikipedia with 2.5 billion words. This model is suited for small datasets related to specific NLP tasks, for example, the evaluation of coherence in scientific papers.

Fig. 4 shows the neural network architecture of the deep bidirectional BERT and unidirectional (from left to right) OpenAI GPT contextual models [17], in which the unidirectional model generates a representation for each word based on other words in the same sentence. The bidirectional BERT model represents both the preceding and following context in a sentence. However, the context-free models Word2vec and Glove generate a word representation based on each vocabulary word.

Fig. 4. BERT and OpenAI GPT Neural Network Architecture [18].

According to the historical review, BERT has revolutionized the field of NLP by enabling transfer learning of large language models that can capture complex textual patterns [36]. It also has the advantage of offering better performance and scalability over recurrent neural network architectures

since the latter operate sequentially, while BERT can be parallelized. This research work proposes a Second Fine-Tuned model based on BERT to detect inconsistent sentences to evaluate the coherence in abstracts written in Spanish/English. Two formal techniques for generating incoherent abstracts are also proposed in order to improve the training and validation of the aforementioned model.

This paper is organized as follows: in Section II the most recent and important research on the evaluation of coherence is mentioned. In Section III the methodology and the research proposal are described. Section IV presents the experiment with the results. Finally, Section V presents the discussion, conclusions and future work.

II. RELATED WORK

Discovering semantic progression and consistency of ideas is indispensable for understanding coherence. Previous research has relied on the RNN, LSTM and BiLSTM architecture to evaluate coherence; however, these networks do not use a self-attention mechanism to encode sentences and some information is lost [16]. The Transformer-based architecture allows receiving input sequences in parallel making it more efficient; and, specifically, BERT allows capturing the context of a sentence based on bidirectional analysis [18]. Some work based on BERT to evaluate coherence is shown below.

In the work of Muangkammuen *et al.* (2020), a scoring method based on BERT was proposed to score text clarity using local coherence between adjacent sentences. Cause-effect relationship and contrast were considered [25]. First, a local coherence model was trained according to BERT; then the model was retrained to evaluate the clarity of a text. The results show that retraining provides positive results even if the data on which both trainings were performed were not domain related.

In the work of Callan and Foster (2021), a corpus of narrative stories automatically generated by the pre-trained Transformer GPT-NEO model was proposed, which were analyzed by humans and by 2 automated metrics: BERT Score y BERT NSP. This was done in order to evaluate the coherence and level of interest of narrative texts. The results show that greater emphasis should be placed on BERT evaluation techniques and that generative models do not always produce coherent texts; the more natural and coherent the generated text is, the higher its quality [26].

In the work of *et al.* (2021), a comparative analysis of 3 different types of models for the evaluation of coherence in Polish documents has been developed. The first one is based on Semantic Similarity Graph (SSG); the second one is based on Long Short Term Memory (LSTM); and the third one is based on BERT. The results show that the neural network related methods offer better accuracy than the SSG related methods; and within the neural networks, although the LSTM based method shows better accuracy compared to the BERT based method, it is emphasized that the latter can increase the value of said metric with an additional Fine-Tuned [4].

In the work of Nguyen and Zaslavskiy (2021), a Fine-Tuned method based on the BERT model in conjunction with a clustering algorithm was proposed for the detection

of discordant sentences in a corpus of scientific documents written in English and Russian, in order to detect incoherence in scientific writing. Primero generaron ejemplos negativos mediante la métrica BERT Score para calcular la similitud semántica entre pares de oraciones. They first generated negative examples using the BERT Score metric to compute semantic similarity between sentence pairs. Then they trained a model with coherent and incoherent sentence pairs. Finally, they retrained this model with whole paragraph training. The results were positive [27].

In the work of Bendeviski *et al.* (2021), a comparative analysis of different artificial intelligence methods for predicting the coherence score of narrative documents was proposed, where it was evidenced that BERT produces better results compared to traditional machine learning methods such as: Linear Regression, Support Vector Machine, Random Forest. They establish dimensions for coherence which are: Context, Chronology and Theme, each of these dimensions possess narrative texts with a coherence score of 0-3 (4-class classification) [30].

According to the work of Noji and Takamura [31], negative examples contribute to a neural language model's ability to robustly handle complex syntactic constructs and improve its robustness.

III. PROPOSED MODEL AND METHODOLOGY

The principal objective of this study is to build a Second Fine-Tuned model based on BERT to detect inconsistent sentences of abstracts in English/Spanish (coherence evaluation). Two negative example generation techniques have been used for this coherent scientific abstracts are positive examples ($label = 1$), while incoherent scientific abstracts are negative examples ($label = 0$).

A. Data Recollection and Preprocessing

First of all, a program has been developed in Python with the beautifulsoup4 library to perform web scraping to the website of the journal "Comunicar" [32]. From this journal 1,493 scientific abstracts written in Spanish were extracted. Second, the corpus of "Medical Semantic Indexing in Spanish" (MESINESP) was downloaded [33], from which 51,390 scientific abstracts written in Spanish were collected. Thirdly, a corpus of arXiv was downloaded through Kaggle [34], from which 56,181 scientific documents written in English were collected.

In addition, a corpus of 448 scientific abstracts from the "International Conference on Machine Learning and Applications" (ICMLA) were added to this corpus. [35]. As a result, a corpus of 56,629 scientific documents was constructed, 3 corpus were collected, 2 in Spanish and 1 in English. It should be added that the downloaded corpus were subjected to 2 preprocessing stages: Remove blanks and Remove duplicates. Two formal techniques were developed for the generation of negative examples (incoherent abstracts):

1) *Random Manipulation (RM)*: In the first method, every abstract T_i of a corpus D is tokenized in N sentences. This T_i is represented as a set of sentences $T_i = \{S_1, S_2, S_3, \dots, S_{N1}, S_N\}$. Every S_j is a sentence where j is

the position of the sentence in T_j , it must be fulfilled that $1 \leq j \leq N$. The variable i represents the position of a scientific abstract in the corpus D , it must be fulfilled that $1 \leq i \leq size(D)$. Then a S_j is randomly selected, knowing that: $S_j \in T_i, T_i \in D$. Therefore, this S_j is replaced with a $S_{j'}$; knowing that: $S_{j'} \in T_{i'}, T_{i'} \in D$, and $S_j \neq S_{j'}$.

2) *Manipulation Random based K-means (KRM)*: In the second method, embeddings with BERT are generated from all abstracts of a corpus D . Then by clustering with K-Means ($\#clusters : K = 10$) As a partial result, there are 10 clusters of scientific abstracts labeled as C_i , being i the cluster number in the corpus D . These clusters are grouped by similar embeddings. The K-means algorithm minimizes the principle of inertia, according to the following equation 1:

$$\sum_{i=0}^n \min_{\mu_j \in C} (\|x_i - \mu_j\|^2) \quad (1)$$

This measure 1 indicates the internal coherence between the samples belonging to the different clusters. Taking as a reference the variables of the first method; to generate negative examples a $S_k \in T_j$ is randomly chosen, considering that: $T_j \in C_i$ y $C_i \in D$. Then this S_k is randomly replaced with a $S_{k'}$ knowing that: $S_{k'} \in T_{j'}, T_{j'} \in C_{i'} \text{ y } C_{i'} \in D$. It must be fulfilled that: $S_k \neq S_{k'}$ y $C_i \neq C_{j'}$. Having clusters whose similar scientific documents, knowing that the groups among themselves are different, it is ensured that negative examples are explicitly more incoherent than the first RM method. Finally, the corpus are summarized in the following table I.

TABLE I. CORPUS SUMMARY

Features	Comunicar Corpus	MESINESP Corpus	arXiv + ICMLA Corpus
Language	Spanish	Spanish	English
Coherent abstracts	1,493	50,047	56,181
Incoherent abstracts	RM Method	RM Method	RM Method
	1,491	1,491	41,559
Total abstracts	2,984	2,984	97,740

B. Proposed BERT Model

A Second Fine-Tuned model based on BERT is proposed to detect inconsistent sentences in scientific abstracts written in English/Spanish (coherence evaluation), six different experiments have been carried out for this purpose, the same ones as detailed below:

- 1) First Fine-Tuned to the original pre-trained model of BERT with the Spanish-language dataset of the journal "Comunicar". The dataset has been divided into three segments: training, validation and testing. The technique used to generate negative examples was RM.
- 2) Second Fine-Tuned to the model trained in experiment 1 by mixing the MESINESP Spanish dataset and "Comunicar" dataset, the same testing set as experiment 1 has been maintained. The technique used to generate negative examples was RM.

- 3) Second Fine-Tuned to the model trained in experiment 1 by mixing the dataset in English of "arXiv + ICMLA" with that of "Communicate". The same testing segment has been maintained as experiment 1. The technique used to generate negative examples was RM.
- 4) First Fine-Tuned to the original pre-trained model of BERT with the Spanish-language dataset of the journal "Comunicar". The dataset has been divided into 2 segments: training and validation. The same testing segment has been maintained as experiment 1. The technique used to generate negative examples was KRM.
- 5) Second Fine-Tuned to the model trained in experiment 4. The same data segments of experiment 2 and also the same testing segment of experiment 1 have been maintained.
- 6) Second Fine-Tuned to the model trained in experiment 4. The same data segments of experiment 3 and also the same testing segment of experiment 1 have been maintained.

The purpose of the experiments described above is to determine which model is best for evaluating coherence in scientific abstracts written in English/Spanish. Once the positive and negative examples (datasets) have been generated, these experiments have followed the framework proposed in Fig. 5

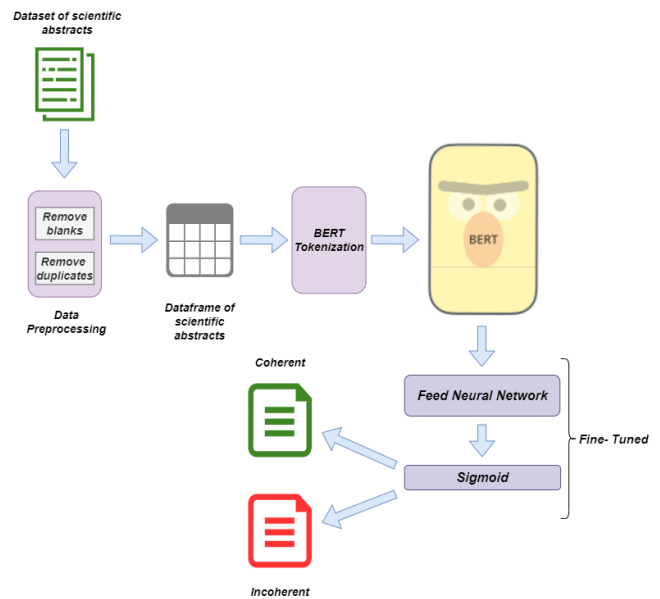

Fig. 5. BERT-Large Coherence Evaluation Framework.

During the tokenization process, an input sequence must be preprocessed to produce tokens (prayer units). In this process, the CASED preprocessor BERT was used, which is a multilingual preprocessor that can process special characters or capital letters/minuscul. A sorting token [CLS] is always included at the beginning of a sentence, each word being a token. To separate one sentence from another, the separation token [SEP] is included.[37]. It is known that an abstract T_i is represented as $T_i = \{S_1, S_2, S_3, \dots, S_{N1}, S_N\}$, applying the preprocessing you get: $\{S'_1, S'_2, \dots\}$.

The BERT Large pre-trained model was used to perform the numerical coding process of input sequences. This is a more complete version with 24 encoders and 340 million parameters [37]. It was ensured that this model used is multi-lingual and also that it is CASED. For each token 3 representations of embeddings were applied, the first is called token embeddings (h_{s1}), is responsible for representing a token as a numerical vector. The second is called segment embeddings (h_{s2}), this indicates to which segment a token embeddings belongs. It is known that a segment is that delimited by the [SEP] separator of another segment. The third is called positional embeddings (h_{s3}), this indicates the relative position of a token embeddings in the sentence. Each word is processed simultaneously [37]. Finally, each numerical representation is added to produce a single resulting vector h_c that will be used to train the Fine-Tuned model. The vector h_c can be represented by the following equation:

$$h_c = [h_{s1}, h_{s2}, h_{s3}] \quad (2)$$

Also, Fig. 6 represents how these embedding layers work with a pre-processed input. Fig. 7 shows the general architecture of the BERT Large model.

Fig. 6. BERT Input Representation [37].

Fig. 7. Architecture BERT LARGE Encoders.

To perform the Fine-Tuned of the pre-trained model, following the six experiments described above, the dataset of the journal "Comunicar" for testing has been divided by 10%. Then 10% was divided for validation and 80% for training. Each experiment has the same percentage of data division. It should be remembered that each experiment was tested with the testing data of the journal "Comunicar". After defining the data sets, a Neural Network Layer Dense has been built with a Rectified Linear Unit activation function (ReLU). This activation function will generate a positive or zero output (if the input is negative). This function is optimal to accelerate

the training of deep neural networks, it is defined with the following equation 3:

$$f(x) = \max(0, x), x = input \quad (3)$$

After the ReLU layer, a Dropout layer was added to avoid overfitting the model during training; as several studies have shown that it reduces this overfitting and improves the performance of deep neural networks for tasks such as document classification [38]. After implementing the Neural Network layer, a simple layer has been added with a sigmoid activation function. This function is commonly used for binary classifications. It has a prediction range of [0 – 1], with those closest to zero being those incoherent abstracts (rounded to 0) and those closest to 1 being the coherent ones (rounded to 1). The mathematical representation of this function is shown in the following equation 4:

$$S(x) = \frac{1}{1 + e^{-x}}, x = input \quad (4)$$

The latter simple layer contains a single neuron, whose output represents the probability of coherence of a group of abstract sentences. It can be mathematically defined by the following equations 5 and 6. Each experiment has followed the same procedure so far mentioned. Considering the above, the 6 experiments possess the same architecture. This architecture is observed in the following Fig. 8.

$$q_c = f(W_{sen}^T h_c + b_{sen}) \quad (5)$$

$$output = \text{sigmoid}(U^T q_c + b) \quad (6)$$

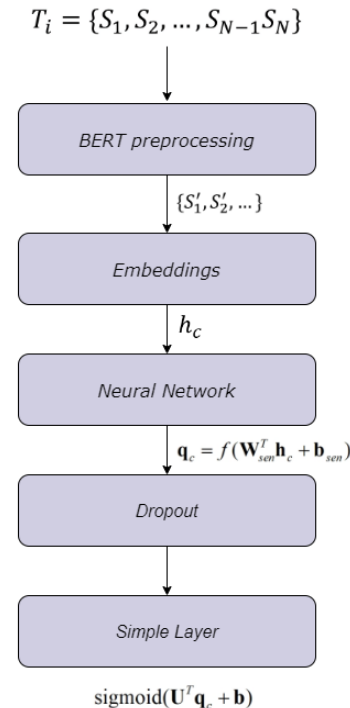

Fig. 8. Based BERT Model Architecture.

IV. EXPERIMENTAL SETTINGS AND RESULTS

In this section, the 6 experiments mentioned in the previous section are in depth. Six models with exact architecture have been generated to Fig. 8. The only difference between the experiments are the positive and negative data sets with which their models have been trained. The following subsections are detailed: The Datasets, Experimental Environments, Parameters Fine-tuning and Performance measurements:

A. The Datasets

According to Table I and described in previous sections; each experiment was assigned training, validation and testing data segments. This is shown in Table II. These datasets feed each model to perform the corresponding Fine-Tuned. It should be mentioned that each dataset generated for the experiments has passed through a preprocessing stage explained in Section III.

TABLE II. PREPARED DATASET

	Training (80%)	Validation (10%)	Testing (10%)	Dataset	Method
Experiment 1	2,416	269	299	Comunicar	RM
Experiment 2	90,000 + 2,416	10,000 + 269	299	MESINESP + Comunicar	RM
Experiment 3	87,966 + 2,416	9774 + 269	299	arXiv + ICMLA + Comunicar	RM
Experiment 4	2416	269	299	Comunicar	KRM
Experiment 5	90,000 + 2,416	10,000 + 269	299	MESINESP + Comunicar	RM + KRM
Experiment 6	87,966 + 2,416	9774 + 269	299	arXiv + ICMLA + Comunicar	RM + KRM

According to Table II, 2 formal methods of generating negative examples have been applied as explained in Section III. Experiment 1 uses only the dataset of the journal "Comunicar". Experiments 2 and 3 depend on experiment 1, in that sense; experiment 2 first uses the dataset of MESINESP and, secondly, the data of the journal "Comunicar" is added (repeating exactly the same training and validation data). Experiment 3 follows the same flow of experiment 2, only that it uses its own dataset as detailed in Table II. Incoherent abstracts of experiments 1,2 and 3 were generated with the RM method.

Experiment 4 is similar to experiment 1 with the difference that its incoherent abstracts were generated by the KRM method. Experiments 5 and 6 depend on experiment 4. In that sense, experiment 5 is similar to experiment 2, with the difference that when performing the training, the techniques of RM and KRM are combined to create a varied dataset. The RM method was applied to the MESINESP dataset and the KRM to the "Comunicar" dataset. Experiment 6 follows the same flow as experiment 5 with the difference that uses its own dataset as detailed in Table II.

In summary, the incoherent abstracts of experiment 4 were generated with the KRM method, therefore, in experiments 5 and 6 they ended up using both KRM and RM methods. It should be remembered that the testing data was generated with the RM method. This set belongs only to the magazine "Comunicar", repeating in each of the experiments without exception.

B. Experimental Environments

Experiments 1 and 4 were executed in the Google Colab environment. This environment serves to create automatic machine learning models for free and with powerful hardware resources such as: Graphic Processing Unit (GPU) and Tension Processing Unit (TPU) [39]. On the other hand, experiments 2, 3, 5 and 6 were executed on a standard server. Resources used for experiments are described in Table III.

TABLE III. EXPERIMENTAL COMPONENTS AND ENVIRONMENTS

Components	Details	
Dataset prepared	Libraries: Pandas, Beautiful Soup 4	
Preprocessor	bert_multicased_preprocess of Tensorflow.	
Model	bert_multi_cased_L-12_H-768_A-12 of Tensorflow.	
Language Programming & Tools	Python 3.9.6, Jupyter Notebook, Colab Notebook.	
Libraries & Frameworks	Tensorflow, Keras, Numpy, Pandas, Scikit-learn, Matplotlib, Seaborn, Nltk.	
Server	Environment 1 (Experiments 1,4)	Environment 2 (Experiments 2,3,5,6)
	Google Colab Cloud, GPU Tesla K80 11 GB Memory.	Ubuntu 64-bit S.O., Intel(R) Xeon(R) Gold 5115, CPU @ 2.40GHz, GPU Quadro P5000 16 GB Memory.

C. Parameters Fine-Tuning

The parameters, hyper-parameters and other configurations of the 6 experiments are detailed in the following Table IV.

TABLE IV. PARAMETERS SETTINGS

Name	Parameters and Hiper-Parameters	Value
Experiments 1, 2, 3, 4, 5, 6	- Model	- bert_multi_cased
	- Platform	- Tensorflow
	- Activation Function	- ReLU and Sigmoid
	- Dropout rate	- 0.1
	- Class_weight	- Balanced
	- Callback Model CheckPoint	- Max val_accuracy
	- Optimizer	- Adam
	- Learning rate	- 1e-05
	- Loss Function	- Binary Cross Entropy
	- Epochs	- 5
	- BatchSize	- 64

D. Performance Measures

The basic components that have been used for the evaluation of the models developed during the six experiments are the following:

- True Positive (TP): When the model correctly predicts the positive class. This means it correctly predicts a coherent abstract.
- True Negative (TN): When the model correctly predicts the negative class. This means it correctly predicts an incoherent abstract.
- False Positive (FP): When the model incorrectly predicts the positive class. This means it predicts an incoherent abstract as coherent.
- False Negative (FN): When the model incorrectly predicts the negative class. This means it predicts a coherent abstract as incoherent.

The basic components of the 6 experiments are detailed in the Table V:

TABLE V. EVALUATION COMPONENTS

Models	True Positive (TP)	False Positive (FP)	True Negative (TN)	False Negative (FN)
Experiment 1	118	70	79	32
Experiment 2	124	60	89	26
Experiment 3	114	55	94	36
Experiment 4	111	62	87	39
Experiment 5	137	83	66	13
Experiment 6	127	78	71	23

The Accuracy, F1-score, precision and recall were the most frequently used metrics to report model performance on benchmark datasets. As metrics for binary classification problems, they can be derived from a confusion matrix, a two by two contingency table of the predicted and observed class labels [40]. Once the evaluation components have been defined, performance measurements were calculated using the following equations: 7 8 9 y 10:

$$Precision = \frac{TP}{TP + FP} \quad (7)$$

$$Recall = \frac{TP}{TP + FN} \quad (8)$$

$$F1Score = 2 * \frac{Precision * Recall}{Precision + Recall} \quad (9)$$

$$Accuracy = \frac{TP + TN}{TP + FP + TN + FN} \quad (10)$$

Applying performance measurements equations to the 6 generated models, the following results were obtained from the Table VI.

TABLE VI. MODELS PERFORMANCE MEASURES

Models	Accuracy	Precision	Recall	F1-Score	Loss
Experiment 1	0.65	0.63	0.79	0.70	0.66
Experiment 2	0.71	0.67	0.83	0.74	0.55
Experiment 3	0.70	0.67	0.76	0.71	0.59
Experiment 4	0.66	0.64	0.74	0.69	0.62
Experiment 5	0.68	0.62	0.91	0.74	0.61
Experiment 6	0.68	0.62	0.84	0.71	0.64

The experiment 2 model offers a better Accuracy (0.71) to detect inconsistent sentences in scientific abstracts. This shows that performing a Second Fine-Tuned mixing data from the same language, but different domain (MESINESP + Comunicar), improves the Accuracy to evaluate coherence.

Experiment 3 shows that performing a Second Fine-Tuned by mixing data from a different language (English) and different domain (arXiv + ICMLA + Comunicar) improves accuracy to detect inconsistent sentences (0.70). This aspect is important, as it is shown that you can increase training data from different languages without worrying about results to evaluate coherence. This is because a multilingual pre-trained model of BERT has been used.

In experiments 4, 5 and 6 it is shown that the KRM method works slightly better than the RM method with few data. The KRM method, at first, better classifies incoherent abstracts,

but if a large set of data is increased whose negative examples were generated with RM, it does not offer higher performance. This happens because the testing data were not created with the KRM method but with the RM method, which negatively impacts predictions.

The authors agree with the work of Bendeviski *et al.* [30] when he mentions that BERT offers better results for the evaluation of coherence than traditional machine learning methods, since the latter cannot understand the context of a text as does BERT, in addition to that BERT offers greater scalability and guarantees the Transfer learning process.

In these studies [4], [6] and [23] they have focused on generating incoherent examples varying the order of sentences (Sentence Ordering Task) unlike the present research that has focused on the detection of inconsistent sentences for the evaluation of coherence in scientific abstracts written in English/Spanish.

V. CONCLUSION AND FUTURE WORK

In this study, it has been shown that abstracts written in different languages/domains can be trained to detect inconsistent sentences of test data whose language and domain is also different from training data. Experiment 2 has proved to be better for the detection of inconsistent sentences of abstracts written in Spanish. Experiment 3 has proved to be more optimal for the evaluation of abstracts written in Spanish using combined training and validation data written in Spanish and English. Also, the variety of incoherent abstracts generated with RM and KRM during the Second Fine-Tuned has proven to deliver no better results than to train with a single method of generating incoherent abstracts when you want to detect inconsistent sentences for coherence evaluation.

Future research will renew the current clustering method (KRM) to a BERT Score-based method for the detection of inconsistent sentences. It will also address the evaluation of coherence as a multi-classification problem taking into account the types of incoherence: contradiction, redundancy and thematic discontinuity.

ACKNOWLEDGMENT

To the Universidad Nacional de San Agustín de Arequipa for the funding granted to the project "Transmedia, Gamification and Video games to promote scientific writing in Engineering students", under Contract No. IBA-IB-38-2020-UNSA. We would like to thank to the "Research Center, Transfer of Technologies and Software Development R+D+i" – CiTeSoft-EC-0003-2017-UNSA, for their collaboration in the use of their equipment and facilities, for the development of this research work.

Abstract—During last years, urban traffic has become one of the most studied research topics. This is mainly due to the enlargement of the cities and the growing number of vehicles traveling in this road network. One of the most sensitive problems is to verify if the intersections are congestion-free. Another related problem is the automatic reconfiguration of the network without building new roads to alleviate congestions. These problems require an accurate model to determine the steady state of the traffic. The present article proposes an adaptive traffic light system based on the BCMP network queuing and cellular automata. The aim of this work is to predict the best red and green time span by combining three important factors: The queue length, the evacuation time and the capacity of the destination roads. This approach can maximize the number of vehicles passing intersection and at the same time can minimize the average waiting time of vehicles as a result reducing the congestion and keep the fluency in intersections. To validate our results, we compared our model with a fixed model to explain the strengths of our proposed algorithm.

Keywords—Traffic light systems; cellular automaton; BCMP; queuing systems; traffic congestion; waiting time; adaptive systems

I. INTRODUCTION

Traffic congestion is nowadays regarded as one of the biggest problems related to mobility in every country, mainly in big cities. This phenomenon causes many problems for people like lost time, fuel consuming and huge waste of energy. The inability to reduce traffic and the imbalance between the infrastructure and traffic demand are the main causes of the congestion. Therefore, the need to build new roads, bridges and tunnels are required, but it's necessary to combine with new technology in order to balance between the traffic demand and the existing infrastructure.

Many researches have been done in recent year in order to propose new technology to manage urban traffic smartly. The researchers concluded that if the intersections are occupied by vehicles, then traffic congestion occurs. And to solve this problem traffic light control system has been proposed in order to control the vehicles in the city, town and village. The most used traffic control systems are static, i.e., the time periods are given in advance as static results by calculating the delay time of the traffic lights using current situation with the help of sensors and cameras. But, in reality, the density in an

intersection is dynamic due to the instability of the traffic conditions in different time like rush hours. Therefore, the fixed strategy cannot match the need of the actual traffic situation. Thus, the intelligent traffic light systems have become an essential need in order to regulate the traffic by adjusting the time span based on the number and speed of the vehicles existing at the intersection in real time. Those systems can maximize the number of vehicles passing the intersection and minimize the number of the blocked one as a result, can effectively minimize the average waiting time of vehicles.

The most famous and successful adaptive traffic light system in the world is SCOOT [1] in England and SCATS [2] in Australia. The main objective of SCOOT system is minimizing the sum of the average queues in the area [3] and SCATS tries to find the best phasing for current traffic situation using a fixed plan [4]. Furthermore, various methods have been applied in the optimization traffic light protocol such as Fuzzy logic control [5] and [6] that use the Fuzzy logic and image processing to vary the timing of the traffic lights controllers. In [7] authors presents different artificial neural network approaches for computer to predict the traffic network. And [8] the authors propose a new algorithm to manage traffic light at the intersection using Genetic Algorithm. Also, cellular automata models are the most of microscopic models have been developed in recent year due to the flexibility and simplicity of modeling. The Biham, Middleton and Levin [9] was the first CA model applied to the urban traffic light, it describes the different state of traffic and identifies the key factors affecting the phase transition [10]. A lot of extensions of this model have been developed wish means that the cellular automata is a good way to describe the urban traffic flow. For example in [11] authors used a cellular automaton to simulate road traffic in order to present a novel application of array DBMSs. Otherwise in [12] authors proposed a new cellular automata model under Kerner's framework that manage vehicles by considering the effect of forward-backward vehicles in the internet of vehicles. In addition, authors of [13] used cellular automata to generate a mixed traffic flow in order to analyze the behavior of manually driven and autonomous vehicles. Otherwise, to predict the traffic situation and model highway traffic researchers use queuing models in order to propose the best set of time based on the queue length of each road in the intersection as result optimizing the traffic flow and evaluating

the system performance [14]. Most of methods developed in the recent period mainly focused on unsignalized intersections [15]. In [16] authors propose a review about queuing models of unsignalized intersections and in [17] authors presented an approach for both signalized and unsignalized intersections. The author in [18] presents an algorithm that identifies levels of congestion in traffic problems. The author in [19] propose a model for an urban road network dedicated to traffic intersection. And [20] represented an urban road intersection with the BCMP queuing network. Authors programmed a simulator to emulate the vehicle behavior at the intersection and they present a comparison with the analytical model and the proposed approach.

Most of the systems mentioned above focused only to optimize the average waiting time of vehicles in queues and it don't take into consideration the evacuation time of the crossroad. This later is an important parameter because if vehicles stay more time in the crossroad automatically the average waiting time of vehicles will increase and congestion will occur. And to solve this problem we need to guarantee the balance between the number of vehicles passing the intersection and the capacity of the destination roads.

The aim of this paper is to present a new adaptive traffic light system in which traffic light time changes in real time based on the queue length and the capacity of roads. To implement this model, the traffic roads have been designed with cellular automaton in order to study the vehicle behavior between intersections. And use the BCMP queuing system to model our network and calculate the performance measure such as the arrival rate, the average queues length and density of roads. The main objectives of our system are maximizing the number of passing vehicles, minimize the average waiting time in the network and ensure that all vehicles can leave the intersection in the least possible time.

The remaining of this paper is organized as follows: Section 2 presents the necessary scientific background about the BCMP queuing systems and the cellular automaton models. Section 3 presents our proposed approach. In Section 4 we will discuss the experimental results and its analysis, then in Section 5 the conclusion will be drawn.

II. BACKGROUND

A. BCMP Queuing System

BCMP is a queuing system that consists of a set of queuing centers or stations. Each service center has a scheduling discipline. Each client in the network has a class wish may influence the routing probabilities and the service time at the stations. The classes are labeled by $1, \dots, R$ and it can be partitioned into chains. The client enters the network from the outside according to a Poisson process with a give probability, waits in the queue for the service and it gets the next available center or exits the network. The BCMP network contains M stations and R client classes. Each client has a class and for each class a routing probabilities must be specified in order to describe the classes behavior throughout the network. A class can be open which means that clients of this class enters from the outside and eventually leave the network. Or closed which describes client that can never leave the network. Note that in this work only the open class has been studied. There are

TABLE I. EXAMPLE OF ROUTING PROBABILITIES

sectors	I_1	S_1	O_1
0	R_{0,I_1}	R_{0,S_1}	R_{0,O_1}
I_1	0	R_{I_1,S_1}	R_{I_1,O_1}
S_1	R_{S_1,I_1}	0	R_{S_1,O_1}
O_1	0	0	0

three sorts of service sectors in an open network. Input sector I_i used by clients to enter the network, output sector (O_i) used by clients to exit the network, and internal sector S_i used to move inside the network. Therefore, the routing probability is a float number R_{S_i,S_j} which describe the probability that a client can move from sector S_i to S_j . Table I presents an example of a routing probabilities values for a network composed by one input sector, one internal sector and one output sector. Note that the sector 0 describes the outsides of the networks. In BCMP network, queuing stations can be classified as one of the following:

- Type 1: The queuing discipline is first in first out (FIFO) and distribution of service time is exponential and class independent.
- Type 2: The queuing discipline is processor sharing.
- Type 3: All the stations have infinite servers (IS) wish means clients never wait in queue.
- Type 4: The service discipline is last in first out (LIFO) with preemptive resume.

And the following variables are used to describe the open BCMP network parameters:

- R: The number of traffic classes in the network,
- K_{ir} : The number of vehicles of the r^{th} class at the i^{th} sector.
- μ_{ir} : The service rate of the i^{th} sector of the r^{th} class.
- $R_{0,js}$: The probability in an open network that a vehicle from outside the network enters to the j^{th} sector of the s^{th} class.
- $R_{ir,0}$: The probability in an open network that a vehicle of the r^{th} class leaves the network after having been served at the i^{th} station.
- $\lambda_{0,ir}$: The arrival rate from outside to the i^{th} sector of the r^{th} class.
- λ_{ir} : The arrival rate of vehicle of the r^{th} class at the i^{th} sector.

The performance measures are described as following [20].

- ρ_{ir} : The utilization of the i^{th} sector by r^{th} class clients.

$$\rho_{ir} = \lambda_r * \frac{e_{ir}}{\mu_{ir}} \quad (1)$$

- k_{ir} : The average number of clients of r^{th} class at the i^{th} sector.

$$k_{ir} = \frac{\rho_{ir}}{1 - \rho_i} \quad (2)$$

- T_{ir} : The average response time of r^{th} class clients at the i^{th} sector.

$$T_{ir} = \frac{k_{ir}}{\lambda_{ir}} \quad (3)$$

- W_{ir} : The average waiting time of r^{th} class client at the i^{th} sector.

$$W_{ir} = T_{ir} - \frac{1}{\mu_{ir}} \quad (4)$$

- Q_{ir} : The average queue length of class r clients at the i^{th} sector.

$$Q_{ir} = \lambda_{ir} * W_{ir} \quad (5)$$

Note that i and j indicating sector numbers, while r indicates traffic class

Most researchers have applied the BCMP network system to solve problems related to urban traffic. In [21] authors present a queuing theoretic framework based on BCMP for modeling autonomous mobility on demand systems within capacitated road networks. The author in [22] approved using an open BCMP queuing network the uniqueness of solution to obtain an optimal static routing. In [23] authors proposed a simulation of parking using a network of service center capacity queues. in

B. Cellular Automaton

Cellular automata were originally proposed by John Von Neumann [24]. It consists of a grid of cells. These cells are all equal in size and the lattice can be finite or infinite in number of cells. Also, its dimension can be 1 wish called a linear string of cells, 2 wishes describe a grid of cells or even higher dimension. Every cellular automaton should have three elements:

- Cell's States: It's an integer represents the state of each cell.
- Cell's neighborhoods: To determine the evolution of the cell it should define neighborhoods for each cell. In the simplest case, for example, in a two-dimensional CA the four west, east, south and north adjacent cells are neighborhoods and their state can affect the state of cell in future steps.
- Transition function: It describes the rule followed so that the CA model evolves in time. This rule developed based on the neighborhoods state and model characteristic.

In recent years, most of the microscopic models developed by using the language of cellular automata (CA) [25]. Cremer and Ludwig [26] are the first whose proposed the first model of cellular automaton applied to the road traffic in 1986 and the Biham, Middleton and Levine model [9] is the first classical model applied to the urban traffic. This later describes the principal factors affecting phase transitions and identifies the different states of urban traffic flow [27]. A lot of researchers have proposed many extensions of the BML model. Fukui in 1996 [28] considered the average velocity in the BML and introduced the individual high-speed of vehicles by using the running speed of the traffic flow. Nagatani in 1995 [29] focused to reduce the numbers of gridlocks in the BML and improve

the running status of the traffic by using the cloverleaf junction. Cuesta (1993) [30] and Nagatani (1995) [29] were the first to propose switch rules in the BML model. Ding et al., 2011 [31] have explored the mean field theory in the BML model and the authors of [32] were the first to propose a modified BML to predict the urban traffic jams in real time.

III. PROPOSAL APPROACH

In this work, the adopted network contains four connected intersections managed by a set of traffic lights poles. An intersection formed by two intersecting perpendicular streets; each street contains bidirectional traffic roads. For the sake of simplicity, the vehicles in this paper can't change their direction which means that if a vehicle enters the network from the north side automatically will leaves the network from the south side. For more details, see Fig. 1.

The traffic lights in a given axis have the green light simultaneously, but they switch to the red at different times because our algorithm calculates time of the red or green color individually for each direction and to simplify more our model it supposed that there was no yellow light. In order to describe our network, the following parameters will be used in this paper:

- P_i : Priority of the green light that equal 1 if in the road i has higher priority to leave the intersection.
- GT : Green light time.
- RT : Red light time.
- ET : Evacuation time of the intersection.
- RC : Maximal capacity of the road.
- FS : Free space in front of each road near the intersection.
- N : The number of vehicles existing in the road.
- S : Light state Boolean that equal 1 if the light is green and 0 otherwise.

A. Proposed Cellular Automaton

In order to describe the representation of the traffic between the intersections a one-dimensional cellular automaton has been implemented. This later represent the road as a line of cells, each car occupied only one cell and each cell can host only one vehicle. All cars move in the same direction and we supposed in this work that lane changing is not allowed. Their positions are updated synchronously, in successive iterations (discrete time steps). Note that the required time for a vehicle to move from cell to another is one second. The motion rules of our model are simply that a car moves if its destination cell is empty and all the vehicles behind can move by one cell. Figure 2 shows an illustration of our transition rules.

In this work the space between all intersections is equal which mean that the cell number N in each road in our network is fixed.

The road density is calculated by the following equation:

$$\rho = \frac{\sum_{i=0}^N C_i}{N} \quad (6)$$

Fig. 1. Adopted Network.

Fig. 2. Transition Rules.

Where C_i present a Boolean variable that equal 1 if the cell is occupied and 0 otherwise.

$$C_i = \begin{cases} 1 & \text{if occupied} \\ 0 & \text{else} \end{cases} \quad (7)$$

B. Proposed BCMP System

In this work the proposed open BCMP queuing network model composed with 8 inputs sectors (I_i), 8 outputs servers (O_i) and every queue in each intersection has internal sectors which means the proposed network have 16 internal sections ($S_{(i,j)}$). The arrival rates in this network following poisson distribution with parameter λ and the service rate following exponential distribution with parameter μ . The queues are type $M/M/1$ and the service policy is with first-come-first-served (FCFS).

The vehicle classes in this paper are defined as the flow of cars coming from the same input sector consequently 8 flow classes are identified and each class entering the network with parameter λ_i .

For example, class 1 is defined by the vehicles entering network through input I_1 with parameter λ_1 and leaving it

TABLE II. ROUTING PROBABILITIES OF THE VEHICLE CLASS 1

sectors	I_1	$S_{(1,1)}$	$S_{(4,1)}$	O_6
0	1	0	0	0
I_1	0	1	0	0
$S_{(1,1)}$	0	0	1	0
$S_{(4,1)}$	0	0	0	1
O_6	0	0	0	0

on sector O_6 . The internal sectors of this class are $S_{(1,1)}$ and $S_{(4,1)}$. See Fig. 3 for more details.

Our BCMP model have 8 traffic classes, for each class, a routing probabilities must be specified based on the previous rules. Vehicles are moved between any two stations according to given routing probabilities. For example (see table II) a class 1 traffic vehicle goes from the input to sector $S_{(1,1)}$ with probability $R_{I_1, S_{(1,1)}} = 1$ then it either move to sector $S_{(4,1)}$ with the probability $R_{S_{(1,1)}, S_{(4,1)}} = 1$ and it leaves the intersection from sector O_6 with probability $R_{S_{(4,1)}, O_6}$.

C. Proposed Algorithm

In this section the details of the adaptive control algorithm will be presented. The algorithm calculate the red/green time for each traffic signal using the following steps presented in algorithm 1.

The main objective of our model is to adapt the traffic signal duration with the intersection situation in order to minimize the average waiting of the vehicles in the network. The selection of the green time duration is based on the queue lane and the free space existing in front of the road (FS).

Fig. 3. Our BCMP Network.

Algorithm 1 Proposal Algorithm

- 1: **Procedure**
- 2: **FOR** $t=1 : T$ **do**
- 3: Take decision which axis has priority to have green time
- 4: calculate the green time using equation 10
- 5: generate the phase duration for all direction based on the decided green time
- 6: execute the phase
- 7: **END FOR**
- 8: **End procedure**

The selection process is performed every cycle and work as below: First from the intersection structure the axis that has priority to have the green time is known, and based on the waiting lane and free space, the algorithm calculates the green time for each direction with the equation below:

$$GT_{i,j} = \min(FS_{i,j}, Q_{i,j}) \quad (8)$$

and

$$FS_{i,j} = N - \sum_{k=0}^N C_{ik} \quad (9)$$

Where i describes the intersection number and j the direction. Note that in every intersection $j = 1$ and $j = 4$ define the horizontal axis and $j = 2$ and $j = 3$ define the vertical one. After the program calculate the green time for each direction, then, calculate the cycle duration by adding the evacuation time of the intersection (ET_i) to the max of the two green times selected. For example, if the horizontal

TABLE III. ARRIVAL RATE VALUE

λ values	Traffic state
0.2	free flow state
0.4	medium flow state
0.9	congested flow state

axis has the priority, the cycle duration is equal to the follow equation:

$$H_i = \max(GT_{i,1}, GT_{i,4}) + ET \quad (10)$$

IV. NUMERICAL SIMULATION

There are two simulated approaches, our model and the fixed model where the green and red time values are fixed. This simulation will lead to explain the differences between these two models and show the performance of the proposed adaptive system.

In this section the arrival and service rates parameters are presented.

A. Arrival Rates

This parameter defines the number of vehicles that arrive at a sector per time unit. As mentioned, we have 8 inputs which mean we have 8 arrival rate $[\lambda_1, \dots, \lambda_8]$.

In Table III we present the different arrival rate with the situation that they occurred.

B. Service Rates

This rate defines the number of vehicles crossing a sector per second, it supposed that all the sectors in our network have

Fig. 4. Comparison of Density for Free Flow State.

Fig. 6. Comparison of Density Congested Flow State Scenario.

Fig. 5. Comparison of Density for Medium Flow State.

the same rate value $\mu = 1$. Note that in this paper, it supposed that the number of cells between the intersections is equal to 40 and the evacuation time is equal to 3 seconds.

V. RESULTS AND DISCUSSION

To study the performance of our proposed model, we need to observe the behavior of the network density during 1 hour with different arrival rate values. For free flow state, the density was on average of 0.12 using our proposed model and 0.16 with the fixed model. See Fig. 4.

For medium flow state, the density was on average of 0.18 using our proposed model and 0.27 the fixed model. See Fig. 5.

For the congested flow state, the density was on average of 0.4 using our proposed model and 0.5 with the fixed model. See figure 6.

The average values show which model guarantee more

fluent traffic and that impact directly the number of vehicles released from the network. From these figures, it can be observed that our proposed model allows vehicles to leave the network earlier than the fixed model Whereas after 1 hour our proposed model release 20% of vehicles with free flow state, 37% of vehicles with the medium flow state and 14% of vehicles with the congested flow state, more than the fixed model.

Fig. 7 presents a special simulation because in this scenario the arrival rate $\lambda = 1$ which mean every second one vehicle enter from every input of the network. and it can be clearly seen that after 500 sec the fixed system was blocked. This phenomenon in reality needs a police agent to regulate the traffic, which explain the importance of the free space parameter in the prediction of the cycle duration. And in order to show the difference between our model and the others model that based only on the queue length, we add a comparison between our model and the same configuration, but without the free space parameter and it's clearly presented in Fig. 7 that our model keeps the fluency of the traffic and reduce the probability to have jammed state.

These results demonstrate that our model is more efficient than the fixed strategy in term of the density. This is because our algorithm makes the decision to turn the green light on when there are vehicles staying in the intersection and turn off when the queue is empty. Otherwise the fixed algorithm turns the green light based on a static strategy whatever the queue length. Also in term of the traffic fluency, the average throughput under free, medium and congested traffic situation is shown in Fig. 8. This later presents that our model keeps the traffic smoothly by minimizing the difference between the arrival throughput and the output flow in different traffic states. Note that when this difference is minimized means that the arrival vehicles can easily enter the network and leave it with a minimal traveling time as shown in the next paragraphs.

In the next figures the difference between our algorithm and the fixed algorithm in term of the average queue length is presented. The average queue length of the first intersection was extracted in order to study the effect of our proposed

Fig. 7. Comparison of Density for Jammed Flow State.

Fig. 8. Comparison of the Average Throughput.

Fig. 10. Results of the Average Queue Length for Congested Flow State.

algorithm on different arrival rate.

In Fig. 9, the average queue length still between 0 and 1 with our proposal with an arrival rate $\lambda = 0.4$ otherwise with the fixed algorithm the average is between 1 and 4.5 which explain an important difference. Also, in congested flow state our model shows an important performance because the maximum of the average queue length was 1.5 where with the fixed strategy was 7.5. See Fig. 10. This can be explained by the fact that, when the queue length is considered to predict the green time, the average queue length decreases automatically.

From this, it can be seen that our algorithm guarantees to the vehicles in the intersection a low waiting time compared to the fixed algorithm. And in order to show more the performance of our system the average velocity in the network was studied in order to analyze the behaviors of the vehicles over time. Fig. 11 confirms that our model maximizes the average velocity in the network. But the most important fact deduced from this figure is that with the fixed algorithm the traffic

block earlier than with our model wish confirm the effect of minimizing the queue length in the intersections.

Fig. 12 presents the average waiting time in our network. The waiting time is defined as the time required for a vehicle to leave the network. In this simulation, it supposed that the arrival rates are equal in order to study the behavior of our model in different status. The results shows that the vehicles wait less with the proposed method under all traffic conditions. In the free traffic, the average waiting time values are 102 s and 180 s with proposed model and fixed model, respectively. Thus, with the medium and congested traffic, the vehicles wait less than 122 s and 187 s, respectively with our control method where with the fixed model wait 185 s and 268 s, respectively. And note that our model ensures the improvements 43%, 34%, and 31% in average waiting time values under free, medium and congested traffic, respectively.

Hence, our proposed model reduces the density, the average

Fig. 11. Results of the Average Velocity.

Fig. 12. Comparison of the Average Waiting Time.

queue length and the average and so it can maximize the average velocity of vehicles at the intersections.

After that and to improve more our model we consider in the next results that the arrival rate from the network inputs are not equal. We supposed that we have 4 type of arrival rates λ_{south} for the vehicles coming from the south of the network, λ_{north} for the vehicles coming from the north, λ_{east} for the vehicles coming from the east and λ_{west} for the vehicles coming from the west. And we implemented 4 scenarios. Firstly, the λ_{south} and λ_{north} are equal to 0.4 which implies that we have horizontally a medium flow and vertically we have a congested flow i.e. $\lambda_{west} = \lambda_{east} = 0.9$. This scenario aims to compare the difference between our model and the fixed model in term of the average queue length for every direction.

Note that, the following parameters are defined:

- AV : Average.

- NV : Number of Vehicles.
- $AVNQL$: Average Queue Length for North Vehicles.
- $AVSQL$: Average Queue Length for South Vehicles.
- $AVEQL$: Average Queue Length for East Vehicles.
- $AVWQL$: Average Queue Length for West Vehicles.

The Table IV shows a big difference between the two models, because our model turns off the green light when all the waiting vehicles in the south and north are served meaning that it give the priority to the others vehicle to be served earlier, while with the fixed model, the vehicles have to wait even if the other directions are empty. Which signifies the difference in term of the average velocity because with our model we can maximize the average velocity with 29% than the fixed model. The others scenarios supposed that vehicles come with a random arrival rate. As shown in the table, we notice that our model is better than the fixed model even if the situation. For example, in the fourth scenario our model maximizes the average velocity by 37% than the other model. Although sometimes there is not a big difference between the two models, for example, in the second scenario the difference between the average south queue length with our model and the fixed model is just 0.2. But our algorithm keeps the most interesting ones. And the reason theoretical of these results is due to the proposed new algorithm which is already explained above.

VI. DISCUSSION AND LIMITATION

Test results shows that the installed algorithm at the intersection ensures traffic flow in conditions of unsaturated flows. In addition, this demonstrates that our method can be successfully used for the construction of adaptive traffic control in conditions where traffic is related to time-varying traffic flows. In our optimization method, the traffic demands are well estimated based on the information from the adjacent intersections, which brings a good coordination among the intersections. It is worth to mention that our optimization method has a chance to obtain a better control scheme and to achieve an optimal solution for the network. However, the selection of the time based on the free space existing in the network affects the performance since using only the average queue length parameter might introduce longer unnecessary traffic delay to intersections just because the vehicles have not enough space in their destinations. Thus, in theoretical analyses, adapting the green time span using the combination between the queue length and the free space may reduce the delay time and keep the traffic fluency.

VII. CONCLUSION

In this paper, an intelligent system based on cellular automaton and BCMP queuing system has been proposed. The main advantage of this model is to avoid congestion at intersections due to the applied algorithm that calculate in every cycle time the free space on the roads and the waiting line in order to give the appropriate green time for every intersection taking into account the priority and intersection evacuation time. The results prove that our approach keeps the traffic fluency at the intersections and reduce the probability to attempt jammed situation than fixed method. Using BCMP

TABLE IV. THE OBTAINED RESULTS FOR DIFFERENT SCENARIOS

Scenario	Approach	λ_{north}	λ_{south}	λ_{east}	λ_{west}	AV Velocity	AV NV	AVNQL	AVSQL	AVEQL	AVWQL
Scenario 1	Proposed	0.4	0.4	0.9	0.9	0.97	106.76	1.79	0.65	2.95	2.85

performance measures helps us to manage the queues in our network, which guarantee an optimal average waiting time for vehicles.

Note that this approach can not only applied in transportation domain it can also apply in different situation like bank service, hospital out-patient service, etc.

In the future works, we will integrate other technologies like machine learning and multi-agent system to develop more our approach and guarantee a good vehicle experience in cities.

Ateneo de Manila University
Quezon City, Philippines

Abstract—Anomaly detection is a widely studied field in computer science with applications ranging from intrusion detection, fraud detection, medical diagnosis and quality assurance in manufacturing. The underlying premise is that an anomaly is an observation that does not conform to what is considered to be normal. This study addresses two major problems in the field. First, anomalies are defined in a local context, that is, being able to give quantitative measures as to how anomalies are categorized within its own problem domain and cannot be generalized to other domains. Commonly, anomalies are measured according to statistical probabilities relative to the entire dataset with several assumptions such as type of distribution and volume. Second, the performance of a model is dependent on the problem itself. As a machine learning problem, each model has to have parameters optimized to achieve acceptable performance specifically thresholds that are either defined by domain experts or manually adjusted. This study attempts to address these problems by providing a contextual approach to measuring anomaly detection datasets themselves through a quantitative approach called *categorical measures* that provides constraints to the problem of anomaly detection and proposes a robust model based on autoencoder neural networks whose parameters are dynamically adjusted in order to avoid parameter tweaking on the inferencing stage. Empirically, the study has conducted a relatively exhaustive experiment against existing and state of the art anomaly detection models in a semi-supervised learning approach where the assumption is that only normal data is available to provide insight as to how well the model performs under certain quantifiable anomaly detection scenarios.

Keywords—Neural networks; autoencoders; machine learning; anomaly detection; semi-supervised learning

I. INTRODUCTION

Anomaly detection is a widely studied field in computer science dating back to 1887 (Edgeworth) with applications ranging from intrusion detection, fraud detection, medical diagnosis, quality assurance and manufacturing. Anomalies / outliers / novelties are observations that exhibit characteristics that are not part of the usual pattern or expected behavior of what are considered as normal observations. These often result from an erroneous recording of information or fault in producing the information or in some cases, an intended act of disruption as with the case of intrusion in a computerized network system. The definition of what is normal however and consequently what constitutes to an anomaly, is largely dependent on the context of the domain being observed or practiced. For example, medical diagnosis might yield a relatively larger magnitude of deviation to consider something to be malignant

rather than benign compared to quality assurance in manufacturing where a relatively smaller magnitude of deviation is observed to consider something to be acceptable or not. In this case, it is a simplistic definition of a large bias occurring or an extremely uneven ratio that defines anomalies. Often, this magnitude of deviation is defined by a domain expert in order to determine the impact of identifying anomalies. Otherwise, the measurement of deviation to define normal from anomalies is empirically defined through numerous experimentation to determine an acceptable value for discrimination which is also influenced by either policy or industry standards. From this, we can say that the study of outlier detection and its applications are generalized as a binary classification problem where observations are categorized as either normal or anomalous and that it is contextualized within the domain at hand. Its value in an operational or business perspective is that the identification of anomalies would always result in actionable items to either fix a system or process to improve the overall output of the application [1]. Mathematically, anomaly detection can be expressed in general using the following equation:

$$f(x) > t \quad (1)$$

where t is some threshold value, x is some unknown data point and $f(x)$ gives a score for the data point. If the score falls above (or below depending on context) of the threshold t then x is considered to be an outlier. The value of t is defined *a priori* usually by a domain expert or through experimentation.

II. RELATED WORKS

A. Anomaly Detection

The study of anomaly detection can be generalized as a binary classification problem with labels *normal* and *outliers*. As a classification problem, observations whether labelled normal or anomalous are characterized with a fixed set of attributes. Anomalies are observations whose attributes deviate from normal data based on some acceptable magnitude. In general, anomalies comprise of an extreme minority of the overall data having very low occurrences. Other terms for anomalies are *outliers*, *novelties* or *abnormalities*. Regardless of normal or anomalous data, these observations can either be univariate or multivariate in nature.

B. Types of Anomalies

Depending on the problem at hand, an anomaly can be described in either of three major categories – point, contextual or collective anomalies.

1) *Point Anomalies*: Point anomalies are the simplest type of anomalies that are described as a single data point in n-dimensional space (regardless of it being univariate or multivariate data). Each data point weather anomalous or normal exist based on the values of its attributes. Point anomalies are also the easiest to visualize as they are simply points in the search space of the problem. For example, Fig. 1 illustrates data as point anomalies in the waveform dataset:

Fig. 1. Point Anomalies Example (TSNE Waveform)

Red points are considered anomalies if they deviate from majority of the normal data points (blue). Normal point data often cluster together as they exist more and exhibit similar measurements compared to anomalous observations. Thus this cluster of normal observations tend to form a cluster boundary. Points that lie beyond the boundary are considered to be outliers.

2) *Contextual Anomalies*: Also known as conditional anomalies, contextual anomalies are that which are bound to a specific context. A simple example of this would be the context of time. An outlier can be defined based on its measurement occurring at a specific point in time. When formulating an anomaly detection problem, it is integral to first define if the data can be simply described by its attributes (thus it is can be categorized as point anomalies) or if it can be contextualized by some dependent variable making it a contextual anomaly.

3) *Collective Anomalies*: Collective anomalies are defined to be a grouping of related data instances in relation to the entire data set. Individual observations may not be considered anomalies but if grouped together to form a higher level of observation, then we say that it is a collective anomaly. Defining collective anomalies are approached differently depending on the problem at hand. For example, in intrusion detection, a single observed usage of a protocol in a network may not be considered anomalous but if done in a certain sequence (a collection of protocol usage), such as network packets that use http, then ssh, then ftp protocols can be considered an attack vector (anomalies in this sense are defined as intrusions or attacks in the network).

C. Measuring Anomalies

As of this writing, there is no concrete definition of anomalies or anomaly detection datasets that distinguishes itself from any other binary classification problem. Furthermore, defining what anomalies are in a dataset are subject to the concrete problem at hand. Emott et. al however has proposed a set of measures to define how anomalies are measured in a local context. In their paper *Systematic Construction of Anomaly Detection Benchmarks from Real Data*, their study proposed four quantitative measures for defining anomalies relative to nominal data [2]. Of the four, three were implemented. Given a "parent" or "mother" dataset, it is possible to derive anomaly detection subsets based on difficulty constrained with a K parameter relating to the intended ratio of anomalies against a dataset. The three implemented measures for a given outlier data point are as follows. The fourth measure, *Feature Relevance* wasn't included in the paper and was open for interpretation and implementation. A portion of this study contributes to the implementation of this measure and the reasoning for the chosen approach. In depth discussion on the computation for the implemented scores are discussed in the methodology section.

D. Methods in Anomaly Detection

Defining a solution or training a model for anomaly detection can be categorized as either parametric or non-parametric. Regardless of approach, each category has its own share of advantages and disadvantages. Both categories are considered to be statistical approaches in anomaly detection.

1) *Parametric Models*: Anomaly detection models are considered to be parametric models if the problem assumes that the data being observed or generated follow a specific distribution. There are two key components for parametric model approaches. First would be the parameters θ for the assumed distribution. Second would be the probability density function $f(x, \theta)$, where x is an observation. The goal of parametric models is to derive or estimate the values of the parameters from the data itself where the parameters are largely dependent on the type of distribution assumed. The probability density function then outputs a score depicting how fit some observation x is given the estimated parameters of the distribution.

An example of a parametric model would be Gaussian based models. In this example, the structure of the data assumes to be gaussian in nature (exhibiting the normal distribution) that is, a symmetrical distribution where the mean is central and that data nearer to the mean occurs more frequently than data farther away from the mean exhibiting a bell shaped curve.

The parameters θ of the gaussian distribution are $\{\mu, \sigma^2\}$ which can be derived from training data x using equations 3, 4, 5 and 6. Given some unknown observation, we can check its probability score by fitting its attributes to the distribution's probability density function. The anomaly detection model can now be expressed using equation 2 wherein the unknown data \hat{x} is considered anomalous if its probability value falls below some defined threshold t .

$$f(\hat{x}|\theta) < t \quad (2)$$

$$\forall x \in \{1 \dots I\} x_{\mu_i} = \mu_i = \frac{\sum_{n=1}^N x_i}{N} \quad (3)$$

$$\forall x \in \{1 \dots I\} x_{\sigma_i} = \sigma_i^2 = \frac{\sum_{n=1}^N (x_i - x_{\mu_i})^2}{N} \quad (4)$$

$$f(\hat{x}_i | \mu_i, \sigma_i^2) = \frac{1}{\sqrt{2\pi\sigma_i^2}} \exp\left(-\frac{(\hat{x}_i - \mu_i)^2}{2\sigma_i^2}\right) \quad (5)$$

$$f(\hat{x}, \mu, \sigma^2) = \forall \hat{x} \in \{1 \dots I\} \prod_{i=1}^I f(\hat{x}_i | \mu_i, \sigma_i^2) \quad (6)$$

As opposed to parametric models, non-parametric models allow the data to determine the underlying structure and boundaries for classification. No distribution is defined *a priori* unlike parametric models where it is largely based on an assumed distribution and its respective parameters.

2) *Classical Outlier Detection Models*: The following models are known to be used for outlier detection in literature and have served as standard benchmarks for newer models:

- Isolation Forest [3]
- Local Outlier Factor [4]
- Robust Covariance [5]

These models will be considered as part of performance measures against this study's proposed model.

3) *One-Class Support Vector Machines*: The One-Class SVM classification method is an extension of the original support vector machine classification algorithm as developed by Vapnik [6]. This approach however does not require data to be labeled as the algorithm returns a function that samples a small region from the probability distribution of the data that serves as the probability density of the training data. Because of this, One-Class SVM is categorized under the parametric class of anomaly detection algorithms. The function returns +1 for data points within the subregion and -1 elsewhere. The minimization function of One-Class SVM is slightly different from the original function and is characterized by equation 7.

$$\min_{w, \xi_i, \rho} \frac{1}{2} \|w\|^2 + \frac{1}{Cn} \sum_{i=1}^n \xi_i - \rho \quad (7)$$

subject to:

$$(w \cdot \phi(x_i)) \geq \rho - \xi_i \text{ for all } i = 1, \dots, n$$

$$\xi_i \geq 0 \text{ for all } i = 1, \dots, n$$

where ϕ is the kernel function to project data to a higher dimensional space, ξ_i are slack variables and C , as opposed to the original, decides the smoothness giving it a solution that a) sets an upper bound on the fraction of outliers and b) sets a lower bound on the number of training examples considered as support vectors. The solution creates a hyperplane characterized by w and ρ which has the maximum distance from the point of origin of the feature space and separates the data

points from the origin. As such, this can be categorized as an unsupervised learning algorithm since it takes into account all data points regardless of label. The mathematical equations for this algorithm are explained more in detail in [7].

4) *Autoencoders for Anomaly Detection*: Autoencoders are neural network models whose output is the same as its input. It approximates how to reconstruct the input by first compressing the data into lower dimensional space to represent a more generalized version of the input in what is called the encoding process. The lower dimensional representation of data, otherwise known as the latent layer as seen in Fig. 2, is then forwarded to the output layer which has the same dimensionality as the input in what is called the decoding process. thus this neural network looks for correlations of features in a data set while taking advantage of non-linear properties of neural networks.

Fig. 2. Autoencoder Neural Network

Mathematically, the approximation of some input data x by the autoencoder model can be expressed in equation 8.

$$f(x) \approx x \quad (8)$$

During training, the error score of some input is the distance between the original input and resulting output. This is otherwise referred to as the reconstruction error. The distance or loss function commonly used is the mean of squared errors as computed in equations 9 and 10.

$$\text{MSE}(x, y) = \text{MSE}(x, f(x)) \quad (9)$$

$$\text{MSE} = \frac{1}{n} \sum_{i=1}^n (x_i - y_i)^2 \quad (10)$$

The MSE value expresses the difficulty in reconstruction where the data fed to the network does not conform to what the model has learned from normal data. Thus if the value exceeds some threshold t , it can be concluded to be an outlier. This can be expressed in equation 11.

$$\text{MSE}(x, f(x)) > t \quad (11)$$

Applications of autoencoders in anomaly detection has been used extensively in the field of performance assessment in computing systems such as [8]. It has also been applied to numerous outlier benchmarking datasets where outlier ratio for validation falls below 30%. This can be seen in [9] wherein Yoshiao et. al proposed a method for estimating reconstruction capabilities of the autoencoder by disregarding high reconstruction errors produced by the model during mini-batch training resulting in partially selecting sets of training results to update the model during back propagation. This however only attempts to address the efficiency of training the autoencoder models while still maintaining a high enough accuracy as compared to standard autoencoders, autoencoder ensembles as well as One-Class SVM.

5) *One-Class Neural Networks*: The One-Class Neural Network as popularized by Chalapathy et. al., is typical feed forward neural network with a single node as its output [10]. However, this method's novelty can be described in its objective function which takes inspiration from One-Class SVM as well as its utilization of autoencoders. The objective function can be described in equation 12.

$$\min_{w, V, r} \frac{1}{2} \|w\|_2^2 + \frac{1}{2} \|V\|_F^2 + \frac{1}{v} \cdot \frac{1}{N} \sum_{n=1}^N \max(0, r - (w, g(VX_n))) - r \quad (12)$$

The key insight of the objective function is to replace the dot product from One-Class SVM's $(w, \phi(X_n))$ with the dot product $(w, g(VX_n))$ where V is the weight matrix from input to hidden layer that is optimized using an autoencoder. The change here allows transfer learning from an autoencoder model to be able to learn how the data points are reconstructed before applying it to a feed forward neural network. The values derived from the autencoder w and V are then used to optimize r which is theoretically the v -quantile of the array $(w, g(Vx_n))$. After getting the value of r , a score can be derived using equation 13:

$$S_n = \hat{y}_n - r \quad (13)$$

where \hat{y}_n is the output of the feed forward network for data point n . If S_n is greater than or equal to 0 then x_n is considered normal. Else, the point is said to be anomalous.

E. Well Known Autoencoder based Anomaly Detection Models

1) *Unsupervised Novelty Detection using Deep Autoencoders with Density based Clustering*: Deep autoencoders with density based clustering (DADBC) is a system developed by Amarbayasgalan et. al. to solve the anomaly detection problem in a fully unsupervised fashion. The main steps of the method is a) dimensionality reduction and b) novelty identification through clustering [11]. An illustration of the system can be seen in Fig. 3.

F. Problems in Anomaly Detection

In this research, we try to address key problems in anomaly detection. These have been identified both in literature as well as observations in the nature of existing solutions weather it

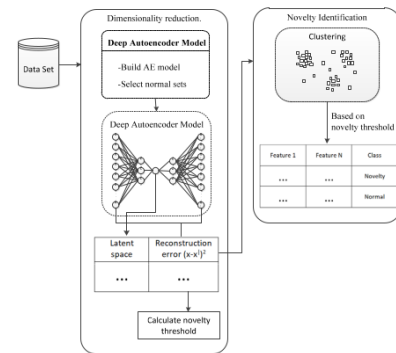

Fig. 3. Deep Autoencoders with Density based Clustering

be parametric or non-parametric. The fundamental problems are identified as follows:

- 1) If the model for anomaly detection contains parametric properties, there is heavy reliance on the assumed statistical distribution the data takes up.
- 2) Anomaly detection applications are largely contextual. In a non-parametric statistical setup, configuration of bins and clusters to profile data points have to be defined by a domain expert or empirically validated through experimentation. A wide variety of anomaly detection models require the definition of some threshold parameter to indicate the magnitude of variety between normal and anomalous data. This threshold is often defined by the practitioner or expert.
- 3) Anomaly detection datasets have a significantly low volume of data that are considered to be anomalous. In the preliminary results of this study, available standard anomaly detection datasets range from as little as 0.4% to at most 30% of data as anomalies making supervised learning techniques not viable. As such, this research only considers semi-supervised and unsupervised models for anomaly detection.

III. METHODOLOGY

This study's methodology is divided into two main parts. The first part contains the processes involved in defining quantitative measures of anomaly detection datasets which is largely based on Emott et. al's work on systematic construction of anomaly benchmarks. The main differences are the implementation of the feature relevance metric, removal of the constraint on selecting a user defined K relative frequency value and providing a global semantic variation score considering multidimensional nature of the data points. This modified approach in providing quantifiable features for anomaly detection datasets benchmarks is referred to as *categorical measures*. The second part of the methodology involves the construction of a neural network autoencoder based approach in solving the problem of anomaly detection. The novelties of the model lie in its non-parametric approach in defining a threshold value during inferring allowing it to adapt to the patterns exhibited by the data set itself and improving its performance with a stochastic component and a new loss function that prevents it from overfitting.

A. Categorical Measures

Given a data set, Emott et. al defined a set concrete measurable attributes to its outliers. An anomalous point can be measured according to its *a) point difficulty*, *b) semantic variation* and *c) feature relevance*. Although originally the study for these measures was intended to generate anomalies, our study modifies it in order to give quantitative features to an anomaly detection dataset D which can be simply expressed by equation 14:

$$D = \{f_1, f_2\} \quad (14)$$

f_1 corresponds to the ratio of anomalies present in the dataset relative to normal points whereas f_2 corresponds to the dataset's *semantic variation* score. Both these values are constrained to the following:

- 1) $f_1 \leq 0.05$ (5% contamination at most)
- 2) $f_2 \leq 1.5$ (score should be at most 1.5)

1) *Contamination Ratio (f_1):* The contamination ratio is allows a dataset to have the same characterization of anomaly detection situation as seen in literature to express its rarity of occurrence such as those in [9], [4], [5] and [2]. However the datasets used in these studies did not have consistent contamination ratio and only went to what was available in the dataset. In our experiments, given an initial dataset, we sample anomalies to force a ratio of 1%, 2%, 3%, 4% and 5% contamination in order to test the behavior of models under these circumstances. It is important to take note that there is a possibility that the sampled subset could maintain a ratio less than 5% but still have a semantic variation score higher than 1.5. In this case, we do not consider such a subset to be an anomaly detection dataset and resample until both the contamination ratio and semantic variation score is satisfied.

2) *Semantic Variation Score (f_2):* Semantic variation refers to the measure of how an anomalous data point is widely dispersed from the nominal group and fellow outliers. This means that the measure of dispersal should consider both labels of data points in terms of relative distance. Emott et. al chose a random seed point and computed $K - 1$ data points that are closest to it using euclidean distance. This study's approach does not perform any random seeding since we compute a global score for all datapoints within a dataset that has already been subsampled to meet the first constraint of contamination ratio. This is also known as normalized clusterdness measure which can be expressed by equation 15:

$$\log\left(\frac{\sigma_{\text{normal}}^2}{\sigma_{\text{anomaly}}^2}\right) \quad (15)$$

where:

- 1) σ_{normal}^2 is the variance of normal data
- 2) $\sigma_{\text{anomaly}}^2$ is the variance of anomaly data

To deal with multi-dimensional data, we compute for the variance σ^2 of anomaly (or normal) data points X by taking its covariance matrix using equation 16:

TABLE I. INVALID ANOMALY DETECTION DATASET

Dataset	Semantic Variation Score
Iris Versicolor Anomaly	1.63198
Iris Virginica Anomaly	1.57
Iris Setosa Anomaly	1.57212

$$\mathbf{Var}(X) = \mathbf{E}[(X - \mathbf{E}(X))(X - \mathbf{E}(X))^T] \quad (16)$$

We then take trace of the covariance matrix to give us the overall variance using equation 17:

$$\sigma^2 = \text{tr}(\mathbf{Var}(X)) \quad (17)$$

Although in the original paper, it was suggested that such a score did not provide any means of what threshold value constitutes to anomalies (also noting that it was used as a measure for ideal anomaly generation which is a separate study in itself). The data used by most literature suggests that datasets that exhibit an SV score of less than 1.5 tend to be the ones used for benchmarking anomaly detection models thus the constraint was applied together with the context of contamination ratio. An SV score greater than 0 suggests clustered anomalies as opposed to a score less than 0 which suggests more scattered data points. The intuition is that having more clustered anomalies has a higher chance of exhibiting a pattern since it's not simply an incorrect recording of data but also can be repeated with minimal variation within the class. This makes it difficult for density based methods to perform well as clustered points tend to be treated as normal instead of anomaly classes [2].

It is important to note that with these measures and constraints, anomaly detection datasets are not simply defined by the rarity of anomalies that occur but how clustered they are to reflect its difficulty in terms of detection. For example, Table I shows the popular Iris dataset used in [12] is known to be linearly separable but is also treated as an anomaly detection dataset by defining anomalies as part of the tail ends of an interquartile range. If this is the case, we can take a sample of such defined anomalies with a contamination ratio of 5% that exists within the tail ends of interquartile ranges of a class and treat the rest as normal but still have a high semantic variation score. Such conditions will not be treated as anomaly detection benchmarks.

B. Non-Parametric Stochastic Autoencoder Scoring

The proposed method discussed in this research primarily tries to solve for an acceptable t that will yield reliable results for anomaly detection as defined by the expression $f(x) > t$. The method is largely based on training an autoencoder model in order to address non-linear data and providing a new scoring mechanism that takes into account a non-parametric adaptive value assuming no distribution for the data as well as a new loss function that acts as an adaptive regularizer to prevent overfitting. To improve performance, a stochastic process is included and empirically proven to work better compared to using a vanilla autoencoder. Thus, this study names the model the *Non-parametric Stochastic Autoencoder Scoring* model.

1) *Autoencoder Setup*: The first step in the method is to train a standard autoencoder. The topology of the autoencoder will be a shallow one that it will only consist of three layers, the input, the latent and the output layer which has the same dimensionality as the input. The number of latent variables is set to be approximately 3/4 of the original input size. The initial weights of the model are also set symmetrically that is given the initial weights W_{input} connecting the input to the latent layer, the initial weights W_{output} from the latent to the output layer will just be the transpose of W_{input} . Thus, $W_{output} = W_{input}^T$.

For the latent layer, the activation function used was the rectified linear unit (ReLU) given by the equation 18:

$$A_{latent}(x) = \max(x, 0) \quad (18)$$

For the output layer, the activation function used was the sigmoid activation function 19:

$$A_{output}(x) = \frac{1}{1 + \exp(-x)} \quad (19)$$

2) *Autoencoder's Mean Loss*: The new loss function, *Autoencoder's Mean Loss*, to be used for training is a variation of mean squared errors. This loss function is composed of the sum of two terms. The first one is the standard mean squared errors and the second term is the sum of mean squared errors relative to each dimensionality's mean. This is unique to autoencoders as the parameter μ_i can be derived initially from the data set and y_i is simply x_i unlike fully supervised learning methods where y has to be known. This property allows the loss function to adapt to

$$\epsilon(x) = \frac{1}{n} \sum_{i=1}^n (\hat{x}_i - y_i)^2 + \frac{1}{n} \sum_{i=1}^n (\hat{x}_i - \mu_i)^2 \quad (20)$$

A loss function is said to be valid if it is proven to be convex. This is considered to be a valid loss function as proven mathematically since the sum of two convex functions is also convex. Standard back propagation was used for training the autoencoder model.

3) *Stochastic Latent Noise*: A relevant part of the model is adding stochasticity to the latent layer of a trained autoencoder which is referred to as *Stochastic Latent Noise*. The intuition behind this is that if the model is trained only using positive / nominal data points, then determining a threshold to discriminate reconstructed points with high residual errors will still yield to a lot of false negatives. According to the original definition of outliers by Edgeworth, a possible reason for anomalies is the error of observation is the joint result of considerable, but finite, number of small sources of error. This concept is applied to the latent set Z from a trained autoencoder by determining its statistical properties μ_{z_i} and σ_{z_i} and sampling a normal distribution from it with parameter K corresponding to the size of data points found in the distribution. Another parameter d is given referring to the number of dimensions the sampling is applied to. Finally a parameter r is given to represent the ratio of random points taken at the tail end of each distribution to replace the value

at latent index i . Using the trained autoencoder, the decoder part is then ran against these synthetic anomalies to get the reconstructed version at the original dimensional space. These values are then added to the histogram of residual errors to determine t as explained in the next section.

Another way of looking at *Stochastic Latent Noise* is that it's cyclical process of artificial reinforcement learning unique to autoencoders. Traditional machine learning algorithms rely on data to dictate the value of weights whereas reinforcement learning lets the model itself dictate the data. In a similar fashion, the autoencoder first learns of the approximation of the identity function from the data set and based on the weights forces some random aspect to its latent layer representing a compressed version of the data. This is then projected to reconstructed data or randomly synthesized instances that resemble the data as understood by the autoencoder model. An illustration of this can be seen in Fig. 4.

Fig. 4. Stochastic Latent Noise

4) *Determining the Threshold*: The value of t is taken as the midpoint of the identified bin threshold for a histogram of residual errors as built by the reconstructed data points from the trained autoencoder including the added synthetic points from the previous section.

Histogram of Residual Errors: From the set of \hat{X} , the set of residual errors X_ϵ are used to build a histogram of q bins with starting range $\min(X_\epsilon)$ and ending in $\max(X_\epsilon)$. Each bin has its own local minimum and maximum values whose interval is given by equation 21.

$$\text{interval} = \frac{\max(X_\epsilon) - \min(X_\epsilon)}{p} \quad (21)$$

The value of p is automatically set using Freedman-Diaconis rule as seen in equation 22:

$$p = 2 \left(\frac{\text{IQR}(X_\epsilon)}{\sqrt[3]{n}} \right) \quad (22)$$

An example result of the generated histogram of residual errors is seen in Fig. 5.

Determining t From Histogram of Residual Errors: To solve for t , given the histogram of residual errors, we first apply a head-tail break function (HTB) to return an array of possible break points. The following shows an implementation of the HTB algorithm:

Listing 1: HTB Python Implementation

```
def htb(data):
```

Fig. 5. Histogram of Residual Errors

```

outp = [] # array of break points

def htb_inner(data):
    dl = float(len(data))
    dm = sum(data) / dl
    head = [_ for _ in data if _ > dm]
    outp.append(dm)
    c_head = len(head) > 1
    c_thresh = len(head) / dl < 0.40
    while c_head and c_thresh:
        return htb_inner(head)

htb_inner(data)

return outp

```

For each break point, we get a candidate threshold by passing the bin configuration which is an array of values representing the bins (i.e. bin_0 and bin_1 defines the minimum and maximum value ranges of the first bin) and the occurrence counts in the form also of an array (i.e. in this case, the size of the occurrence counts). The final threshold is then naively selected to be the minimum from the array of candidate thresholds.

The implementation of fetching the threshold from the histogram is given by the following:

Listing 2: Fetch Candidate Threshold

```

def fetch_threshold(bs, counts, bp):
    index = 0
    m = 999999999
    t = -1

    for i in range(len(counts)):
        if abs(counts[i] - bp) <= m:
            m = abs(counts[i] - bp)
            index = i
            l = ((bs[i + 1] - bs[i]) / 2)
            r = bs[i]
            t = l + r

    return t

```

Now that t is determined, to classify an unknown data point x as either an outlier or an anomaly, x is passed to the trained autoencoder and its corresponding x_ϵ is taken. If the value is greater than t , then there is reason to believe that the model had

a hard time reconstructing it and thus flagging it as an anomaly. A visual example of this can be seen in the illustration in Fig. 6.

Fig. 6. Threshold Example

C. Methods for Benchmarking

To test the performance of the proposed method against existing, it was compared against 12 standard and state of the art methods for anomaly detection (summarized in Fig. 7 together with year of release) in a semi-supervised fashion where parameters of these methods were manually optimized to get the best possible results. These methods are grouped according to the nature of their methodologies as follows:

Ensemble	Linear	Probabilistic	Proximity
Isolation Forest (2008)	R. Covariance (1994)	ABOD (2008)	LoF (2000)
LODA (2016)	OneClass SVM (2001)	SOS (2012)	CBLOF (2003)
LSC-POE (2019)	MCD (2004)	COPOD (2020)	HBOS (2012)

Fig. 7. Summary of Methods

1) Ensemble:

- 1) Isolation Forest (ISO-F) [3]
- 2) Lightweight On-line Detector of Anomalies (LODA) [13]
- 3) Locally Selective Combination of Parallel Outlier Ensembles (LSCP) [14]

2) Linear:

- 1) Minimum Covariance Determinant (MCD) [5]
- 2) Robust Covariance (ROB-COV) [15]
- 3) OneClass SVM (OC-SVM) [6]

3) Probabilistic:

- 1) Angle-Based Outlier Detection (ABOD) [16]
- 2) Stochastic Outlier Selection (SOS) [17]
- 3) Copula-Based Outlier Detection (COPOD) [18]

4) Proximity:

- 1) Local Outlier Factor (LOF) [4]
- 2) Clustering-Based Local Outlier Factor (CBLOF) [19]
- 3) Histogram-Based Outlier Score (HBOS) [20]

D. Evaluating Performance

To evaluate the results of the proposed method against existing categories of methods mentioned in the previous section, for each sampled dataset (80 datasets in total), 10 simulations were conducted (total of 800 runs: 16 initial datasets

partitioned to five different contamination configurations) with the MCC (Matthew’s Correlation Coefficient) score extracted and applied to a two tailed t-test score with a significance level of 0.05. This allowed the study to determine with confidence if the proposed method is either:

- 1) Significantly better than other methods
- 2) Better but not significantly better than other methods
- 3) Poorer (at least one method is better than the proposed method) but not significantly poorer
- 4) Significantly poorer (at least one method is significantly better than the proposed method)

MCC (Matthew’s Correlation Coefficient) was preferred over the commonly used F1-score due to the mathematical properties mentioned in [21] making it more ideal for anomaly detection with extremely biased data. For each initial dataset, 70% of normal data was randomly sampled and used for training with the remaining 30% used for evaluation. MCC is a measure of correctly predicting both majority of nominal and majority of anomalies. A value of -1 is reached for a perfect misclassification. A value of 1 is reached for a perfect classification. A value of 0 indicates a performance the same as a coin toss. This score can be computed by equation 23

$$MCC = \frac{TP \cdot TN - FP \cdot FN}{\sqrt{(TP + FP) \cdot (TP + FN) \cdot (TN + FP) \cdot (TN + FN)}} \quad (23)$$

E. Datasets

Given the quantitative measures to define anomaly detection datasets, the following datasets were sampled from 16 datasets to meet the constraints mentioned in order to come up with a total of 80 datasets as shown in Tables II, III, IV, V, VI, VII, VIII, IX, X, XI, XII, XIII, XIV, XV, XVI and XVII. These tables show the values for each dataset’s *categorical measures* in terms of contamination ratio and semantic variation score that characterizes it as an anomaly detection problem which also meets the constraints as mentioned previously.

IV. RESULTS AND ANALYSIS

A. Overview

A summary of the results is illustrated in Fig. 8 where:

- Green cells ● mean that the proposed method did significantly better
- Blue cells ● mean that the proposed method did better but not significantly better
- Yellow cells ● mean that the proposed method did poorer but not significantly poorer
- Red cell ● mean that the proposed method did significantly poorer

To better assess the results of the proposed model, each dataset was treated as a point in two dimensional space where each dimension corresponds to the a dataset’s categorical measure. This allowed us to see if the proposed method performs relatively well in a certain range as bound by the

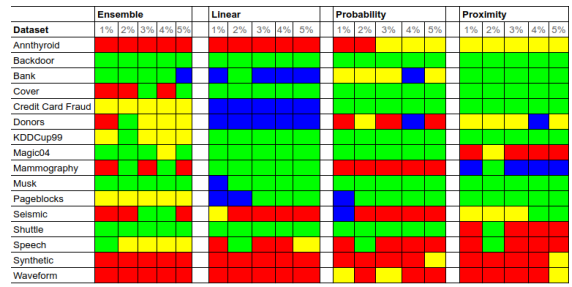

Fig. 8. Overview of Experimental Results

values of categorical measures. Consequently, this allowed us to see at what range the method fails and where a certain category of outlier detection models would prove to be more useful. The next few sections would go through each anomaly detection category and how the proposed method performed comparatively.

B. Performance vs Ensemble Methods

The projected categorical measures can be seen in Fig. 9 where majority of the datasets that the proposed method did significantly better against fall under the range of -0.75 at minimum and 0.60 at maximum in terms of semantic variation score regardless of outlier ratio.

Fig. 9. Performance vs Ensemble

Ensemble methods require calibration of the sub-algorithms used and parameter tuning for each which makes it dependent on which exact algorithms are part of the ensemble. These methods tend to perform better than the proposed method semantic variation scores are negative contrary to the other method categories as seen in the next section. It is still noted though that the proposed method doesn’t require such dependency on other algorithms making it less complex to calibrate.

C. Performance vs Linear Methods

The projected categorical measures can be seen in Fig. 10 where majority of the datasets that the proposed method did significantly better against has a semantic variation score of at most -0.50 regardless of outlier ratio. Although there are some instances beyond -0.50 that the proposed method can

outperform linear methods, in most cases linear methods work significantly better.

Fig. 10. Performance vs Linear

As with the results of proximity and probability based methods, linear methods fail to outscore the proposed methods in the negatively scored datasets in terms of semantic variation. This suggests that neural network based models can take advantage of non-linear properties that are not otherwise captured by more statistical properties of linear methods. In addition, it suggests that because of the negative values, the anomalies present in such datasets tend to be more scattered (less clustered) with more variation expressing a non-linear behavior.

D. Performance vs Probability Methods

The projected categorical measures can be seen in Fig. 11 where majority of the datasets that the proposed method did significantly better against has a semantic variation score of at most -0.50 regardless of outlier ratio. As with linear methods, compared to probability methods, the method may at times perform better if the semantic variation score is greater than -0.50 but in most cases it performs either poorer or significantly poorer in that domain.

Fig. 11. Performance vs Probability

E. Performance vs Proximity Methods

The projected categorical measures can be seen in Fig. 12 and in similar comparison to linear and probability based

methods, the proposed method performs significantly better than proximity based methods if the semantic variation score of the dataset to be evaluated is less than -0.50 regardless of outlier ratio.

Fig. 12. Performance vs Proximity

As with the previous categories, the proposed method tend to perform better when the anomalies are less clustered. As with the nature of proximity based methods which is largely based on distance metrics such as nearest neighbors, a large variance of anomalies present will tend to fail as seen in the datasets that are negatively scored in terms of semantic variation.

F. General Discussion

As a general statement, it can be seen that in terms of the MCC performance against datasets constrained with the categorical measures, the proposed model can perform significantly well regardless of outlier ratio in most cases if the semantic variation score leans towards negative values, specifically -0.05 . As mentioned by Emott et. al. [2], a dataset quantitatively characterized with a negative semantic variation score suggests that anomalies are more scattered in nature due to having a higher value in terms of variance that exceeds that of the variance of normal data points (taking the log of a value less than 1 as computed by semantic variation, will yield a negative value as a result of the variance of anomalies is higher than that of normal points).

Restricting the contamination ratio to at most 5% keeps it aligned with the concept of rarity as what most literature in anomaly detection states. It is important to note however that not all the initial datasets (that is, the dataset's original form without the sampled subsets for evaluation with applied categorical measures) necessarily comply with the constraints of categorical measures. Violating these constraints would not constitute to proper anomaly detection studies as it will have a positive semantic variation score (suggested threshold of the study is 1.5) that suggests occurrences of anomalies would tend to form certain patterns which does not appropriately reflect the description of anomalies in literature (incorrect data production and rare occurrence) and therefore could be a means of it being treated as either a biased two class classification problem wherein the minority class is not considered an anomaly.

In terms of application, if a scenario in the real world can determine anomalies that tend to cluster in such a way,

then the proposed method is ideal for it in a sense that it will allow researchers / practitioners / stakeholders to take advantage of not needing to manually adjust inferencing parameters (reconstruction error threshold) upon usage. Being a neural network based model, it does seem to validate the approximation of non-linear functions that tend to address the unpredictable behavior of occurrences of anomalies. On the flip side however, anomalies that tend to be more clustered together thus exhibiting a higher semantic variation score (greater than -0.50 or a positive value for that matter), would still fall under the notion that the effectiveness of an anomaly detection algorithm will still be on a case to case basis.

Applying categorical measures allowed us to quantify the nature of an anomaly detection dataset and observe the behavior of various methods in terms of its MCC performance. With these measures, we can derive insights as to which possible range of values certain methods can work well against as opposed to the general characteristics of the anomaly detection problem where anomalies are simply said to rarely occur or fall within a certain deviation from what is normal. Such deviation can't be quantified as anomalies themselves are subject to the domain where data is captured or produced thereby not allowing a standard objective definition of it. With categorical measures, we can at the very least, quantify the structure of the dataset in relation to the existence of anomalies and its relation to normal data points.

V. CONCLUSION

The effectiveness of classification methods for anomaly detection are traditionally dependent on looking for the best parameters that fits a certain scenario or dataset at hand. This is primarily due to the fact that anomalies themselves cannot be quantified or given objective characteristics for all domains. Even in current literature, anomalies are restricted to definitions that vary from scenario to scenario in terms of rarity and what value to be used to express magnitude of deviation from what is normal. Given these, this study pushes the definition further by providing a quantitative definition not to the anomalies themselves but in context of datasets that are considered to be an anomaly detection problem so as to give insights as to how well anomaly detection methods perform. The study refers to these as *categorical measures*.

Anomaly detection datasets (specifically point anomalies and not context or time series type) characterized with *categorical measures* in this study was constrained to the following conditions:

- 1) The point anomaly instances comprise of at most 5% of the evaluated dataset to ensure its rarity of occurrence.
- 2) The dataset's semantic variation score does not exceed 1.5, since higher scores generally imply that there is clustering among the point anomaly instances, and this may indicate the presence of a non-anomalous process that generated the "anomaly" instances.

Both conditions have to be satisfied before a dataset can be considered as part of an anomaly detection study. Violating these constraints would not constitute to proper anomaly detection as the score suggests certain clusters forming depicting

a pattern where methods that are density based are more likely to fail. Since the first constraint expresses rarity, it is still a ratio and one can still derive a subsample that meets the first criteria but fails in the second. Therefore, both have to be met to constitute to a valid anomaly detection problem instead of just leaning on the notion of rarity.

With the proposed method with a neural network autoencoder model as its base, it can be modified to be adaptive in terms of automatically setting the parameter in the inferencing stage that allows scoring of anomalies to not be dependent on prior information such as assumed distribution on the data itself or domain expert. This was done by allowing the discovery of the threshold value, a parameter that has traditionally been set manually by neural network based models, to be naturally formed by the distribution of reconstruction errors which assumes to exhibit a long tail distribution. Compared to existing methods that have been tested throughout this study, the proposed method performed comparatively well in an identified domain of negatively scored semantic variation value of anomaly detection datasets suggesting that it works well in scenarios with more variation in the anomalies present. This has been proven through experimentation on the MCC metric where in most cases, the proposed method performed significantly better if the dataset has a score of -0.5 or less in terms of semantic variation even when parameters of the existing methods have been optimized whereas the proposed method had its parameter configured automatically all throughout. Apart from the family of ensemble method where the performance of the proposed method works better in the range of -0.75 to 0.60 , as well as the positively scored datasets, it still remains a case to case basis as other methods work better or worse than the proposed method without any evident generalization. This could be up for investigation in future work.

Anomaly detection in general is still an open problem without any standard objective definition. But with the case of this study, the narrative can be progressed towards examining behavior of methods given categorical measures of the datasets themselves to constitute to a working quantitative definition of an anomaly detection problem.

ACKNOWLEDGMENT

The authors would like to thank the Ateneo de Manila University and the University Research Council for supporting this study.

Abstract—COVID-19 has recently manifested as one of the most serious life-threatening infections and is still circulating globally. COVID-19 can be contained to a considerable extent if a patient can know their COVID-19 infection at a possible earlier time, and they can be isolated from other individuals. Recently, researchers have explored AI (Artificial Intelligence) based technologies like deep learning and machine learning strategies to identify COVID-19 infection. Individuals can detect COVID-19 disease using their phones or computers, dispensing with the need for clinical specimens or visits to a diagnostic center. This can significantly reduce the risk of spreading COVID-19 farther from a probably infected patient. Motivated by the above, we propose a deep-learning model using CNN (Convolutional Neural Networks) to autonomously diagnose COVID-19 disease from CXR (Chest X-ray) images. The dataset used to train our model includes 10293 X-ray images, with 875 X-ray images from COVID-19 cases. The dataset contains three different classes of the tuple: COVID-19, pneumonia, and normal cases. The empirical outcomes show that the proposed model achieved 97% specificity, 96.3% accuracy, 96% precision, 96% sensitivity, and 96% F1-score, respectively, which are better than the available works, despite using a CNN with fewer layers than those.

I. INTRODUCTION

Wuhan, a business hub in China's Hubei province, saw a fresh coronavirus outbreak in 2019. Researchers in China termed the novel virus the 2019 n-Cov or the Wuhan virus [1]. Officially a study group found this virus, and they named it SARS-CoV-2. During the coronavirus infection outbreak in 2019, the international committee was labeled coronavirus disease 19 (COVID-19) [2, 3, 4]. In the first place, coronaviruses have caused disease in people who have been exposed to wild animals, primarily bats and rats [5, 6, 7]. After almost three years since its first appearance, COVID-19 shows no signs of abating, and has already infected half a billion individuals and claimed more than six million deaths.

COVID-19 is a disease caused by a virus source that aggravates the lungs, causing pneumonia in patients. However, the treatment and medication of these cases are quite different from pneumonia cases arising from other viruses or bacteria. If an individual shows symptoms of COVID-19, certain precautionary steps are taken in conjunction with the diagnosis. COVID-19 patient is isolated for a certain number of days in order to contain the further spread of the infection. Therefore, to stop the spread of COVID-19, accurate and timely identification of pneumonia caused by the virus is a critical issue.

The WHO approved a testing method based on Polymerase chain reaction (RT-PCR), whereby short DNA or RNA sequences are analyzed and replicated or intensified [8]. In some circumstances, more than one test may be required to rule out the possibility of coronavirus infection. According to the WHO laboratory research, negative results do not always mean that a person is not infected with COVID-19 [9].

Although RT-PCR examination is the most trustworthy technique to diagnose COVID [10], it is a laborious, time consuming, complex manual procedure, with kits in short supply depending on the time and place. Furthermore, the test is unpleasant and slightly invasive, as it entails collecting nasopharyngeal swabs. COVID-19 attacks the human airway epithelial (hAE) cells. Accordingly, X-rays can be used as a potential specimen to know the damaged portions of a COVID-19 patient's lungs. Detection of COVID-19 using X-ray images of a patient might be a helpful technique due to its fast speed, contained cost, and wide range of applications [11].

The insufficient supply of COVID-19 scanning workstations and research kits poses challenges for the medical practitioners and personnel to cope up with COVID-19. Rapid and effective identification of suspicious COVID-19 cases is of fundamental importance to contain the spread of the infection. The need for repeated checks to ascertain the actual condition and make effective decisions is often exponential growth in critical situations for patients. Therefore, we set the following objectives to design a machine-learning based COVID-19 case detection system.

We summarize the objectives as follows:

- Assisting radiologists and medical specialists in detecting subtle and gradual changes in X-rays that might otherwise go unnoticed;
- Many people in developing countries do not have access to radiologists due to high costs. This tool could help them read their X-ray images to classify them as COVID-19, pneumonia, and normal;
- Creating a model to scan complex data such as CT and MRI images to detect COVID-19 cases.

A deep-learning approach, such as CNNs, is able to learn and deduce properties of a very complex nonlinear functions autonomously, without the need for human intervention. CNNs act exclusively on input data after a supervised training phase. For example, the ImageNet Large Scale Visual Recognition Challenge (ILSVRC) reported a well-known scenario when a

model outperformed humans in the task of classifying images in 2015 [12].

The primary purpose of this study is to build a deep-learning paradigm to diagnose pneumonia from CXR images as well as the location and positioning of abnormalities in X-rays. In addition, we propose a deep-learning-based model to detect cases of COVID-19, influenza, and normal X-ray picture classification. This model provides a low-cost method for radiologists and medical professionals to cross-check their interpretations and recognize any possible results that might otherwise have been overlooked. The model is trained with the dataset collected from Kaggle and GitHub. The radiological society and researchers recently formed these datasets from patients' X-ray images during the COVID-19 outbreak. To improve the model's accuracy, we adopt clinical image engineering that has consolidated imaging computing approaches such as pre-processing techniques, classification approaches, and illness screening and localization in a sequential manner.

Following are the contributions of this paper:

- We developed a CNN-based architecture to detect COVID-19 from patients' X-rays after collecting and pre-processing X-ray data. We trained our model by using Keras on top of TensorFlow. The proposed approach achieves 96.3% accuracy for the Pneumonia, Normal, and COVID-19 classes. Despite our model being less complex (as measured by the number of layers in the CNN) than the available ones, it outperforms them all in accuracy.
- Grad-CAM has been employed to detect characteristic features from X-ray images to aid visually interpretative decision-making about COVID-19.

The rest of this paper is summarized as follows: In Section II, recent research works are represented. Our suggested approach and material with CNN-based architecture for the COVID-19 detection system are discussed in Section III. Experimental results and discussion are illustrated in Section IV and Section V concludes our paper and highlights directions for future work. Table I reports a list of the acronyms used in this paper.

II. LITERATURE REVIEW

Researchers have been utilizing different deep-learning strategies to identify COVID-19 from clinical images such as X-rays and CT scans of the chest. Rahimzadeh et al. [13] built a joint CNN-assisted ResNet50V2 and Xception model for categorizing COVID-19 cases by employing CXR images. The dataset fed into this method included 8851 images of healthy people, 6054 images of pneumonia patients, and 80 images of COVID-19 patients. In this model, 633 images were chosen for each of the eight training phases. For COVID-19 cases, this system achieved an experimental result of 99.56% accuracy and 80.53% recall.

Alqudah et al. [14] utilized AI strategies to implement a method for detecting COVID-19 from CXR images. Several machine-learning strategies like Support Vector Machine (SVM) and Random Forest (RF) were picked for classification purposes. The system achieved 95.2% accuracy, 93.3% sensitivity, and 100% specificity. GAN with deep learning

to identify the COVID-19 from CXR images was suggested by Loey et al. [7]. GoogleNet, AlexNet, and ResNet18 are the pre-trained models used by this proposed framework for identifying COVID-19 cases. The GoogleNet pre-trained model was picked as a primary deep-learning technique. The model showed test accuracy of 80.6% within the four classes continuity (79% normal cases, 79% bacterial pneumonia cases, 79% images of pneumonia cases, and 69% COVID-19 cases). In the same way, for three classes continuity, AlexNet gained test accuracy 85.2%, and GoogleNet attained test accuracy of 99.9% for the two classes continuity.

Kumar et al. [15] suggested a deep-learning procedure to identify and classify COVID-19 infected patients. The proposed approach was trained by using nine pre-trained processes to extract features from the CXR images, and for the classification they used SVM. The datasets included 158 CXR images of both COVID-19 and non-COVID-19 cases. Obtaining 95.52% F1-score and 95.38% accuracy, ResNet50 combined with the SVM method was a statistically outstanding technique.

Horry et al. [16] suggested a COVID-19 identifying framework from CXRs considering pre-trained methods. The recommended framework applied Inception, ResNet, Xception, and VGG to classify COVID-19 cases. The dataset employed within the framework encompasses 60361 images of normal cases, 322 images of pneumonia cases, and 115 images of COVID-19 cases. They were found recall and precision values 80% for the VGG19 and VGG16 classifiers.

Ucar et al. [17] introduced a COVID-19 identifying framework by utilizing X-ray photos and deep learning techniques. The data set used for the framework contained 1583 photos of normal cases, 76 photos of COVID-19 cases, and 4290 photos of pneumonia cases, and for COVID-19 cases, the system attained 98.3% accuracy. A transfer-learning technique with the CNN is recommended by Apostolopoulos et al. [18]. By extracting essential attributes from CXR images, this technique could instinctively diagnose COVID-19 patients. This recommended framework used five CNN models, including InceptionResNetV2, MoblieNet, Inception, Xception, and VGG19, to sort the COVID-19 CXR images. The dataset for three classes contained 504 CXR images of normal cases, 700 CXR images of pneumonia cases, and 224 CXR images of COVID-19 cases. VGG19 was chosen as the primary method with 98.75% sensitivity, 92.85% specificity, and 93.48% accuracy within the introduced framework.

A complete unique model introduced by Bandyopadhyay et al. [19] that made use of the LSTM-GRU to categorize confirmed automatically, negative, positive, recovered, and death cases of coronavirus. The above framework attained 67.8% accuracy for negative cases, 62% accuracy for death cases, 40.5% accuracy for released cases, and confirmed cases with 87% accuracy.

A deep-learning network to identify COVID-19 cases autonomously from CXRs was presented by Khan et al. [20]. The dataset includes 310 images of normal cases, 330 images of bacterial pneumonia cases, 327 images of the viral pneumonia cases, and 284 images of COVID-19 cases. With COVID-19, the recommended model acquired 93.5% accuracy, 100% recall, and 97% precision. A complete unique framework

based on a deep-learning approach to identify COVID-19 from CXR images called COVIDX-Net was represented by Hemdan et al. [21]. Authors used eight pre-trained models contained Xception, InceptionResNetV2, InceptionV3, VGG19, DenseNet201, MobileNetV2, and ResNetV2 for their frameworks. The dataset contained 50 CXR images, with 25 images of non-COVID-19 cases and 25 of COVID-19 cases. VGG19 and DenseNet201 achieved 83% precision and 90% accuracy.

In [22], Singh et al. utilized a VGG16 model as a deep transfer-learning framework to identify COVID-19 patients from CT scan images. In this proposed framework, authors used four classifiers models to classify COVID-19 cases, and the PCA extracted the features from CXR images. With the help of the SVM classifier and bagging ensemble method, 95.7% accuracy, 95.3% F1-score, and 95.8% precision achieved effective result.

In [23] the authors presented a lightweight DNN-based mobile app named COVID-MobileXpert, that can use noisy photos of CXRs for point-of-care COVID-19 screening. In addition, they created a new 3-players Knowledge Transfer and Distribution (KTD) framework that includes a pre-trained attending physician network that extracted photo attributes from a gigantic set of lung infection CXR photos. Furthermore, a fine-tuned RF network retains the fundamental CXR imaging attributes to distinguish COVID-19 cases from normal and pneumonia CXR images.

To detect COVID-19 symptoms, Ahuja et al. [24] suggested a transference learning strategy employing a three-phase approach. With a view to indicating the abnormality of the image, several pre-trained models had been applied with the augmented image using ResNet18 deep-learning model, and thus, 99.4% of test cases accuracy were obtained. In [25] the authors

talked about deep learning emerged case study utilizing CMC & fuzzy rule induction to deal with the delimited information for forecasting strategies. To identify COVID-19 cases, Ashraf et al. [26] presented a framework called COVID-CAPS. In [27] authors introduced a deep-learning algorithm, which can perform fast detection of COVID-19 cases, and their system attained 95% accuracy. Karthik et al. [28] suggested a custom CNN-based architecture to detect COVID-19 cases, and for each kind of pneumonia, it can learn unique convolutional filter patterns.

TABLE II. NUMBER OF CNN LAYERS IN THE REVIEWED MODELS

Year	Ref.	Number of Layers
2020	[13]	6
2020	[14]	8
2020	[15]	≥ 1000
2020	[16]	≥ 200

Aside from that, researchers continually contribute to inventing feasible methods to identify COVID-19 cases from CXR images. The above review establishes that deep learning, especially CNN, plays an important role in COVID-19 diseases

detection and classification in medical imaging. However, the recent study has limitations in identifying the COVID-19 virus in normal cases from the CXR images. Our proposed model is novel and different from the others presented above. It has fewer layers, which entails smaller complexity. The number of layers used in the methods reviewed in this section is shown in Table II, and is always larger, and often considerably so. As we will show later, despite being less complex, our model achieves better performance in most metrics.

III. PROPOSED COVID-19 DETECTION SYSTEM

This section presents the primary contribution of the paper: the architectural design and implementation of the suggested methodology.

A. Methodology

The architecture of our system for COVID-19 detection consists of several building blocks as illustrated in Fig. 1.

Initially, raw CXR images are provided in the pre-processing pipeline for performing pre-processing tasks like resizing, normalization, flipping, zooming, and rotation. After the pre-processing phase, the data set is divided into a training and a test set. Next, the proposed system is trained using the training data. Training and validation accuracy and loss are determined after every epoch. The following evaluation metrics have been adopted for performance measurement: accuracy, sensitivity, specificity, F1-score, precision, Area Under the Curve (AUC) using Receiver Operating Characteristics (ROC) and confusion matrix.

1) *Collection of Dataset and Explanation:* As COVID-19 has recently broken out, datasets with more sample X-rays tagged with COVID-19 cases are not available yet. As a result, collecting data on various image sources of normal, COVID-19, and pneumonia cases need to be collected. For COVID-19 cases, 2875 CXR images have been collected from GitHub [29] and Kaggle [30]. For pneumonia and normal cases, 4200 and 3218 CXR images are collected from the Kaggle repository [30, 31]. In total, our dataset contains 10293 CXR images. Later, the images are resized to a resolution of 224x224 pixels. Fig. 2 depicts the visualization of several CXR images of every class.

The number of CXR images of each set was partitioned in Table III

TABLE III. DATASET

Normal	Covid	Pneumonia	Total
3218	2875	4200	10293

2) *Image Pre-Processing:* To improve the model's efficiency, pre-processing of the image is required. In this work, we also carried out certain pre-processing activities to produce better performance. The pre-processing techniques used in this research are listed in this section.

A.1 Resize Picture to Capture the Central Portion and Remove Black Bars: Typically, square images are required to train CNN models. The CXR data obtained from various sources differs in sizes. So, in order to feed CXR images into

the model, we need to scale the images down to a square shape. However, this causes an asymmetry of the images as seen in the Fig. 3.

To tackle the distortion of the input images, we applied Pasa et al. [32]'s technique to remove the central area and delete black bars. Fig. 4 depicts a pre-processed image obtained by carrying out the following operations:

- 1) If any black bands appear at the image's margins, they are discarded;
- 2) The image's dimension is warped until the minimum boundary counts 224 pixels;
- 3) Retrieve the 224×224 pixel core area.

A.2 Normalization: Subsequently, images are normalized and transformed to the proper data type. Original images are grayscale with individual pixels coded as Unit8 type with values in range 0-255. For the Keras model, data is provided in float32 type. Therefore, the pre-processed images have to be converted into float32, normalized to a range [0; 1]. To normalize every pixel, the data value is divided by the highest value of uint8, which is 255.

A.3 Data Augmentation: Deep-learning methods, such as CNN, generates more accurate outcomes if larger numbers of full-sized images can be used. As a result, data augmentation is useful in creating the first training images that are backed up by extra data. We conducted the subsequent data augmentation procedures during training:

- 5 to 10 degrees of spontaneous rotation;
- Zooming within a range of +10% and -10%;
- Flipping horizontally.

3) *Proposed CNN Model Development:* A deep-learning model has been built in this paper to diagnose COVID-19 incidents. The model is trained using a dataset having three types of CXR images. The suggested CNN model structure for COVID-19 detection is shown in Fig. 5.

The proposed CNN model has five convolutional blocks. Each convolutional block has multiple layers, and each layer has one activation function named Rectified Linear Unit (ReLU). The third block and fourth block have a dropout layer to reduce the over-fitting problem. Two fully connected layers (FCLs) have been used, the first FCL is used with the dropout layer, and the last FCL is connected with the softmax classifier.

A.1 Convolution Layer: Every convolution block of this model has multiple convolution layers. The first convolution block consists of conv1-layer1, and conv1-layer2. Similarly, second convolution block has conv2-layer1, and conv2-layer2. Third convolution block has conv3-layer1, conv3-layer2. Fourth convolution block consists of conv4-layer1, and conv4-layer2, and final fifth block has conv5-layer1, and conv5-layer2. The fourth block and fifth block have an extra dropout layer to reduce the overfitting problem. Conv1 block has used a total of 32 filters where every filter size is 5×5 . Conv2 block uses a total of 64 filters where every filter size is 3×3 . Conv3 block uses a total of 128 filters where every filter size is 3×3 . Conv4 block uses a total of 256 filters where every filter size is 3×3 , and similarly, Conv5 block has used a total of 512 filters where every filter size is 3×3 .

is:

$$F(i, j) = (J \times K)(i, j) = \sum \sum J(i + p, j + q)K(p, q), \quad (1)$$

where the input matrix is represented with J , a 2D filter of size $p \times q$ is indicated by K , and F denotes a 2D feature map's output. $J \times K$ describes the operation of the convolutional layer.

A.2 Rectified Linear Unit: Each convolution layer has an activation function. Here this model used the ReLU activation function. To extend nonlinearity in feature maps, the ReLU layer is utilized [33]. ReLU itemizes activation by maintaining the threshold input at zero. It is mathematically represented as follows:

$$f(y) = \max(0, y) \quad (2)$$

A.3 Zero Padding Layer: The application of this layer is to add columns and rows of zeros to the left, right, top, and

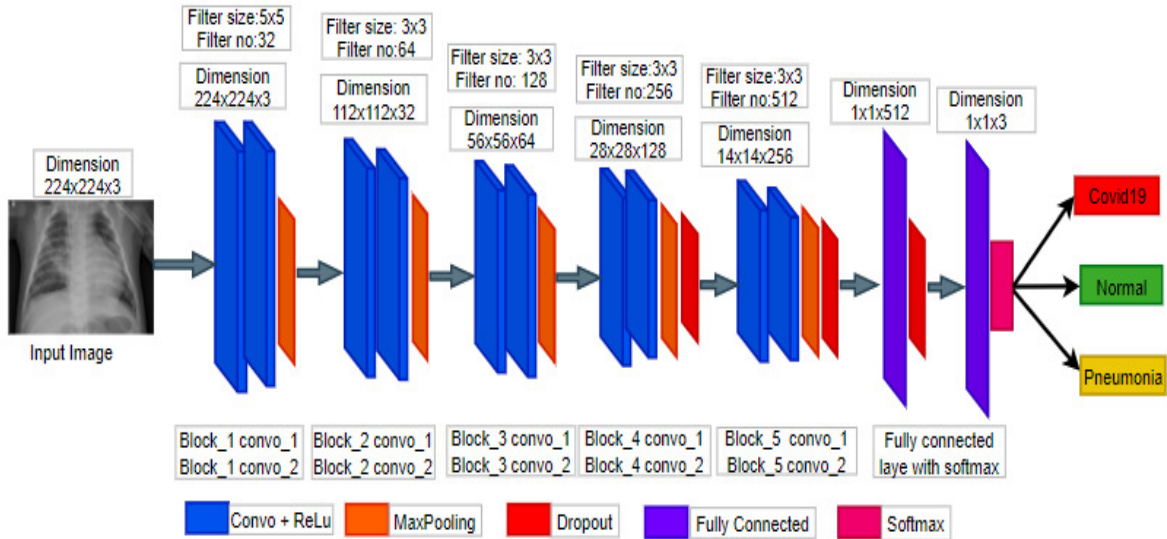

Fig. 5. Proposed CNN Architecture.

bottom sides of an image. We have applied 1×1 zero padding during our work.

A.4 Pooling Layers : The next layer that we applied is a pooling layer. This layer is used to reduce the number of consumption and parameters in the network by dynamically shrinking the spatial size of the images. The pooling layer aids in reducing the problem of overfitting and executes distinct operations on each depth slice of the input and resizes it spatially using the MAX function. The most common MAX pooling layer with filters of size 2×2 is used with a stride of 2. MAX pooling is applied to downsample the input by two along width and height, discarding 75% of the activation. The pooling layer is represented below:

- 1) Accepted a volume of size is $w1 \times h1 \times d1$
- 2) Required two hyper parameters:
 - F is their spatial extent
 - S is the stride
- 3) Produced a volume of size is $w2 \times h2 \times d2$:
 - $w2 = (w1 \times F) / S + 1$
 - $h2 = (h1 \times F) / S + 1$
 - $d2 = d1$
- 4) It presents zero parameters since it calculates a specified function of the input.
- 5) Zero padding is not commonly used in the pooling layers [34].

A.5 Dropout Layer : There are many methods to handle a CNN's capacity to eliminate overfitting. For example, the dropout layer [35] is an effective regularization method to prevent overfitting problems. During training time, the dropout layer randomly sets some neuron's activation to zero and those neurons will not update their weights. Dropout is activated with some probability during training, otherwise it is inactive. Some

neurons do not learn all characteristics due to dropout. There is no dropout layer added throughout the testing period. Most of the times, a dropout ratio $p = 0.5$ shows good results, hence is selected as default. The p value can be tuned during data validation as well.

A.6 Fully Connected Layer: Each neuron in one layer is connected to another neuron in another layer, hence FCLs are formed. The layer basically takes an input image or object and outputs an N -dimensional vector as a response, where N is the number of given classes that the model or program has to choose from [36]. The working technique is as follows: the system looks at the output of the preceding layer and identifies which features are most commonly associated with a specific class. Fundamentally, a FCL considers which high-level features are most closely associated with a certain class and assigns weights to them, resulting in the classification value when the products of the weights and the preceding layer output are computed.

A.7 Softmax : The softmax function with loss [37] is used, which crushes an N -dimensional vector x of random real values to an N -dimensional vector ($\sigma(x)$) of real values in the range from 0 to 1 that will sum up to 1. The function is given by the following equation 3:

$$\sigma(x)_j = \frac{e^z_j}{\sum_{k=1}^k e^z_j} \quad (3)$$

Here, $j = 1, 2, \dots, k$. For this model, the output feature map will be for three classes. In the output feature map, the pixels belonging to the predicted class will be 1, and for that same pixel, other classes will contain zero.

4) *Cost-Sensitive Learning*: Our proposed method focuses on learning features automatically from CXR images based on CNN. Cost-sensitive learning (CSL) [38] is a mechanism in which the method that ranks each class in a classification problem can be penalized. When using CNNs, CSL helps prevent prejudices in classification and then assists in overcoming the issue of imbalance as a tool. We have chosen CNN as our data set is imbalanced. The approach of class weight is used in this research as one possible way to mitigate the future effects of data imbalance. We adjust the weights in the class weight system in inverse proportion to the number of occurrences of each class in the raw data. We have used a Sci-Kit Learn feature for all this, which acquires numbers to match the number of cases centred on logistic regression concepts [39][40]. The weight W_k in class k is calculated using the following equation 4.

$$W_k = \frac{\sum \text{Cases}}{\sum \text{Classes} \times \sum \text{Cases in class}(k)} \quad (4)$$

The weights of the groups are utilized to match the standard. As a result, in the loss function, we assign higher values to cases involving smaller groups. The estimated loss would then be a weighted average, with W_k denoting the weights assigned to each class inside each sample throughout the loss calculation.

5) *Loss Function Used: Categorical Cross-Entropy*: The objective of network training is to maximize the probability of correct classification. This is gained by minimizing the cross-entropy loss for each training sample. The loss function utilized in our work is the categorical cross-entropy loss. Our cases are divided into three categories. The failure is determined independently for each class, and the values are then combined together. In the equation 5 [41] below, categorical cross-entropy is specified.

$$L(p, q) = - \sum W_k \times p_k \times \log(q_k), \quad (5)$$

where k is the class number (in this work, the classes are COVID-19, Normal, and Pneumonia), q is the predicted probability or softmax function of class k and W_k is the weight for class k .

6) *Screening and Localizing Pathogens*: In order to better understand the stimulation of the last convolutionary layer of the developed model, we have applied the Gradient-Weighted Classes Activation Mapping (Grad-CAM) [42] algorithm. This layer is the only one that delivers the parameters for the logistic layer of the final parameters to determine a probability distribution output. For constructing the Grad-CAM of an input file, the gradients of this layer have been used. Grad-CAM thus gives a coarse localization map that shows the most significant areas in the picture (radiological features).

IV. EXPERIMENTAL RESULTS AND DISCUSSION

In this section, we discussed the implementation phase and evaluated the classification efficiency of the proposed architecture. The performances and the characteristics of our proposed system are also compared with existing works for COVID-19 detection.

A. Experimental Process

The experiment performed in this research are described in this section.

1) *Experimental Environment*: The proposed approach uses a 0.001 learning rate and a 25-epoch number. On the 1.80 GHz Intel (R) Core i5-8265U Processor, the proposed CNN was developed utilizing *Keras* and the *Python* package with the *TensorFlow2* backend. Additionally, the experiments were conducted utilizing Google Colab's graphical processing unit (GPU).

2) *Split Data into Training set and Testing set*: We divide the data into training data, consisting of 90% (9264 images) and testing that makes 10% (1029 images). For validation, we further divide the training data again as 10%. The images were distributed randomly across the test and training datasets, ensuring that the two datasets are shared roughly evenly between the two groups. It is also crucial that the model is trained in a variety of ways. To put it in another way, it would be overfitted, which is not a good thing.

3) *Model Training Methodology*: The Adam optimizer was used to train every layer of the improvement parcel with the normal performance parameters ($\beta_1 = 0.9$ and $\beta_2 = 0.999$) using batches of size 32 and running throughout every epoch through the whole dataset. Eventually, adding an effective learning rate scheduler called "ReduceLROnPlateau" defines a lookup to control the relevance of the loss of reliability. It starts with a learning rate of 0.001 on demand.

We reduced the hyperparameter learning rate by a factor of 0.5 after 5 epochs, with no improvement recorded by the detector. We have also included an early stop to prevent the network from over-learning in the regularization step. We stopped training the model after 5 epochs because the loss score had not changed. The hyperparameters used in the proposed model are shown in Table IV.

B. Performance Evaluation Metrics

Five metrics, i.e. accuracy, sensitivity, specificity, F1-score, and precision, are used to assess the proposed system's performance. Some variables are employed in the metrics calculation, as mentioned below:

- True Positives (TPs) are the COVID-19 cases correctly estimated;
- False Positives (FPs) are pneumonia or normal cases that are misclassified as COVID-19;
- True Negatives (TNs) are correctly classified pneumonia or normal cases;
- False Negatives (FNs) are COVID-19 cases that are misclassified as pneumonia or normal cases.

Using the above mentioned variables, performance evaluation metrics can be computed as:

- Accuracy: A metric that normally expresses how the model performs across all classes. It is determined as the proportion between the quantity of right prediction to the all the number of predictions, i.e.:

TABLE IV. HYPER PARAMETERS OF THE NETWORK

Hyper Parameter	Weight
Batch size	32
Cost function	Categorical Cross Entropy
Learning Rate (LR)	0.001
LR Multiplying factor	0.5
LR Decay	5 times after a plateau
Epochs	25
Optimizer	Adam

$$Accuracy = \frac{(TN + TP)}{(TP + FP + TN + FN)} \quad (6)$$

- Sensitivity: It indicates the ratio of individuals who test positive among all those who have the diseases, expressed as:

$$Sensitivity = \frac{TP}{(TP + FN)} \quad (7)$$

- Specificity: The ratio of individuals who test negative among all those that actually do not have that disease, expressed as:

$$Specificity = \frac{TN}{(TN + FP)} \quad (8)$$

- F1-score: The F1-score is a count of a test's accuracy. This score may be interpreted as a weighted average of the precision and defined as:

$$F1 - Score = \frac{2TP}{(2TP + FN + FP)} \quad (9)$$

- Precision: The proportion of the correctly predicted positive individuals to the total number of actual positive individuals and calculated as:

$$Precision = \frac{TP}{(TP + FP)} \quad (10)$$

It is required to evaluate classification findings using graphical approaches such as the ROC curve and its general ranking, and the region below, i.e., the AUC.

C. Results Analysis

The confusion matrix enables us to quantify the metrics of our categorization study's results. The confusion matrix for the test cases of the proposed CNN framework is illustrated in Fig. 6.

The suggested approach misclassified 44 of the 1029 test images, with adequate and consistent true negative and true positive scores. As a result, the suggested CNN architecture can effectively classify COVID-19 cases.

Furthermore, the CNN classifier performance evaluation is graphically represented in Fig. 7 in terms of loss and accuracy within the validation and training phases. At epoch number 25, the training, as well as validation accuracy, is 96.6% and 95.3%, respectively. Furthermore, the validation and training loss achieved by the proposed system are 0.205 and 0.102, respectively.

The general accuracy, sensitivity, specificity, F1-score, and precision for every issue of the proposed system are

Predict	PNEUMONIA	82	1	6
	COVID19	1	232	19
	NORMAL	0	17	671
		PNEUMONIA	COVID19	NORMAL
		Actual		

Fig. 6. Confusion Matrix for the Proposed Architecture.

summarized in Table V. The proposed CNN has accuracy 96.3%, sensitivity 93%, specificity 97.4%, F1-score 92%, and precision 92% for COVID-19 cases. For normal cases, accuracy 99.2%, sensitivity 99%, specificity 99.3%, F1-score 92%, and precision 95% have been recorded. The pneumonia cases have obtained an accuracy of 95.9%, sensitivity 96%, specificity 94.9%, F1-score 97%, and precision 98%. The highest accuracy, specificity, and sensitivity are obtained within the normal cases. For example, the best F1-Score and precision have been found in pneumonia cases, along with the highest specificity value.

For better understanding, the classification measurements for every class in terms of accuracy, specificity, precision, recall, and F1-score are shown visually in Fig. 8.

In addition, ROC curves are presented between the false positive rate and thus the true positive rate to check the general performance, which is shown in Fig. 9. The AUC has been determined to be 96.6% for the proposed CNN architecture.

Experimental findings show that the proposed architecture has achieved 96.3% accuracy, 96% AUC, 97.4% specificity, 92% F1-score, 92% precision, and 93% sensitivity for the COVID-19 infected cases.

1) *Screening for Pathogens:* Grad-CAM is often referred to as a heat map that uses the gradients of an identifying and mapping to view our test dynamically. In order to highlight the significant portions within the image for forecasting, a rough localization map is generated after passing into the last layer. The most important region (processed attributes) from which

D. Comparative Assessment

The investigation of the outcomes demonstrates that a CNN architecture is highly effective in detecting COVID-19 by sustaining automated feature removal from CXR images. As a result, our proposed approach can separate COVID-19 from normal and pneumonia cases with significant accuracy.

Moreover, to compare the presented framework with existing frameworks, we have re-constructed the methods used in [15], [20], [22] and [23]. All the models are evaluated on the same training, validation, and testing data set to guarantee the fairness of the comparison. Table VI shows a comparative analysis of our system with the above works. Graphical comparisons of the proposed approach with [15], [20], [22] and [23] is shown in Fig. 11.

To assess the performance of our suggested system, we compared the execution results of some existing models to the results of our model, as shown in Table V.

As shown in Table VII, our suggested COVID-19 detection model outperformed a number of other state-of-the-art detection frameworks. Note that it is not feasible to check the performance of the suggested framework with other existing frameworks because of the number of test images; furthermore, because the data sources do not seem to be the same. Accordingly, the correlation between these frameworks is for expository purposes. However, it demonstrates the capability of our methodology in this undertaking. From Table VII, we can

state that the results of our proposed framework are generally better than most of the existing frameworks. More specifically, our framework achieves the highest accuracy, F1-score and precision, while it is within a percentage point of the maximum specificity and sensitivity achieved by other methods.

V. CONCLUSION

This study designed a deep CNN-based system to classify chest X-ray images to detect COVID-19 cases, pneumonia, and healthy cases. To identify COVID-19 cases, we used CNN as a motif identifier. The proposed approach has successfully isolated COVID-19 cases from the normal cases and can produce 97% specificity, 96.3% accuracy, 96% sensitivity, 96% F1-score, and 96% precision. The empirical result shows that our proposed framework achieves better accuracy than existing works, and the radiologists assess these performances. In addition, the system is ready to be tested with a more extensive database. It can be employed in local areas where people are affected by the COVID-19 to overcome the lack of expert radiologists.

The suggested framework has a limitation in using a small number of X-ray images for the COVID-19 cases. Future work, which is already under way at the time of writing, includes running our experiments on more such X-ray images from remote hospitals to make our model robust and effective.

BERT-based Approach to Arabic Hate Speech and Offensive Language Detection in Twitter: Exploiting Emojis and Sentiment Analysis

Maha Jarallah Althobaiti
Department of Computer Science
College of Computers and Information Technology
Taif University
Taif 21944, Saudi Arabia

Abstract—The user-generated content on the internet including that on social media may contain offensive language and hate speech which negatively affect the mental health of the whole internet society and may lead to hate crimes. Intelligent models for automatic detection of offensive language and hate speech have attracted significant attention recently. In this paper, we propose an automatic method for detecting offensive language and fine-grained hate speech from Arabic tweets. We compare between BERT and two conventional machine learning techniques (SVM, logistic regression). We also investigate the use of sentiment analysis and emojis descriptions as appending features along with the textual content of the tweets. The experiments shows that BERT-based model gives the best results, surpassing the best benchmark systems in the literature, on all three tasks: (a) offensive language detection with 84.3% F1-score, (b) hate speech detection with 81.8% F1-score, and (c) fine-grained hate-speech recognition (e.g., race, religion, social class, etc.) with 45.1% F1-score. The use of sentiment analysis slightly improves the performance of the models when detecting offensive language and hate speech but has no positive effect on the performance of the models when recognising the type of the hate speech. The use of textual emoji description as features can improve or deteriorate the performance of the models depending on the size of the examples per class and whether the emojis are considered among distinctive features between classes or not.

Keywords—Deep learning, hate speech detection; offensive language detection; sentiment analysis; transformer-based model; BERT; emoji

I. INTRODUCTION

The pervasiveness of hatred and offensive content on the internet has become disturbing, raising an alarm over negative consequences for the target individuals' mental health and the internet society's well-being [1], [2]. Online hateful and offensive language detection aims to make the internet not only accessible but also safe, as hateful speech online threatens society by encouraging hate crimes [3]. It also enables the scientific analyses of such abusive languages, covers their causes, and establishes possible solutions. Thus, in recent years, Artificial Intelligence (AI) and Natural Language Processing (NLP) communities have investigated various techniques as potential solutions for automatically detecting offensive language online with high performance [4], [5], [6], [7], [8], [9], [10].

Recently, a series of workshops and shared tasks have been conducted to explore the problem from various perspectives.

Significant attention has been given to defining the problem and investigating the automatic detection techniques of offensive language with all its types and ways, including abuse, aggression, cyberbullying, and hateful content. For example, in 2018, there was the first workshop on Trolling, Aggression and Cyberbullying (TRAC-2018) [11], [12]. In addition, there have been a series of five workshops on online abusive language and harms since 2017 [13], [14], [15], [16], [17]. The sixth edition of this workshop (6th WOA) will be held on July 14th with the 2022 Annual Conference of the North American Chapter of the Association for Computational Linguistics (NAACL) [18]. Two editions of shared tasks on offensive language identification were organised at the international workshop on Semantic Evaluation (SemEval) in 2019 [19] and 2020 [20]. Regarding Arabic, there was a shared task on offensive language detection for Arabic at the 4th workshop on Open-Source Arabic Corpora and Processing Tools (OSACT4) [21]. Another shared task on fine-grained hate speech detection on Arabic Twitter will be held on 20 June at the 5th workshop on Open-Source Arabic Corpora and Processing Tools (OSACT5) co-located with LREC 2022 [22].

Several categories have been adopted to define aggressive languages in online content. Among them, [23] classifies online content into hate speech, offensive, neither offensive nor hate-speech, while [24] classifies online content into abusive, hateful, normal, or spam. The study of [25] classifies online comments as racist, sexist, or neither. In addition, [4] proposed a typology of all works that have been grouped under the label of hate speech, cyberbullying, and online abuse. They synthesised the work on online abusive language in a two-fold typology that considers whether (a) the abuse is directed at a specific target and (b) the degree to which it is explicit.

In this study, we propose methods for the following three tasks: (a) offensive language detection (identifying whether a tweet is offensive or not), (b) hate speech detection (i.e., identifying whether a tweet has hate speech or not), and (c) fine-grained hate speech detection (i.e., identifying and recognising the type of hate speech: disability, gender, ideology, race, religion, or social class). We utilise the dataset released by [26] which contains 12,698 Arabic tweets annotated for the three aforementioned tasks. We also investigate the use of two conventional machine learning techniques: Support Vector Machine (SVM) and Logistic Regression (logit). We also explore Bidirectional Encoder Representations from Trans-

formers (BERT), a state-of-the-art transformer-based machine learning technique for deep-contextualised word representation. In addition, sentiment analysis and emoji description are explored as potential features that can be utilised in training any model to improve its performance, as our intuition indicates that hate speech and offensive language mostly express negativity which can be exploited. The contributions of this study are summarised as follows.

- We investigate and compare conventional machine-learning techniques and a transfer-based model (BERT) for offensive language and fine-grained hate speech detection.
- We examine the use of sentiment analysis and emoji descriptions as additional textual features for both transformer-based models and conventional machine learning methods.
- We examine our proposed methods on relatively small unbalanced data and with different preprocessing settings.
- We develop a novel and simple method for offensive language and hate-speech detection that outperforms the best benchmark systems reported in the literature with the released dataset used in our study.

II. RELATED WORK

A considerable number of studies for detecting online hate speech and offensive language have been suggested and investigated in the literature in the past ten years but intensively since 2017 [27], [28], [29], [30], [7], [31]. Workshops and shared tasks organised for the task of detecting and recognising online offensive language, hate-speech, and abusive content played a vital role in attracting the attention of the research community to propose potential techniques for the task [14], [13], [11], [15], [20], [18]. Many studies have examined generalised solutions for offensive language detection from online content in multiple languages, while other studies concentrated on examining the suitable features and techniques for one language, such as Greek [32], Chinese [33], Slovene [34], and Croatian [35]. Significant attention has been paid to detect offensive language from online English content [36], [5].

Few studies have been conducted to address the problem of online anti-social behaviour on Arabic; most have targeted offensive language detection, while the remaining studies have investigated the problem of hate speech detection [21], [37], [38], [39]. One of the early works, conducted by [38], targeted vulgar and pornographic obscene speech on Arabic social media using a list-based approach. They used tweets to build a list of seed words for obscene phrases. Then, they employed the list to construct three sublists of obscene words and phrases using multiple measurements, such as the Log Odds Ratio (LOR) for unigrams and bigrams. Conventional Machine Learning (ML) techniques have also been investigated for offensive language and hate speech detection [40], [41]. The most commonly used traditional ML techniques for offensive language and hate-speech detection are SVM [37], [39], [42], [43], [44], Naive Bayes [43], [44], and Logistic Regression (logit) [45], [46].

The study in [47] examined the use of FastText Deep Learning (DL) model on a dataset containing 36 million tweets to detect offensive speech. They reported that the FastText DL model outperformed an SMV classifier trained on character n-gram features. Mohaouchane, Mourhir, and Nikolov [48] explored the use of AraVec word embeddings and four DL models: Bidirectional Long Short-Term Memory (Bi-LSTM), Bi-LSTM with an attention mechanism, Convolutional Neural Network (CNN), and a combined model of CNN and LSTM. The experiments illustrated the outperforming results of the CNN over all other models. Many other architectures of deep neural networks have been investigated, such as Gated Recurrent Unit (GRU) [49], RNN [41], [45], and contextual embeddings (e.g., multilingual BERT [46], [50] and AraBERT [51]).

The results of the techniques in most of the aforementioned studies cannot be compared because every study used their own dataset and the available datasets for Arabic offensive language and hate-speech detection are limited [39], [43], [44]. However, the shared task on offensive language and hate speech detection in the fourth workshop on Open-Source Arabic Corpora and Corpora Processing Tools (OSACT4) provides a manually annotated Twitter dataset, consisting of 10,000 examples, for offensiveness (labels are: OFF or NOT_OFF) and for specifying the offensive content type of an offensive example as hate speech or not (labels are: HS or NOT_HS). This provides an opportunity to compare techniques for both tasks: offensive language detection and hate speech detection. The winning team for Arabic offensive language detection has employed an ensemble system of traditional machine learning technique (SVM) and two DL models: CNN+BiLSTM and multilingual BERT with an F1-score equal to 90.51%, while the best performing system for hate speech detection used SVM and achieved 95.2%, outperforming the second-place system by 12.9%. The winning team has attributed the performance of the winning model to the intensive preprocessing steps which included emoticons and emoji to textual description conversion, dialectal to MSA conversion, word categorisation (e.g., all animal names included in tweets were reduced to only one word.), letter normalisation, stop-word removal, and hashtag segmentation.

A study by Mubarak et al. [26] released an Arabic dataset for detecting offensive language and hate speech, consisting of 12,698 tweets. To our knowledge, this is the largest and most recent corpus so far. It was manually annotated for offensiveness, and fine-grained hate speech. In order to encourage comparisons between future studies, the providers of the dataset experimented with different transformer architectures and SVM to benchmark the dataset for detecting offense and hate speech to encourage comparisons between future studies. They fine-tuned mono- and multilingual transformer models using their training data. For the monolingual task, they utilised AraBERT and QARiB; for the multilingual models, they fine-tuned mBERT and XLM-RoBERTa. It was obvious in their reported results that monolingual models significantly outperformed the multilingual models. For offensive classification, the QARiB model achieved an F1-score equal to 82.31%, outperforming all other models, including AraBERT which came second with an F1-score equal to 80.02%. In contrast, AraBERT outperformed QARiB, achieving an F1-score of 80.14% and winning first place for hate speech detection.

III. DATASET PREPARATION

A. Dataset Description

We used the largest and most recently released dataset for offensive language and hate speech detection in Arabic [26]. The dataset consists of 12,698 tweets and defined according to the following: offensive language is a language containing any kind of impolite language such as insults, slurs, threats, and encouraging violence. Hate speech is any kind of offensive language that targets a person or group of people based on six common characteristics: disability, gender, ideology, race, religion, or social class. The task of offensive language detection was annotated using two labels OFF (offensive example) and NOT_OFF (not offensive example). Hate speech detection was annotated using two labels HS (hate speech example) and NOT_HS (not hate speech example). The fine-grained hate speech was annotated using 7 labels: HS1 (race/ethnicity/nationality), HS2 (f religion/belief), HS3 (ideology), HS4 (disability/disease), HS5 (social class), HS6 (gender), and NOT_HS (not hate-speech).

In our study, we passed the dataset through a set of preprocessing levels that started with cleaning the data to remove noise, followed by converting emoji into textual description, and then finding the sentiment of the tweet (i.e., positive, negative, and neutral) and appending the sentiment to the text of the tweet as additional textual features. Indeed, various levels of improved preprocessing have been examined when utilised with different techniques to identify their role in improving the performance of every built model.

B. Cleaning

The key component of any successful NLP application is to remove noise and reduce data sparsity as much as possible. It is well known that Arabic used in user-generated online content, including social media, is written in Arabic dialects which have many lexical, syntactic, and morphological differences, increasing the data sparsity of any corpus collected from online sources [52], [53]. In addition, online content is usually noisy, with a considerable number of tags, excessive spaces, repeated characters, Arabizi in which some people, when writing online, transliterate Arabic using Latin letters and numerals. In preprocessing step, we cleaned the text in order to reduce noise and data sparsity by the following:

- removing HTML tags and other symbols such as <LF>
- removing hashtags # and mentions @
- replacing underscore symbol _ of hastags into space
- removing URLs and retweets RT
- removing all types of diacritical marks, punctuation marks, mathematical signs and symbols
- removing repeated letters
- removing symbols different from emojis
- normalising different forms of alif into a bare alif (alif without hamzah), normalising taa' marbutah to haa' and normalising the dotless yaa' (alif maqsurah) to yaa'.

To perform normalisation and repeated letter removal, we used the AraNLP library [54].

C. Textual Emoji Description

An emoji is a pictograph embedded in text in electronic communication and web pages that conveys emotional cues, attitudes, and feelings that cannot be concluded from typed conversations. They exist in various forms such as facial expressions, common objects, animals, places, and types of weather. Thus, emojis can play an important role in the detection of offensive languages. In [55], the authors observed that the most frequent personal attack on Arabic Twitter is to call a person an animal names such as (*kalb*, “dog”)¹ and (*HmAr*, “donkey”). The same observation was reported in a previous study of [57]. In addition, some face emojis (anger and disgust) and objects (shoes) are widely used in offensive communication [57].

Converting an emoji to its textual description was one of the intensive preprocessing steps used to prepare the text before using it to train an SVM model in the study of [40]. Their SVM model achieved F1-score equal to 95% for detection of hate speech in Arabic text, ranking first in the shared task on Arabic offensive language detection in the OSACT4 workshop co-located with LREC 2020. We investigated the use of emoji descriptions as additional textual features that can be appended to tweets with the original text. Different settings can be examined, such as the technique utilised as well as the size and balance of the annotated examples for each class. We plan to investigate the importance of emojis themselves or their textual descriptions when used with deep contextualised word representation techniques, such as BERT, and compare it with other traditional ML techniques, such as SVM and logit.

We used “demoji” package in python [58] which accurately find emojis from a blob of text using data from the Unicode Consortium’s emoji code repository. After finding emojis in each tweet, we replaced them in the text with their code (i.e., textual description) equivalents. Fig. 1 shows the results of using the demoji package on a tweet from the training data. The results of the textual descriptions of emojis are in English. Thus, we utilised the Google Translate API to convert the textual descriptions from English to Arabic.

D. Sentiment Analysis

Sentiment analysis can generally be defined as the use of NLP techniques to detect, recognise, and quantify affective states and subjective information. However, the basic idea of

¹Throughout the paper, Arabic words are represented as follows: (HSB transliteration, ‘English gloss’). More details about the Habash–Soudi–Buckwalter (HSB) scheme can be found in [56]

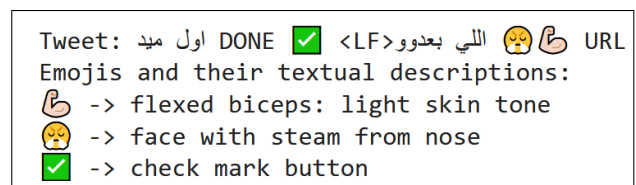

Fig. 1. Extracting Emojis form a Tweet and Finding their Descriptions.

A. BERT Model Classifier

BERT [65] is a multilayer bidirectional Transformer encoder based on the original implementation of transformer architecture introduced by Vaswani et al. [66]. The BERT model resulted in significant improvements in a considerable number of downstream tasks. Furthermore, a wide range of research works on Arabic hate speech and offensive language detection, including those participating in the 2020 shared task on Arabic offensive language detection, have proven its potential to handle the task [21]. In addition, the BERT-based model was the best benchmark system trained on the same dataset we employed in this study, allowing us to compare our proposed method with the best benchmark system.

In our study, we built a BERT-based model by fine-tuning AraBERT [67] on the training data. We selected “AraBERTv0.2-Twitter-base” variant of AraBERT that supports emojis and dialectal Arabic words. We also applied a segmentation function using Farasa to segment the text for the model. We built five BERT models for each task (i.e., offensive language detection, hate-speech detection, and fine-grained hate-speech detection), resulting in a total of 15 models. The five models were built using five versions of the dataset according to various levels of preprocessing, as previously illustrated in Table II.

B. SVM Classifier

We used word n -grams with n in the range [1, 3] weighted using Term Frequency-Inverse Document Frequency (TF-IDF). We also used character n -grams with n in the range [2, 5] only from the text inside word boundaries using token counts. The word-based TF-IDF vector and character-based count vector were used as features to train the SVM. As in the BERT model, we built 15 SVM classifiers to examine the various situations: three tasks in addition to the five levels of preprocessing the dataset to prepare it before building the models.

C. Logistic Regression Classifier

The same features used in the SVM were examined using a logistic regression classifier. Therefore, we used word n -grams with n in the range [1, 3] weighted using Term Frequency-Inverse Document Frequency (TF-IDF). We also used character n -grams with n in the range [2, 5] only from the text inside word boundaries using token counts. The word-based TF-IDF vector and character-based count vector were utilised as features to train the logistic regression classifier. The sklearn package in Python was used to train the classifier. The maximum number of iterations for logistic regression in the package was set to 100 by default. In our experiments, we increased this value to 800 iterations to obtain the trained model. Similar to the BERT model and SVM classifier, we built 15 logit classifiers.

V. EXPERIMENTAL SETUP

We used the same splits prepared by the data providers where the dataset was partitioned into three parts: 8,888 (70%) for training, 1,269 (10%) for development, and 2,541 (20%) for testing. Table III and Table IV show the distribution of offensive and hate speech data.

TABLE III. DISTRIBUTION OF OFFENSIVE AND HATE SPEECH DATA [26]

	Train	Dev	Test	Total
OFF	3,172	404	887	4,463
NOT_OFF	5,716	865	1,654	8,235
HS	959	109	271	1,339
NOT_HS	7,929	1,160	2,270	11,359
Total	8,888	1,269	2,541	12,698

TABLE IV. DISTRIBUTION OF FINE-GRAINED HATE SPEECH DATA. “N.A.” STANDS FOR NOT AVAILABLE

	Train	Dev	Test
HS1	260	28	N.A.
HS2	27	4	N.A.
HS3	144	14	N.A.
HS4	1	0	N.A.
HS5	72	10	N.A.
HS6	456	52	N.A.
NOT_HS	7928	1161	2,270
Total	8,888	1,269	2,541

At the time of writing the paper, the gold-standard labels for the training and development sets were publicly available, whereas only the tweets of the test set were available without the gold-standard labels. The providers of the data, however, accepted our request and helped us evaluate our best-performing model on the labelled test set and provided us with the results of our best performing model for all three tasks. Therefore, we utilised the results of our built models evaluated on development set in order to compare between them and to evaluate the various preprocessing settings we suggested in this paper. Next, the results of our best-performing model when evaluated on the test set were then compared with the benchmark systems [26] that were trained and tested using the same dataset we used in this study. The employed evaluation metrics in our study are macro-averaged precision, recall and F1- score, in addition to accuracy.

VI. RESULTS AND DISCUSSION

The results of the SVM classifiers evaluated on the development set for the three tasks are presented in Table V. These classifiers are trained on the versions of the dataset resulting from the five different levels of preprocessing: Orgi (original tweets), CLN (after cleaning tweets from noise), CLN+SA (after cleaning and appending the sentiment of the tweet to its text), CLN+EmoTxt (after cleaning and replacing emojis with their textual descriptions), and CLN+Emotxt+SA (after cleaning, replacing emojis with their textual descriptions, and appending the sentiment of the tweet to its text). We used the macro-averaged F1-score to rank the various classifiers for each task. For offensive language detection, we observe that the SVM classifier leads to the best results after cleaning the dataset, replacing emojis with their textual descriptions and appending the sentiment of each example to its text. For hate speech detection, the best performing SVM classifier is obtained using sentiment analysis, but without the need for emojis conversion. For fine-grained hate speech detection, it

is sufficient to clean the dataset from noises before training the SVM classifier in order to obtain the best results of the algorithm for the task.

The results of the logistic regression (logit) classifiers for the three tasks are presented in Table VI. The logit classifier for hate speech detection achieves the best performance when using sentiment analysis as well as cleaning noisy data, yielding an F1-score of 67.77. Both SVM and logit classifiers require the same preprocessing level (CLN+SA) to achieve the best performance. For offensive language detection, the use of emojis conversion and sentiment analysis when preparing the dataset plays an important role in obtaining the best performing logit classifier, achieving an F1-score equal to 76.50 (slightly better than the best SVM classifier for the same task which achieves F1-score = 76.28). For fine-grained hate speech detection, the only required preprocessing of the data to build a logit classifier with the best performance is to clean the text from noise. In fact, the use of sentiments as additional features or converting emojis into their textual code leads to a decline in the performance of the built classifier. This observation matches what we noticed with the SVM classifiers for fine-grained hate speech detection.

The BERT models outperformed all other SVM and logistic regression classifiers regardless of the preprocessing level used to prepare the dataset, as shown in Table VII. The best performing BERT models achieved an F1-score equal to 85.93, 81.89, and 48.72 for offensive language detection, hate speech detection, and fine-grained hate speech detection, respectively. Regarding the optimal preprocessing steps that can be applied to the dataset before training to improve the model's performance regardless of the utilised ML technique, we observe

that CLN+EmoTxt+SA (i.e., cleaning the data, converting emojis to textual words, and appending sentiments as additional textual features) always improves the performance of the model for the offensive language detection task. This can be attributed to the fact that offensive language detection is considered easier than detecting hate speech or identifying the exact type of hate speech. In offensive language detection, every tweet that contains an impolite language, including hate speech, is considered offensive language according to the annotation guidelines followed by the providers of the dataset [26]. Therefore, adding additional features, such as textual descriptions of emojis or sentiments, to each tweet will confirm the boundaries that should be learned by the algorithms to distinguish between normal and offensive tweets. That is, almost all offensive tweets have the sentiment "negative" added as additional features, while normal tweets usually have "positive" or "neutral" sentiments added as additional features. Emojis on the other hand are also considered distinctive features in the case of offensive language detection as offensive emojis that express anger and disgust are not commonly found in normal tweets (i.e., not offensive). Thus, converting emojis to textual descriptions increases the number of additional distinctive features. That is, instead of having only one emoji, we will have, by converting emoji to description, a phrase with words expressing anger and disgust. In contrast, the CLN+EmoTxt+SA usually has a fluctuating impact on the performance of the model for the task of hate speech detection, as it sometimes slightly improves the performance of the model as seen in Table V and Table VII, and sometimes deteriorates the performance of the model, as shown in Table VI. However, CLN+EmoTxt+SA did not allow the model to achieve the

best performance. This can be attributed to the fact that hate speech in the utilised dataset is considered a type of offensive language. That is, a tweet may contain impolite language and is considered offensive but not “hate-speech”. Also, the general unbalance between various classes in the dataset, as seen in Table III, is more obvious in the case of hate speech as there are few annotated hate speech examples compared to not-hate-speech examples. Therefore, converting emojis to textual descriptions actually increases data sparsity and cannot be seen as a vital preprocessing step in the case of hate speech detection, as seen in Tables V, VI, and VII. In the case of fine-grained hate speech detection, there are six types of hate speech, and there is a huge unbalance between the number of annotated examples for these types. For example, we have 260 tweets labelled as “HS1” (race/ethnicity/nationality), 27 tweets were annotated as “HS2” (religion/belief), and 7,928 were annotated as not-hate-speech. Therefore, the preprocessing step of emoji conversion does not have a significant positive effect on the overall performance of the model, as it may increase the data sparsity, especially for unbalanced datasets with few annotated examples and overlapping classes. However, we observe that cleaning the data improves the performance of the model, regardless of the utilised training algorithm. In addition, the use of sentiments as additional features appended to the tweet’s text has a good impact on the overall performance of the model. This positive impact is less obvious when the number of annotated examples is insufficient, to distinguish between a large number of overlapping classes, such as in the case of fine-grained hate speech detection.

The best performing model (BERT model) for each task was selected to be evaluated on the test part of the dataset. The results are presented in Table VIII, which shows that

our best performing model with its suggested preprocessing levels outperforms all other benchmark models for two tasks: offensive language detection and hate speech detection [26]. The study in [26] did not provide a benchmark system for fine-grained hate speech detection. However, our proposed BERT-based model achieved an F1-score equal to 45.10% on the test set. The precision, recall, and accuracy were 48.20%, 46.10%, and 92.10% respectively.

VII. CONCLUSION

In this study, we proposed an automatic method for detecting offensive language and fine-grained hate speech from Arabic tweets. We compared BERT with two conventional machine learning techniques (SVM and logistic regression). We also investigated the use of sentiments and textual descriptions of emojis as appending features in the dataset, along with the textual content of the tweets. The experiments clarified that the BERT-based model results in the best performance, surpassing the best benchmark systems in the literature, for all three tasks: (a) offensive language detection with an 84.3% F1-score, (b) hate speech detection with an 81.8% F1-score, and (c) fine-grained hate-speech recognition (e.g., race, religion, social class, etc.) with a 45.1% F1-score. Analysing the sentiment of each tweet and using it as a feature slightly improves the performance of the models when detecting offensive language and hate speech, but has little positive effect on the performance of models for recognising the type of hate speech. The use of textual emoji descriptions as features can improve or deteriorate the performance of the models depending on the size of the annotated examples per class and whether the emojis are considered distinctive features between classes. That is, when the number of annotated examples is limited while the classes overlap in the feature space, emojis may not be considered as distinctive features, and converting them to their textual description as additional features may increase the data sparsity and, therefore, deteriorate the performance of the model. However, our proposed models and various levels of preprocessing lead to better results than the benchmark systems reported in the previous study.

A Survey of Sink Mobility Models to Avoid the Energy-Hole Problem in Wireless Sensor Networks

Ghada Al-Mamari, Fatma Bouabdallah, Asma Cherif

King Abdulaziz University
Jeddah, Saudi Arabia

Abstract—Wireless Sensor Networks (WSN) refer to networks where the sensors are deployed in an environment to sense and select data. WSN sensor nodes have limited power and cannot be recharged easily. Consequently, the faster sensor nodes to deplete their energy budget are those close to the sink as they have to relay all data emanating from any sensor in the network. Thus, a hole of energy around the sink is created as the sink coverage nodes have drained their initial energy thus leading to sink unreachability. The WSN lifetime maximization problem has always been a hot research topic. Collecting data in WSN using a mobile sink is an efficient approach for achieving WSN longevity and preventing the energy hole problem. However, finding the optimal trajectory along with its appropriate flow routing is a challenging problem since many constraints should be considered. This paper discusses and compares several existing WSN-lifetime-maximization using sink mobility solutions. These solutions are mainly classified into two types: Linear Programming and Artificial Intelligence-based solutions. The state-of-the-art solutions are compared in terms of network topology, sojourn points and duration, buffer size, and overhearing. Finally, a discussion of the WSN lifetime maximization constraints is provided to define a promising sink mobility model.

Keywords—Energy hole problem; mobile sink; wireless sensor networks; linear programming; artificial intelligence

I. INTRODUCTION

Now-a-days, Wireless Sensor Networks (WSN) are used to sense and collect data from many environments that are not easy to reach. WSN consists of: (1) a sink node, which oversees collected data from the wireless sensor nodes for further processing, and (2) many sensor nodes usually scattered in a harsh environment to collect data and deliver it to the sink to serve a given application such as environmental monitoring [1] and military applications [2]. Wireless Sensor nodes rely on batteries power. Once they are scattered, it is hard to replace or recharge the batteries. Therefore, maximizing the WSN lifetime by optimizing nodes' energy is crucial.

The sensor nodes close to the sink are always responsible for forwarding other distant nodes' data to the sink. Consequently, due to this burdening, they are usually the earliest nodes that deplete their energy, while the other sensor nodes still have a good amount of energy [3]. Furthermore, if the sensors that are closer to the sink drain their energy budget, they create an energy hole around the sink. Fig. 1 illustrates the energy hole problem caused by the batteries' depletion of sensor nodes within the sink coverage (nodes with a red

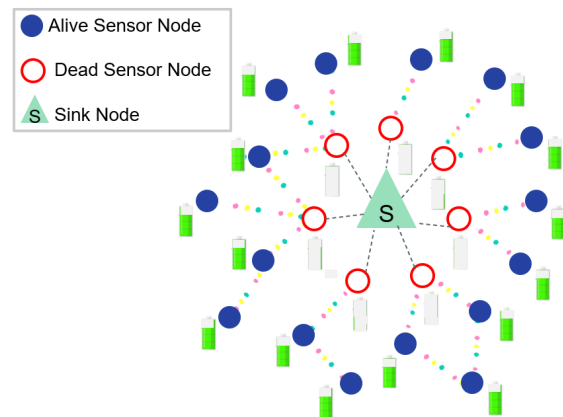

Fig. 1. Wireless Sensor Network and the Energy Hole Problem

border). If this energy hole occurs, the sink will become unreachable, and hence, the network is no longer operable as it won't be able to deliver the sensed data to the sink for further processing. To overcome this issue, many approaches have been proposed such as assigning sensor nodes multiple transmission power, nonuniform initial energy budget distribution, and sink mobility [4] (see in Section II). This survey focuses on maximizing WSN by exploiting sink mobility. Thus, the sink can move and stop at many points in the network to receive sensed data. Besides the sink mobility, the appropriate flow routing is defined to balance the energy consumption between sensor nodes.

This work considers only the algorithms that apply to delay-tolerant networks. This means that, when the sink is at location i , only the sensor nodes within the transmission range of the sink at this location can transmit their data, while the others have to delay their transmissions. So, in one round the sink has to collect data from all the nodes and returns back to its first location in D time which is the maximum delay-tolerant time [5].

The remainder of the survey is organized as follow: Section II presents some proposed approaches to overcome the energy hole problem, and the main constraints that are considered in WSN. Section III, IV and V discuss the most cited linear programming-based (LP-based), artificial intelligence-based (AI-based) and other solutions that are neither LP-based nor AI-based for maximizing the WSN lifetime using

a single mobile sink. Moreover, a comparative study among these existing WSN-lifetime maximization approaches will be conducted in Section VI. Finally, in section VII, we discuss some additional constraints that impact the WSN lifetime in order to define an optimal mobile sink solution that maximizes the network lifetime and other future research directions.

II. MITIGATING ENERGY HOLE PROBLEM APPROACHES

WSN nodes have limited resources (e.g., transmission range, buffer size, and batteries). Due to the battery constraint, the sink coverage nodes are the first nodes that deplete their energy due to the burdening of the relaying task from the distant nodes, causing the energy hole problem. Therefore, the energy hole problem is addressed in many research works. Many approaches had been proposed to mitigate the energy hole problem as shown in Fig. 2 such as: assigning sensor nodes multiple transmission power, nonuniform initial energy budget distribution, and sink mobility [4].

First, in the multiple transmission power approaches, to balance the energy consumption among sensor nodes in the WSN, two or three hops away sensors can send data to the sink directly by passing one or two hops away sensors. As a result, the sink coverage nodes are highly alleviated from the relaying task, and hence the WSN lifetime is improved. [6] and [7] proposed two different routing protocols that both aim at allowing the sensor nodes to either send a message to its immediate neighbors or send it directly to the sink node. Simulation results show that both protocols achieve longer network lifetime especially compared to the nominal transmission range solution. Regarding the nonuniform initial energy budget distribution approach, the sensor nodes that are closer to the sink are given a higher amount of energy than distant nodes. So, the sink coverage nodes will not die quickly because they have a higher energy budget. Nevertheless, their lifetime is always constrained as they have to forward all the remaining nodes data messages. Finally, the third approach considers a mobile sink that moves between the sensor nodes to relieves the sink coverage nodes from their heavy relaying task and aims at balancing the energy consumption among WSN sensor nodes such that every node will drain its energy budget smoothly and uniformly throughout the network. In our survey, we focus on work related to exploiting the sink mobility for

distribute the energy consumption hence maximizing the WSN lifetime.

It is worth noting that most of the reviewed papers agreed on three main constraints that describe the behavior of sensors and the sink in WSN, these constraints must be fulfilled to make the WSN work correctly. The constraints for the sensor node were defined as follows:

- The energy constraint: the total energy consumption at a node i due to the reception and transmission of data over the network lifetime T must not exceed its initial energy.
- The flow conservation law between sensor nodes: for any node, the sum of total incoming flow rates plus the self-generated data rate must be equal to the sum of the resulting outgoing flow rates at time t

As for the constraint related to the sink, it is defined as follows:

- The total traffic going into a sink in a duration of time must be equal to the amount of total generated data from all sensor nodes in that duration.

III. LINEAR PROGRAMMING-BASED SINK MOBILITY MODELS

After extensive research, we end up reviewing many papers that have proposed different sink mobility models using different approaches. We classified these research works as Linear Programming-based (LP-based), Artificial Intelligence-based (AI-based), and other sink mobility models as shown in Fig. 3.

In this section we will start discussing the LP-based models.

A. Exploiting a Single Mobile Sink

Many researchers proposed WSN maximization models that used a single mobile sink to collect data from WSN sensor nodes. These models are classified based on the decision-making placement as centralized and distributed solutions. They also vary based on their movement as discrete and semi-continuous.

Y. Yun et al. [8] formulated a distributed algorithm for the WSN-lifetime maximization problem. First, they convert the WSN lifetime maximization problem into a network flow problem on an expanded graph. For each possible sink location, correspond an expanded graph G_l , and a set of coverage nodes are defined. A path links each node in G_l to the sink. For each G_l , the sink takes T time to collect data from all sensors in that graph. So, the problem of WSN lifetime maximization is to maximize the number of sink tours T . The authors formulated the main three constraints of WSN as a linear problem to minimize the WSN maximum energy consumption. Then, they divided the problem into sub-problems using the fractional knapsack problem. Thus, they develop a distributed algorithm to decide at each node whether data should be transmitted to the sink or buffered locally. The distribution of the algorithm allows the solution to be built-in network protocols, and the decisions can be made at each sensor. The authors proved

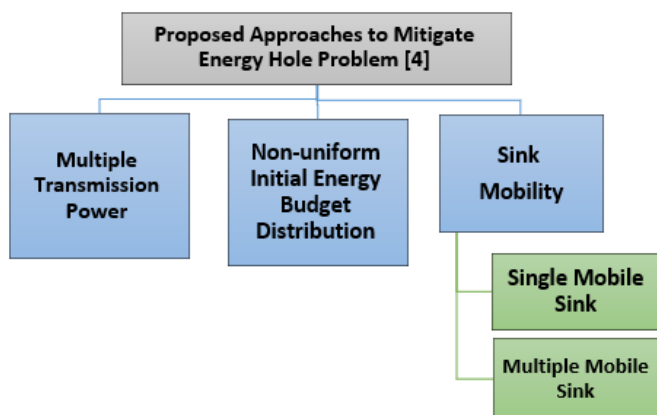

Fig. 2. Proposed Approaches to Mitigate the Energy Hole Problem

Fig. 3. Taxonomy of Reviewed Sink Mobility Models.

the efficiency and convergence to the optimal value. Moreover, they measured the Lyapunov drift at every iteration and proved that the queue size is bounded from above, which is equal to the maximum delay time D , and the average value of the total queue size has increased along with iterations. As a result, the increasing D will increase $T \times D$, which is the WSN lifetime.

On the other hand, many centralized sink mobility models were proposed. For instance, [9] proposed a joint algorithm to determine the sink movement and sojourn duration in a grid network topology. The suggested algorithm states that, when a sensor node is located at the same vertical or horizontal line as the sink, there is a single unique path between them which is the direct one. Otherwise, only the two routes are considered with equal hop count revealed by the rectangle boundary defined by a sensor i and the sink. To generate the energy model of their algorithm, a pair of horizontal and vertical dotted lines to enclose the nodes associated with the column and the row of the sink in the network is defined resulting in eight sub-areas of the grid as shown in Fig. 4: UL (Upper Left), UR (Upper Right), HL (Horizontal Left), HR (Horizontal Right), VA (Vertical Above), VB (Vertical Below), LL (Lower Left), LR (Lower Right).

Given a grid topology of size L (L being equal to the square root of the sensor nodes number), a sensor node i , its

sub-area, and position (i.e., column and row indexes (x, y)), the energy consumption is calculated as follows:

$$C_i^k \begin{cases} er[(x+1)(1+L)-1], & \text{if } i \in HL \\ er[(L-x)(1+L)-1], & \text{if } i \in HR \\ er[(y+1)(1+L)-1], & \text{if } i \in VA \\ er[(L-y)(1+L)-1], & \text{if } i \in VB \\ er(1+x+y), & \text{if } i \in UL \\ er(L-x+y), & \text{if } i \in UR \\ er(L+x-y), & \text{if } i \in LL \\ er(2L-x-y-1), & \text{if } i \in LR \\ er[(x+1)(1+L)-1], & \text{if } i \in HL \\ er, & \text{if } i = k \end{cases}$$

To find the optimal sojourn times at the grid cells that maximize the network lifetime, this energy model is converted to a linear programming model as follows:

$$\begin{aligned} \text{Max } z &= \sum_{k \in N} t_k \\ \text{Such that } \sum_{k \in N} C_i^k \times t_k &\leq e_0, & K \in i \\ t_k &\geq 0, & K \in N \end{aligned}$$

where the WSN lifetime denoted by z is the sum of all sink sojourn duration t_k (in seconds) at all sojourn points k , e_0 is the node's initial energy (in Joules), and C_i^k is the energy consumption of data transmitted in node i while the sink sojourns at position k (in Joules/bit).

Finally, the authors implemented their solution using LINGO [10] and provided visualization of the sink sojourn duration and the nodes' energy consumption during the network lifetime. The results showed the sink sojourn duration follow a pattern that is distributed between the four corner nodes of the two-dimensional grid. This pattern achieves a balanced energy consumption among sensor nodes, thus maximizing the WSN lifetime. As a limitation, there is a computational overhead for finding the optimal sojourn points and duration.

It is worth noting that the previously-mentioned solutions propose discrete mobility models. Other works such as [11] and [12] proposed a semi-continuous novel flow routing solution to solve the Unconstrained-Mobile Base station (U-MB) problem, wherein the base station is continuously roaming anywhere in the WSN environment. This proposed algorithm is driven from the Constrained-Mobile Base station (C-MB) problem, where the base station can only move to predefined points. Once the authors realize and prove the conversion from the temporal optimization problem to the location-based one, they drive a solution for the C-MB and prove that it converges to the $(1 - \epsilon)$ optimal solution. To do so, they convert the infinite number of mobile base station locations to a finite number.

First, the base station movement space is narrowed down to the smallest enclosing disk (SED) for all WSN nodes. Then, the SED is divided into subareas as follows: The possible minimum distance D_{min} and maximum distance D_{max} between

Fig. 4. Divided Subareas, and Data Flows Received and Transmitted at Node i [9]

Fig. 5. WSN with Four Nodes and their Divided Sub-Areas [11].

each node i within the SED and the base station is calculated. Then, several H_i circles are drawn with a common origin at the sensor node i . The first circle's radius $D[1]$ equals to D_{min} , and the second equals to $D[1] \times (1 + \epsilon)^h$ (as shown in Fig. 5). Generally speaking, since $D[h] = (D[1] \times (1 + \epsilon)^h)$, then the energy cost can be discretized following the geometric sequence with a factor of $(1 + \epsilon)$ for each circle. The intersections between all circles of all nodes are the divided subareas. Each sub-area is presented by the fictitious cost point (FCP), which is the cost vector that embodies the upper bound of the cost of any point within this sub-area to any other node in the network. These FCP are not physical points, but they are fictionally used to prove the $(1 - \epsilon)$ -optimality of the algorithm.

Finally, the C-MB solution is applied using the FCPs in the U-MB problem. This work proved that the total sojourn duration for the base station in each sub-area is maximizing the WSN lifetime is greater than the C-MB optimal lifetime and $(1 + \epsilon)$ U-MB lifetime. This guarantees that the suggested algorithm lifetime is at least $(1 + \epsilon)$ far from the optimal lifetime obtained by the U-MB algorithm. We believe that the proposed solution will be better if it considers the optimal path for the base station mobility. Indeed, choosing the shortest path will minimize the travelling time between FCPs and the nodes' buffer size, thus maximizing the WSN lifetime.

B. Exploiting a Mobile Relay or a Special Property

Other researchers propose to use more than one mobile entity to collect data, which we refer to in our survey as the mobile relay. Moreover, some works exploit a special property (such as recharging batteries) to make the mobile entity collect data more efficiently.

In [13], the authors proposed a framework to investigate the wireless sensor network lifetime maximization based on the graph model using joint discrete sink mobility and routing problem. First, they expanded the network as two graphs: on-graph and off-graph. On-graph is when the sink is co-located at a sensor node location, while off-graph is when the sink is not. The authors proved that using predefined sink sojourn points with variant sojourn duration for the sink is a simplified version of the Maximizing the Network Lifetime (MNL) problem. Consequently, they formalized a linear program solution for the MNL problem using a single mobile sink (MNL-SMS) for the on-graph case. Then, they formulate the Primal-dual

algorithm for the set of paths between a node i and the sink, and the set of paths that go through the node i in the k^{th} sink sojourn duration after reformulating it as a path-flow. They used an extension of the Floyd–Warshall algorithm to compute the all-pairs shortest path. The resulted paths are organized into clusters, each containing paths with the same end. Then, they run a search algorithm to find the best sink sojourn duration t_k that achieves minimum energy consumption. Consequently, they generalized the primal-dual algorithm to the MNL problem using multiple mobile sinks.

Finally, they proved that using a sink layout schedule will maximize the WSN lifetime longer than maximizing the WSN lifetime by any sink with a fixed layout and referred to this problem as the TO MOVE OR NOT TO MOVE (TMNTM) decision problem. Moreover, they found that the mobile sink in the on-graph case relieves the forwarding load from the co-located sensor node and thus saves the energy consumption of that sensor node. However, the suggested algorithm still has a high computational complexity even though it is an approximated version from the Floyd–Warshall algorithm.

In [14], the authors investigated the WSN lifetime achieved using either a mobile relay or a mobile sink and their trade-offs. The mobile relay is a sensor node with unlimited energy (i.e., batteries can be replaced or recharged). First, the authors compute the WSN lifetime achieved by a static routing when the sensor nodes are all static and know the relay node location. In this case, the optimal data routing schedule is determined by sorting the static nodes' lifetime in ascending order. Then, these nodes are visited accordingly to collect data. As for the dynamic routing, where the static nodes don't know the relay node's current location to send their data, the authors proposed a linear programming model for the data routing while assuming that the relay node is co-located with a static node. The author proved that using the mobile sink will maximize the network lifetime better than the relay node. But, sometimes, it might not always be possible for the sink to be mobile as in hostile terrains. In this case, using a mobile relay will be efficient. Consequently, using a mobile relay along with a mobile sink will maximize the WSN lifetime four times compared to using a static sink. For achieving this, the mobile relay has to stay two-hop away from the sink. The authors constructed a joint mobility and routing algorithm. When the sink modifies its position, it will select a new node as an aggregation node marked to send its new position to all sensor nodes in the network. Nodes in the one-hop radius of the sink (P_1) send data to the sink directly. Those outside P_1 require to know the location of the mobile relay to send data to OM line, O being the position of the sink and M that of the mobile relay. As such, this data will be sent to the aggregation node through OM , then to the sink, which is called an Aggregation Routing Algorithm (ARA). Finally, the authors showed through simulation how using a mobile relay with a mobile sink maximizes the WSN lifetime. This approach is efficient because it applies to large-scale networks with a high density of nodes. However, since two mobile entities are used (a mobile sink and a mobile relay), building a new routing incurs more communication and computation overhead since the routing changes when their positions are changing.

Xie L et al. [15] step forward by proposing a mathematical

model to move the Wireless Charging Vehicle (WCV) which is used to both collecting data and recharging the sensor nodes. The main goal of designing their model is to minimize the entire system's energy consumption. This goal is reached by the following: 1) minimizing the energy used to move the WCV along the predefined path, which is equivalent to the maximization of the ratio of the WCV vacation time to its travelling time; and 2) minimizing the energy rate used to charge the sensor nodes, which will vary depending on each node and its distance to the WCV. Thus, to achieve these two goals, the authors proposed a mobile WCV travel path that minimizes the WCV energy while ensuring data collection from nodes and recharging all sensor nodes in a balanced manner. Beside the three main constraints in WSN they defined their own: time constraint and energy criteria constraint. The time constraint imposes that the WCV total travelling time which depends on the path distance and the velocity of WCV plus the total stopping time must be less than the WCV vacation time. As for the energy criteria constraint, it dictates to ensure that each sensor node energy which equals E_{max} at the beginning of the network ($t = 0$) must be fully charged back to E_{max} at any time of the renewable cycle before its end. Based on these constraints, the authors developed a time-dependent optimization problem. However, since the time-dependent problem is an NP-hard problem, they solved it by considering a special case of the problem that depends on the WCV's location (space-dependent) instead of the time dependency and they replaced each time variable by a space variable. Then, they proved that the time-dependent solution is equal to the space-dependent solution by showing that for any value achieved by a time-dependent feasible solution (in a time t), there is a same value achieved by the space-dependent feasible solution (in location p). That being said, the space-dependent problem has an infinite number of stop points in the WCV travelling path. So, to find the near-optimal solution, they discretize the path into a finite number of segments and assign a logical point to each segment. Then, the upper bound of each segment is determined by calculating the best case (where a node has a minimum energy consumption and is charged by the maximum energy). On the other hand, the lower bound corresponds to the worst-case (i.e., a node has a maximum energy consumption and is charged by the minimum energy). Afterwards, the gap between these two bounds is calculated; if it is not small enough, then this segment is discretized until reaching a gap within $(1 - \epsilon)$ between upper bound and lower bound. The authors proved that their algorithm finds the threshold between collecting data and recharging the sensors, and of course, this makes the WSN work continuously. A summary of all these LP models is provided in Table I

IV. ARTIFICIAL INTELLIGENCE-BASED SINK MOBILITY MODELS

In this section we will present several artificial intelligence solutions proposed to solve the energy-hole problem. Some of them are applied to the cluster-based network model while the others consider a non-cluster based architecture.

A. Non-Cluster based Models

Anwit et al. [16] proposed a variable-length chromosome genetic algorithm to find the optimal set of sink sojourn

TABLE I. SUMMARY OF LP-BASED SOLUTIONS

Ref No.	Key Concept	Advantages	Limitations
With Exploiting A Single Mobile Sink			
[8]	Distributed sink mobility algorithm. Execute locally, in parallel at each node.	It is a distributed algorithm, that means lower computation overhead	
[9]	A joint algorithm to defined sink movement, and sink sojourn duration.	Balance the energy consumption	Overhead of computation and communication is high
[11]	Continuous sink mobility solution by deriving a solution for (U-MB) problem from the (C-MB) problem solution. (Shi Y, 2012)	Near to the $(1 - \epsilon)$ optimal solution	It has a polynomial complexity
With Exploiting A Mobile Relay or A Special Property			
[13]	A primal-dual algorithm that generalized the single mobile sink solution to the multiple mobile sink problem. (Luo J, 2010)	The algorithm gives jointly mobility and routing solution for lifetime maximization, and it applies to many network topologies.	Has a computational complexity and it is not suitable for line network
[14]	Maximizing WSN lifetime using a mobile relay by determining his optimal mobility area to collect data. (Wang W, 2005)	It is appropriate to the large-scale networks that have a high density of nodes	Has a high overhead of computation and communication since there are two mobile entities.
[15]	Moving wireless charging vehicle (WCV) that used to recharge nodes and collect data from them, by developing a space-dependent algorithm.	They used WCV to recharge sensor nodes while trying to maximize the WSN lifetime.	The path must be predefined, the algorithm only found the sojourn points that maximize the WSN lifetime.

points and their locations. They applied their algorithm as follows: First, they start by generating a variable number of chromosomes from size $(0.2 \times \text{the number of sensor nodes in the WSN } (n))$ to size $(0.5 \times n)$. Each chromosome consists of a sequence of IDs numbers of random sojourn points' locations. After that, for each chromosome, they generate a population with fixed-sized. To evaluate these chromosomes, a balance between two factors is necessary. The first factor is the chromosome length which equals the number of sojourn points IDs in this chromosome. The second factor is the mobile sink path length, which is the total distance that the mobile sink cross when it moves through all these sojourn points. A high number of sojourn points may produce a longer path while there is a shorter path covering the same nodes. However, a small number of sojourn points may result in a longer path that uncovers some sensor nodes. So, to ensure the compromise between these two factors, a Fitness Function is used to filter all the unfit chromosomes that do not satisfy the threshold between making the sink path short but covering all nodes. the solution proceeds as follows:

- 1) One chromosome from two different populations is selected using the roulette wheel selection algorithm.
- 2) After that, the multi-points crossover technique is applied on these two selected chromosomes based on a predefined probability.
- 3) Then, the mutation operation is performed to the child chromosomes that were generated from the crossover operation. In the mutation operation, the gene position value to be changed is also selected using a predefined probability.

At the end of this cycle, the children's chromosomes are compared to their parents' chromosomes. If they are better, they replace them in the new population. Otherwise, they are rejected. This cycle repeats until a predefined termination condition is reached. Finally, the simulation results showed that the proposed algorithm outperforms the traditional Travel Salesman Problem (TSP) algorithm by reducing the path length and

the data collection time. However, the authors did not consider the energy consumption at each node and its impact on the path selection, which is the main goal of the sink mobility research.

In [17], a data collection strategy is proposed using a mobile sink that moves based on an ant colony optimization algorithm. First, the authors introduce a method to select the rendezvous nodes that can communicate directly with the mobile sink. These nodes are selected based on the entropy weight method of many indicators (e.g., the relative residual energy and density of the nodes) to select the optimal access path for the mobile sink. This optimal solution should minimize the WSN energy consumption and tolerate some delay to compensate for energy consumption. The simulation of the proposed algorithm showed the energy consumption is balanced between all sensor nodes. Nevertheless, the main limitation of this research is that the solution focuses on minimizing the whole network residual energy amount instead of maximizing the network lifetime.

Zhu et al. [18] proposed a WSN scheme inspired by the honey-comb structure to collect data from the WSN sensor nodes. First, they assumed that the first position of the sink is the WSN's centre point. Then, they divide the network into a number of hexagons, each hexagon is called a partition. Each partition must contain at least one sensor node and its side length (a) must be bigger than or equal to the power two of the sensor node's sensing radius (r^2). Besides, they established the Cartesian coordinate system in the network with an origin O located at the WSN's centre point. After the network partition, they gave each hexagon a partition ID and a direction value. Like the Cartesian coordinate, the partition ID is represented by two integers (m, n) , where m is increasing along the x -axis and n is increasing along the y -axis progressively. It is worth noting that n increases by two for the vertical partitions and by 1 for the non-vertical partitions. As for the direction, each partition's direction value is determined based on the sink position. The sink position is at the Cartesian coordinate centre point $(0,0)$ and its direction value is 0. As the suggested scheme

Fig. 6. Direction Value for Each Partition [18]

Fig. 7. Updating Directional Value for Partitions in Sink Vertical Movement Case. [18]

consists of many hexagons, each edge of the sink's hexagon is represented by a number n from 1 to 6. When the hexagon partition is located on the (n^{th}) side direction, the direction value of these partitions is equal to the (n^{th}) number. The remaining partitions have a combined direction value, i.e. the values of the surrounding partitions (e.g. the partition between partitions 1 and 2 has the value 12 as shown in Fig. 6).

Regarding the sensor nodes, they will be assigned a combined addressing values containing (i) partition ID, (ii) the direction value, and (iii) the node ID which is a unique number used to distinguish sensor nodes. Once every sensor is assigned to a given partition, then there are three aspects of this data-gathering scheme: 1) data forwarding between partitions, 2) sink moving strategy and 3) updating the direction value. For the data forwarding, the node will forward its data to the sink partition through its direction value. For the sink moving strategy, first of all, the sink has a counter to count the number of received packets; if it reaches a threshold, then the sink will move and change its location. There are three strategies for sink movement:

- 1) The random movement (RM), where the sink selects one of its partition's neighbours randomly.
- 2) The data volume-based greedy movement (DGM), where the sink has counters on each hexagon side, used to count the number of the received data packets, then the sink chooses the side with the highest counter to move to.
- 3) The energy-based greedy movement (EGM), where the sink employs an agent node for each hexagon side to calculate the average residual energy for sensor nodes on that side, then the sink will choose to move to the side with the highest residual energy.
- 4) For the direction value update, the sink moves either vertically (to sides numbered by 1 or 4) or non vertically (to sides numbered by 2, 3, 5, or 6). When the sink moves, it discloses its new location to some partitions. Indeed, there is no need to broadcast the new position to all sensors since the many partitions will still locate at the same partition regarding the sink position, thus achieving energy efficiency (see Fig. 7).

Finally, the author simulated their three proposed schemes using MATLAB, then they compared them based on 1) sensor nodes density, 2) ratio of the source nodes in WSN, and 3) the hexagon side length. The main performance criteria are the average energy consumption, the maintenance cost, packet collected, and packet loss rate. They found that their HSDG scheme with DGM for the sink (HSDG-DGM) is outperforming other data gathering schemes HSDG-EGM and HSDG-RM in the energy-efficiency with low data loss. As an advantage, this algorithm is energy efficient since the broadcast and update of the sink's new location is limited to a given direction partition. Moreover, it avoids the routing void. Indeed, when there is no sensor node to forward the data to in a partition, the forwarding scheme states that the data packet is transmitted to another neighbour partition.

Gharaei et al. [19] proposed Energy-Efficient Mobile sink Sojourn Location Optimization (EMSLO) algorithm. Their algorithm consists of two phases: 1) Evaluating sensor nodes residual energy, and 2) Optimizing sink sojourn points. First, to evaluate the sensor nodes in the network, the remaining alive time for each sensor is calculated by dividing the residual energy by the energy consumption rate. After that, the sensor with the minimum lifetime is chosen to be the Critical Node (CN). Next, all nodes are given a weight calculated by dividing the CN lifetime by its lifetime. Accordingly, the CN is the start point of the sink sojourn location, to find the next point, the genetic algorithm is used to select the sensor nodes with the minimum cost. This cost is calculated by a function based on two factors: 1) The variance of residual energy of sensor nodes. 2) each sensor weight that has been calculated before depending on CN lifetime. Finally, the authors simulate their scheme and found that their model decreases the variance of sensor residual energy, which means a good distribution of energy consumption. Moreover, they compare their model to EPMS [20] and DCHS [21] in terms of WSN lifetime, and found that their model EMSLO maximizes the WSN lifetime more than others. Moreover, they compare their algorithm to CMS2TO [22] and CM2SV2 [23] to prove that optimizing the sink sojourn location is better than optimizing the sojourn duration or the speed of the sink, and the result emphasizes that.

B. Cluster based Models

Lu et al. [24] and Jong et al. [25] both inspired from bees and queen honeybee behaviour respectively. First, in [24] they proposed a path optimization strategy for the mobile sink in WSNs using an artificial bee colony algorithm. They improve the data gathering ability by obtaining the optimal trajectory design of the mobile sink. First of all, they cluster the nodes in the grid and select some nodes as cluster heads by the traditional method LEACH [26]. These cluster heads are considered as the rendezvous points of the mobile sink. Then, they transform the WSN energy consumption problem into a minimization of the total hops between all rendezvous points and the sensor nodes by establishing the constraints' criterion that makes the WSN lifetime maximized. Moreover, they optimize the artificial bee colony (ABC) algorithm to solve this problem. As the ABC algorithm, where employed bees are randomly selected to search for the initial food sources, the authors proposed a formula to select the initial rendezvous points. After selecting the initial individual, they compare their fitnesses to a newly generated individual to determine which one is better. If the new individual is better, then they replace the old with it, if not then increase the cumulative factor by one. This cumulative factor is used to indicate the quality of this individual, the more quality they have, the higher its probability to be selected. Then the food source or the rendezvous points will be selected using the roulette method based on their probabilities. Besides, the authors used the Cauchy mutation detection operator based on the current solution. By using this operator, the feasible solution diversity is increased, and the randomness of the solution is avoided. Moreover, the convergence to the optimal solution is achieved, which will increase the accuracy of the solution.

Jong et al. [25] proposed a scheme to maximize the WSN lifetime inspired by the migration process of the Queen called a QHBM algorithm. First of all, based on the nature of the Queen migration such as travel for food, depending on scout bees to look for new food sources or places, follow the scout bees with high sign (excitement), stop to rest at several points, and repeat all of these till they decide where to build its hive. By applying this scenario in the network, let the Queen be a sink. For the sensor nodes, they are clustered randomly. Each cluster has some CH sensor nodes selected randomly too. These CH nodes are responsible for forwarding the cluster sensor nodes data to the sink, if their residual energy becomes below a threshold, they will send an alert to the sink to start its journey and leave this cluster, so this cluster could replace the weak CH nodes and assign the nodes with the highest residual energy as the new CH nodes. In the proposed algorithm, these CH nodes will take place of bee scouts, they will lead the sink to come over. To mimic the honeybee migration, by knowing that the Queen honeybee travel to one of the 8 cardinal directions poles, and between every two poles, there is a sector containing bees scouts. Moreover, let the residual energy of the CH nodes become the sign (excitement) of the scout bees. Consequently, the proposed algorithm steps will be as follows:

- 1) Set the variables: sink initial position, sink communication radius, the confidence factor.
- 2) Assign the scouts from the CH nodes.
- 3) Group the CH nodes located in the same sector.
- 4) The sink calculates the average residual energy of the

CH nodes in each sector.

- 5) Then the sink calculates each sector probability. After that, the sink selects the sector that has the highest probability, which means that this sector has the CH nodes with the highest residual energy.
- 6) After selecting the sector, the sink compares the probability of the two adjacent sectors of the selecting one, then selects the pole in the edge of the sector with the highest probability as a destination.
- 7) Finally, the sink start its journey after receives an alert from the CH nodes.

The authors proved that their proposed algorithm is maximizing the WSN lifetime compared to a static sink since the re-position of the sink is alleviating the energy-depletion on the same nodes. Moreover, QHBM algorithm is alleviating the routing overhead since the sink only communicates with the CH nodes, so only these nodes require the update of the sink position. Additionally, the QHBM provides a balanced energy consumption since there is a scanning phase, where the sink looks for the CH nodes that have the highest residual energy to travel to. As a limitation, the authors did not find the optimal value of the sink communication radius, and the confidence factor is still calculated randomly.

Kumar et al. [27] proposed an Energy-Aware sink Mobility model (EASM). First of all, they proposed to logically divide the grid into a number of sub-grids, each sub-grid has an ID number, and this ID number is embedded also in each sensor node ID that belongs to it. After that, to determine the movement direction of the sink, the sink first calculates the average residual energy of its one-hop neighbors at each sub-grid. Then, it categories these sub-grids into 4 levels of energy called: Adequate Level, Operation Level, Warning Level and Danger Level. If the energy level of the sojourn grid reaches the warning or danger level, then the sink has to move by calculating each sub-grid's average residual energy then selecting the grid with the maximum residual energy level as a destination. After the sink reaches the new sub-grid, it applies the Breadth-First Search (BFS) technique to generate a spanning tree that connects all sensors in that sub-grid to the sink with the shortest path. Finally, the authors simulate their algorithm and compare it to a static sink and Energy-Aware Sink Relocated model in terms of the number of alive sensors, average residual energy, and amount of collected data. They found that their algorithm EASM is outperforming the others.

Wang et al. [28] proposed a path planning model for the mobile sink to minimize the energy consumption of the sensor nodes and make the sink travel path as short as possible. Namely, to create this path, a number of Rendezvous Points (RP) were selected after four phases: 1) tree formation, 2) RP candidate, 3) RP selecting and 4) Finding the shortest path. The tree formation is done simply by applying the spanning tree algorithm. While for the RP candidate, they follow the bottom-up manner and check the buffer remaining space for each sensor while considering the amount of data that comes from its child sensors. If a node with a full buffer capacity is found, then this node will candidate to be one of the final RP. After that, each candidate RP with its sub-tree will be evaluated by Depth-First Search (DFS) based on hop count and distance. Finally, by connecting these RP and finding the TSP, the travel path of the mobile sink is created. Moreover,

the authors proposed an enhancement of their model to further reduce the travel path length. Their enhancement is done by finding better RP by replacing it or combining two of them depending on some calculation of its RP and RP-1 and RP+1.

Finally, the authors evaluate their model in terms of the dropped packet, energy consumption, computational time and buffer exploitation. They proved that their model exploits the RP buffer better than other models (CB-E [29] and WRP [30]). Consequently, the number of dropped packets is minimized. Moreover, they proved that their model is energy and computationally efficient.

Table II summarizes the AI-based solutions. It provides the key concept, advantages and disadvantages of each work.

V. OTHER SINK MOBILITY MODELS

Some of the proposed models are dependent on the sinks statistical and operational decisions made for moving. Shah et al. [31] proposed a model using Mobile Ubiquitous LAN Extensions (MULEs). MULEs also are not suitable for a real-time data system. First of all, the authors consider that the network consists of (i) several Access Points, which are uniformly distributed, (ii) several sensor nodes, randomly distributed, and (iii) several MULEs. Additionally, they assumed that:

- The MULEs move with 0.25 probability to any of the four main directions of the grid (North, South, East, West) with every global clock tick.
- The MULEs can't communicate or exchange data with other sensor nodes or access points unless they are co-located at the same grid points.
- Due to the limitation in MULEs' and sensor nodes' buffer size, any amount of data transferred to them will be dropped, if it is full.

They relied on Markov chains and its transition probabilities to estimate the average values of the inter-arrival time of the MULE to a sensor, the number of steps that the MULE takes to complete one round, and the average number of data amount that MULE picks up and transfer to the AP. After that, to measure the performance, they consider the following criteria: Data Success Rate and Buffer Size (keep it as small as possible) From the performance result, the authors found that:

- The sensor buffer size is increasing linearly with the grid size.
- Data latency at sensor nodes is increasing linearly with the sensor nodes' buffer size.
- MULEs buffer size is increasing with the square of the grid size.
- Data latency to reach the access point is increasing linearly with the grid size.

As a result, if the grid size increases, it is required to use multiple MULEs and multiple access points, to achieve a high success data rate while keeping an appropriate buffer size. Indeed, using a large buffer size will lead to energy consumption, which is against the goal of maximizing the

WSN lifetime. As benefits of using MULEs, it can increase scalability, flexibility, and robustness for the WSN. But it may have some drawbacks because of its unpredictable and constrained movement. Indeed, sometimes the MULE is unable to reach the sensor nodes due to the change in terrain that causes limitations in the MULEs movement.

Gosh et al. [32] proposed a new sink mobility approach based on the sensors request. First of all, they assume that the sink has a limited queue with size n . When a sensor node's buffer becomes near to be full, it sends a request to the sink to move and collect data directly through a single hop. On the sink side, the sink save these request on its queue and serve them based on two scheduling schemes: 1) First Come First Serve (FCFS), 2) Nearest Job Next (NPN). The main contribution of the authors is joining new schemes to the previous two. Thus, additionally there will be 3) Earliest Deadline First-First Come First Serve (EDF-FCFS), and 4) Earliest Deadline First-Nearest Job Next (EDF-NPN).

First, it is important to point out that each request has to be served before its deadline. Moreover, each request has a service time, which is the time taken to completely transmit the data from the sensor's buffer to the sink. There is also a movement time, which is the time taken by the sink when it moves between the sensors based on the serving queue order. Due to the different sensor locations and the nodes' geometric distribution, the order of serving the sensors' requests is a critical thing, since the sink moving time will be considered. Accordingly, the authors first apply the first two schemes: FCFS and NPN, if all requests in the queue will be served before their deadlines, then this queue order is good and there is no need to change it. Else, if there is a request i that will miss its deadline, the two newly proposed approaches will be applied: EDF-FCFS and EDF-NPN. According to these approaches, if there is a request i that will miss its deadline, then this request will reverse the order with the request $(i-1)$, if it is still, then reverses it with $(i-2)$, if it is still, then this request will not be served and dropped from the queue. Finally, the author evaluated the four schemes and compared it based on the number of not-served request and the response time. They proved that their adapted schemes (EDF-FCFS and EDF-NPN) have outperformed the originals (FCFS and NPN) with less number of not-served requests and faster responses. But, still, these schemes are not suitable for large scale networks.

Table III summarizes the previously-mentioned solutions.

VI. DISCUSSION

We compare in Table. IV the research works that were discussed earlier are based on the following criteria:

- *Network Topology*: many types of networks have been investigated including (i) grid (regular) network, (ii) random network, and (iii) scale-free network. The network topology of the reviewed papers varies between grid and random. Some of the random typologies are clustered by (i.e. See SectionIV-B)
- *Sink Sojourn Points*: sojourn points are points where the sink stops to collect data from the sensor nodes. Most of the reviewed papers under LP models are using predefined sojourn points while the AI-based

TABLE II. SUMMARY OF AI-BASED SOLUTIONS

Ref No.	Key Concept	Advantages	Limitations
Non-Cluster Based Models			
[16]	A genetic algorithm to find the optimal number of sink sojourn points and their locations	It is used to find the shortest path	The energy consumption at each node is not considered, which of course impact on the path selection.
[17]	A data collection strategy Using ant colony optimization algorithm to move the sink.	It is used to find the best path between the sojourn points.	It minimizes the whole network residual energy consumption, instead of maximizing the network lifetime.
[18]	Sink mobile through a WSN scheme inspired by the honey-comb for data collection	Energy efficient, and avoiding the routing avoid	
[19]	Use genetic algorithm to select sink sojourn points after calculating the cost for each sensor nodes	Easy to implement, applicable for high density WSN.	
Cluster Based Models			
[24]	Moving the sink using Bee colony optimization algorithm.	Avoid the randomness of the solution Using the Cauchy mutation detection	
[25]	QHBM algorithm inspired by the migration process of the Queen Honey Bee	Due to the scanning phase in the algorithm, it provides a balancing energy consumption	Many variables need to be restricted, such as the confidence factor which is calculated randomly.
[27]	First, divided the grid to sub grids, then calculate the average residual energy and determine the energy level for each sub-grid. After that if the sojourn sub-grid energy level decreased to 4th, the sink mobile to the sub grid with the highest energy level.	Efficient for high density WSN.	
[28]	Applying the spanning tree, then go bottom-up and check the buffer to find sojourn points.	It ensures transmission and exploits the whole amount of buffers.	

TABLE III. SUMMARY OF OTHER SINK MOBILITY MODELS SOLUTIONS

Ref No.	Key Concept	Advantages	Limitations
[31]	MULEs mobility routing, Based on the Markov chains transition probabilities.	Easy to implement	The MULE is unpredictable and physically moved so it is affected by the changes in its environment.
[32]	Sink Mobility based on two sachems of serving sensor request EDF-FCFS and EDF-NJN.	Easy to implement	Many packet will be loose because the sink has a limited queue size, and the request has a deadline. Hence, it is not scalable.

solutions define the sojourn points randomly (*e.g.*, [16]), actively (*e.g.*, [18]), or based on sensor query (*e.g.*, [32]).

- *Sink Sojourn Duration*: it refers to the time the sink takes at a sojourn point to complete collecting data from the sensor nodes. The WSN lifetime is actually the sum of all sink sojourn duration. So it is important to find the trade-off between maximizing the sojourn duration while taking into account the delay-tolerance time.
- *Buffer size*: it is the size of the sensors' temporary storage that is used to store data until the sink comes. All reviewed papers assume that the buffer size is infinite, though it is an unrealistic assumption.
- *Overhearing*: in WSN, the nodes are always listening to the traffic in their transmission range, hence consume an additional amount of energy. However, none of the reviewed papers has considered the overhearing while it is an important source of energy consumption that should be taken into account in WSN.

VII. FUTURE RESEARCH DIRECTIONS

We provide in the following some insights on possible future research directions to pave the way towards building more realistic and robust solutions for the energy hole problem.

A. Considering Additional Constraints

Based on the aforementioned comparative analysis, we deduce that two constraints are always considered in all WSN-lifetime-maximization solutions namely (i) the energy constraint and (ii) the flow conservation law. Consequently, it is highly recommended to consider more constraints that impact the WSN lifetime such as:

- *Buffer Size*: The buffer size is an important criterion as it constrains the sensor capacity to store received and generated data packets which has an impact on the sink sojourn duration at each sojourn point. Besides, a higher buffer size leads to a higher energy consumption. So, finding the optimal sojourn duration that takes into account the size of the buffers that avoid data rejection is one of the main goals

TABLE IV. COMPARISON OF SINK MOBILITY MODELS

Taxonomy	Reference No.	Network Topology	Sojourn Points	Sojourn Duration	Buffer Size	Overhearing
LP	[8]	Random	✓	X	X	X
	[9]	Grid	✓	✓	X	X
	[11]	Random	✓	✓	X	X
	[13]	Grid	✓	✓	X	X
	[14]	Random	✓	✓	X	X
	[15]	Random	✓	X	X	X
AI	[16]	Random	✓	X	X	X
	[17]	Random	✓	X	X	X
	[18]	Random	✓	✓	X	X
	[19]	Random	✓	X	X	X
	[24]	Grid	✓	X	X	X
	[25]	Random	✓	✓	X	X
	[27]	Random	✓	✓	X	X
	[28]	Random	✓	X	X	X
OM	[31]	Grid	✓	X	X	X
	[32]	Random	✓	✓	X	X

for WSN-lifetime-maximization [33] [31]. However, this constraint is generally ignored when solving the energy hole problem.

- *Overhearing Energy Consumption:* Since we deal with wireless sensor networks, ignoring the overhearing is unrealistic and gives flawed results for the WSN lifetime as it inevitably consumes energy. However, none of the reviewed papers considers overhearing. Thus, it is important to devise new models that take it into account when searching for the optimal sojourn duration for the sink using techniques that reduce the overhearing as in [34].
- *Link Capacity:* Similarly to the buffer size, the link capacity constrains the number of received and transmitted data packets, which consequently impact the energy consumption since it is calculated per data unit. As such, new models that consider this constraint are required in the field.

B. Reducing Latency

Even though the reviewed models are applicable for delay-tolerant WSN, reducing latency is important to avoid the data loss due to the buffer size limitation. Many approaches have been suggested to reduce the latency by using multiple mobile sinks that cover the WSN simultaneously, which allows to collect data faster. However, this solution has a higher cost which is undesirable in WSN [35].

Another alternative is to use a powerful mobile sink that can move between sensor nodes at a higher velocity. Similarly to the previous approach, this will be more efficient than a single sink but would incur higher costs. Meanwhile, as the WSN is usually used in harsh environments, the moving in a high speed can be difficult to achieve.

Consequently, more research is required to find the trade-off between the efficiency and the total cost of the proposed solution while taking into account the geographical characteristic of the environment and the buffer size constraint.

C. Utilizing Additional Energy Resources

One of the approaches to prolong the WSN lifetime is to recharge sensors' batteries. Even in a harsh environment,

there are many ways to recharge sensors such as using the solar power, microwave energy transfer, radio-frequency energy transfer, and wireless charging stations where the mobile sink could be used as a recharging station [15]. Joint data gathering using mobile sink and sensors' battery recharging is a promising solution to optimize the WSN lifetime [36] [37][38][39]. Even though lots of these approaches had been proposed, few works combine both techniques. A possible future research direction would be to investigate the strengths of both techniques (*i.e.*, maximizing the WSN lifetime and energy recharging) to design a promising WSN lifetime optimization solution.

VIII. CONCLUSION

In this survey, numerous sink mobility models were discussed in the literature review to mitigate the WSN energy hole problem and maximize the WSN lifetime. These sink mobility models were classified into three categories: Linear programming-based solutions (LP-based), Artificial Intelligence-based solutions (AI-based), and other computation models. Regarding the LP-based models, four solutions used only one mobile sink, while the rest used either an additional entity or a special property (*e.g.*, recharging sensor nodes). As for the AI-based models, they have two categories: cluster based models (*i.e.*, sensors are organized into clusters, where each cluster has a cluster head), and a non-cluster based models. Finally, the last section discusses additional solutions that neither used LP nor AI-based.

All the solutions are discussed in detail and compared according to a set of criteria. The comparative analysis shows that most of the research ignored important constraints that fully impact WSN lifetime, namely, limited buffer size, overhearing, and link capacity. Finally, future research directions were suggested to develop a more comprehensive WSN lifetime maximization using a mobile sink.

Abstract—Recently, Morocco has started to invest in IoT systems to transform our cities into smart cities that will promote economic growth and make life easier for citizens. One of the most vital addition is intelligent transportation systems which represent the foundation of a smart city. However, the problem often faced in such systems is the recognition of entities, in our case, car and model makes. This paper proposes an approach that identifies makes and models for cars using transfer learning and a workflow that first enhances image quality and quantity by data augmentation and then feeds the newly generated data into a deep learning model with a scaling feature—that is, compound scaling. In addition, we developed a web interface using the FLASK API to make real-time predictions. The results obtained were 80% accuracy, fine-tuning it to an accuracy rate of 90% on unseen data. Our framework is trained on the commonly used Stanford Cars dataset.

Keywords—Vehicles classification; deep learning; compound scaling; transfer learning; IoT

I. INTRODUCTION

Intelligent Transportation Systems (ITS) represent a combination of advanced information and communication technologies. They are used in transportation and traffic management systems to enhance road transportation networks' safety, efficiency, sustainability, reduce congestion, and improve the driving experience. The performance of road networks can be monitored and adjusted in real-time. Video surveillance systems have become so used in ITS. With the massive adoption of high-definition cameras, advanced analytics, and AI, surveillance systems are faced with increased workloads and are no longer just for security purposes. An intelligent transportation system should include the minimum requirements for managing traffic, including vehicle detection [1], vehicle tracking [2], [3], and vehicle type classification [4], [5]. Because of traffic jams, lack of vehicle parking spots, and pollution, traffic control has always been a problem in the urban areas of Morocco [6]. Due to such events, traffic monitoring is crucial for collecting statistical data to design better and plan transportation infrastructure, other functionalities that can be integrated in an intelligent transport system is inter-vehicle distance estimation [7], [8]. Vehicle classification can solve numerous problems and help for a better traffic organization. Motivated by this fact, we have developed a framework to classify models and car makes in real-time to solve practical use case scenarios in ITS. In general,

identifying car make and model has not been an easy process for computers because of its visual complexity and differences between classes. However, Humans can simply identify a car by its logo or hood ornaments. Given the complexity of the problem, various approaches were used, starting from classical machine learning models to intricate deep learning models that achieved state-of-art results. Deep learning has been talked about a lot in recent years. And for a good reason, this subset of machine learning has imposed itself impressively in several research fields of which car classification was a part. Several methods and algorithms of deep learning were used to classify car make and model, primarily, Convolutional Neural networks (CNN), which are powerful programming models allowing in particular image recognition by automatically assigning each image provided as input a label corresponding to its class. Also, deep Neural Networks(DNN) a multilayer neural networks which can include millions of neurons, divided into several dozen layers. Deep learning empowers Artificial Intelligence to learn new rules to be more reliable and efficient. The exponential improvement in computing power and the development of related applications allow artificial intelligence to generate more complex and dense layers of neurons.

The challenge with model and car classification is the fine-grained feature. Compared to basic image recognition, the dataset is more diverse in contrast to the similarities found pixel-wise. The question is whether a model can differentiate between different cars model and make found on the fine-grained dataset. To solve this issue, a deep learning model should be able to adapt and recognize the similarities found in the dataset and enhance the prediction. Hence, a compound scaling model in which width, depth, and resolution are scaled so that the model captures more fine-grained patterns. In this paper, we present a novel approach to classifying models and car makes. Inspired by the recent work on scaling neural networks, we worked with the EfficientNet [9] model pre-trained on the ImageNet dataset. We fine-tuned the model to our needs, thus, adding layers to reduce complexity. We also used transfer learning for prior knowledge of the model weights. With such behavior, the model can adapt to different scenarios, therefore, better prediction accuracy. We conducted experiments on the challenging Stanford Cars dataset [10], which contains 196 different categories of cars taken from different angles. We have used FLASK API to create a web interface so as to achieve real-time prediction.

The paper is repartitioned as follows. First, we present a literature review on the subject of vehicle classification. Then we discuss the methodology in which we formulate the problem, explain the architecture used and discuss the image preprocessing, data augmentation, and transfer learning phase. Following is the experimentation section, where we discuss the dataset used, the model implementation, and the training loss function. After that, the results section is where we discuss the obtained results. Finally, a conclusion and perspective section.

II. RELATED WORK

Car make and model classification problem has widely been addressed using two research category methods. The first method focuses on handcrafted feature engineering. The second one, instead, focuses on machine learning and deep learning techniques. Since our method is based on a deep learning architecture, we mainly focus on related work with similar approaches. Xingyang Ni et al [11] 2021, compared two methods of car models and makes classification: a straight-forward classification and a more flexible metric learning method. They built their model based on the ResNet 50 pre-trained on the ImageNet dataset and retraining it on the VERI-WILD dataset that contains approximately 0.4 million images with 14 types of vehicles, and 149 different car makes. As for the result, upon using a cross-entropy loss, they found a 96.8% accuracy rate on the type classification and 95.6% on the make classification. While for the triplet loss method, they found an accuracy rate of 97.4% on the type classification and 95.3% on the make classification. In addition, they used a lifted structured loss method in which they found 97.7% on the type classification and 96.2% on the model classification. Ye Xiang et al [12] 2019, proposed a four-stage pipeline that consists of part detection, part assembling, topology constraint, and classification for fine-grained vehicle recognitions. They used a backbone model trunked at the middle in the first stage. Afterward, they called for pointwise convolutional layers that put together related parts into the same feature map. Eventually, the topology constraint covers depth wise convolutional layers and approximates the possibility of the topology correlation between associated parts. Finally, they evaluated the model on two public datasets: the Stanford Cars dataset and the CompCars dataset. In both datasets, various car viewpoints can be found. The results obtained were 94.3% accuracy on the CompCars dataset, 94.3% on the Stanford Cars dataset for the model classification and 99.6% for the make classification. Rachmadi et al. [13] 2018, proposed a pseudo-long short-term memory classifier for identifying a single image. The presented technique considers the split pictures to be time-series frameworks. Those images are outlined by cropping input images with a two-level spatial pyramid region configuration given to the P-LSTM classifier in a cycle. And to calculate the prediction of each class, they added a fully connected layer. They used the MIO-TCD dataset, which contains 648,959 vehicle images of 11 types of vehicles. They obtained a 97.98% accuracy rate. Jung et al. [14] 2017, trained ResNet models using actual traffic surveillance recordings. A joint fine-tuning method is employed to fine-tune all parameters and not only the final dense layer. They used DropCNN that arbitrarily drops the probabilities from the aforementioned backbones during training. They used the MOI-TCD dataset. They obtained a 97.9% accuracy rate. Hu et al [15] 2017,

presented a spatially weighted convolutional neural network that accommodates a predefined amount of pooling channels. The model then takes out deep convolutional neural network features with the enlightenment of its learned masks. They have achieved an accuracy of 93.1% on the Stanford Cars dataset and 97.6% on the CompCars dataset. Lee and Chung [16] 2017, proposed twelve local expert networks and six global networks. They used three neural network structures: AlexNet, GoogLeNet, and ResNet18. The local expertise and global networks are trained with the particular subsets and entire training set, respectively. They generated the prediction by combining the predictions of one local expert network and multiple global networks. They used the MIO-TCD dataset to get an accuracy rate of 97.92%. Huttunen et al. [17] 2016, presented a deep learning neural network that employed SVM (Support vector machine) on a dataset that contains over 6500 images. They found an accuracy rate of 97.75% for the deep learning method and 96.19% for the SVM method. Dong et al. [18] 2015 proposed a sparse Laplacian filter learning method to minimize the parameters of convolutional layers with a large number of unlabeled samples. They collected the BIT-Vehicle dataset, which contains 9850 high-resolution vehicle frontal-view images. They achieved an accuracy rate of 96.1%. Yang et al. [19] 2015, proposed a model based on pre-trained weights of the ImageNet dataset and fine-tuned it with the CompCars dataset. The result obtained was 82.9% accuracy in the car make, 76.7% in the car model, and 80.8% in car parts. Girshick et al. [20] 2014 proposed the fastest model, taking approximately 2 seconds for an object to be detected. The approach used similar layers for both the detection and classification tasks. First, the model detects the spatial geometric position of an object using a sliding window method. This allowed the model to classify vehicles accordingly, utilizing the image's extracted objects/features). The final accuracy of the model was a fascinating 73.2% in image classification. Although the classification accuracy wasn't that high, the model was fast enough to compensate for the lack. Wang et al. [21] 2013 used SPM (Spatial Pyramid Matching). The method mainly focuses on detecting the spatial distance that can be found between detected objects of an image. In addition to SPM, SIFT was used to extract features, followed by an LLC (Locality-constrained Linear Coding) to extract locations. The classification task achieved a 59.3% accuracy, improved by an SVM classifier later on. Krizhevsky et al. [22] 2012 proposed a low-level features extraction method using Gabor filters. The model was composed of higher layers that deal with classification tasks and lower layers that deal with extracting features, the classifier used was an SVM. The model performed a 93.3% accuracy on image identification and 83.3% on image classification. Cheung et al. [23] 2008 Used SIFT algorithm (ScaleInvariant Feature Transformation), the model matches interest points in car images. The framework consists of an optimization network that uses the geometry of the image to spot interest points in cars. If the matched points in the training model are similar to the test phase, those two points are called inliers; thus, the classification of the car matches. The only drawback of this framework is that it matches images in the dataset for the same angle only, resulting in a mismatch if the angle is modified. Bay et al. [24] 2008 developed an unsupervised learning model that acts on the behavior of labeled image subcategories. These subcategories were generated using a segmentation. The

model allowed only focus on essential image features. Hence, removing the background as it's considered as noise, the extracted features are then used for the classification task using a categorical loss function. This method led to the foundation of segmentation in car and model classification. Many methods have developed a fine-tuned model using segmentation filters. Some models even allowed modification in terms of kernel density. This ability make the model more robust in detecting and filtering important car image features. In recent work on vehicle classification, compound scaling has been used to extract fine-grained features. In our work, we sought to explore more the use of transfer learning with EfficientNet compound scaling coefficients pre-trained on the ImageNet and the MobileNet model architecture to classify model and car make.

III. METHODOLOGY

We describe our method as displayed in Fig. 1. The framework consists of three phases, the preprocessing and data augmentation phase, the model implementation phase, and the transfer learning phase. The model is trained end-to-end, and we developed a web interface for real-time prediction using the trained model weights. We will discuss each of these phases in the following sub-sections.

Fig. 1. The Training Workflow of our System Combining Transfer Learning and EfficientNetB3 Pre-Trained Model

A. Problem Formulation

We define the problem as a categorical classification scenario in which we ought to classify model and car make according to the scalability of the convolution neural network in question—That is, the learning behavior. Therefore we can

define a Convolution network as:

$$N = \bigodot_{i=1..s} \rho_i^{L_i}(X_{\langle H_i, W_i, C_i \rangle}) \quad (1)$$

where:

N defines a list of composed layers.

ρ denotes layer ρ_i is repeated L_i times in i .

$\langle H_i, W_i, C_i \rangle$ denotes the shape of tensor X where H_i , W_i are the spatial dimension and C_i is the channel dimension.

The objective is to find the best ρ , yet we want our model to be scalable in order to extract fine-grained features, so instead of focusing on finding the best ρ , we focus on finding the best scaling dimensions. As described in [9], the model fixes ρ and uniformly explores all layers parameters with a constant ratio. As such, we have an optimization problem, which can be formulated as follows:

$$\max_{d,w,r} N = \bigodot_{i=1..s} \hat{\rho}_i^{d \cdot L_i}(X_{\langle r \cdot \hat{H}_i, r \cdot \hat{W}_i, w \cdot \hat{C}_i \rangle}) \quad (2)$$

where:

d , w and r are the coefficients, depth, width and resolution respectively.

$\langle r \cdot \hat{H}_i, r \cdot \hat{W}_i, w \cdot \hat{C}_i \rangle$ defines the predefined parameters multiplied by the coefficients.

The advantage of scaling optimal d, w, r is that when scaling depth (d), the network tends to capture more complex features. Scaling the width (w) will allow the network to capture more fine-grained features. For the resolution (r), the network will have the ability to capture different patterns due to the enlargement of the resolution, making it easy to extract fine-grained features. With this in mind, the issue persists when maximizing the accuracy in contrast to the scalable parameters. The network will often become challenging as the scaling values depend on each other. Hence, we use EfficientNet with compound scaling parameters. Intuitively, the network scale is according to a compound coefficient determined by a grid search. This allows the network to fine-tune itself according to the optimal need. Fig. 2 shows the scaling behavior of EfficientNet compared with different other methods.

B. Model Architecture

We describe our model as a set of a combination between EfficientNet for compound scaling and MobileNet [25] as the model architecture. EfficientNet is a convolutional neural network that relies on scaling the width, depth, and resolution uniformly. In addition to that, the network has a small number of parameters compared to other models: it has only 12,320,535 parameters, but it has proven to reach better results on the ImageNet dataset compared to other models with a higher number of parameters. Thus, we transfer knowledge of the trained EfficientNet model and use it in our system using transfer learning. Fig. 3 shows the EfficientNet architecture. As for the MobileNet architecture, it uses mobile inverted bottleneck convolution (MBCConv), applying depth-separable convolution with residuals.

Fig. 2. Comparison between EfficientNets and other Existing CNNs on ImageNet

The main difference between the regular residual block and the inverted residual block is that the latter follows a narrow > wide > narrow approach. In contrast, the first follows a wide > narrow > wide path approach. For example, Fig. 4 shows the difference between Residual and Inverted residual blocks.

C. Image Preprocessing and Data Augmentation

Our dataset has a small number of cars in each class: about forty pictures. Training a deep neural network on few images is often challenging: the model having access to only a limited number of observations will tend to Overfit. In this case, the performance is poor on the test set while they are good on the training set. This phenomenon is often solved by increasing the size of the dataset and/or reducing the number of model parameters. The first method is often challenging to set up because the work of collecting/labeling new observations is laborious. The second possibility is conceivable for an image recognition problem. However, even the most miniature complex models can contain hundreds of thousands of parameters, which are tricky to achieve. As data augmentation allows new labeled images to be generated from those already available, it is a relatively more straightforward solution to implement, and the results can be surprising. The most well-known technique of data augmentation is image data augmentation. It combines the methods used to artificially increase the size of a training dataset by creating modified versions of images from the available training images. We can then effectively improve the learning process as it results in more training samples for the neural network model. Augmentation techniques can create image variations that can enhance the ability of training models to generalize what they have learned to new images, which significantly improves model performance. The data augmentation applies only to the training set and not the validation or test set. This differs from data preparation, such as image resizing, which must be performed consistently across the entire dataset interacting with the model. Fig. 5 shows a sample of data augmentation on the Stanford Cars dataset.

Fig. 3. EfficientNet Architecture

Fig. 4. Comparison between Residual Block and Inverted Residual Block

D. Transfer Learning

Transfer learning [26] has become common in the past few years because it has proven to achieve better results even with the use of a small amount of data. In our work, we have used transfer learning, a supervised learning technique that consists of taking a pre-trained model and reusing it on another dataset. Fig. 6 shows the workflow of the transfer learning technique.

Fig. 5. Augmentation Technique Implemented on the Stanford Cars Dataset

Transfer Learning consists of the transfer of knowledge from one task to another. This behavior allows the network to solve similar problems with the same pre-trained model. This will eventually improve the quality of learning and reduce the computation time. However, deep learning requires always having a large dataset to operate the neural networks at their foremost. Therefore, we can adjust using Transfer Learning to get better predictions even with a small dataset.

Fig. 6. Transfer Learning Workflow

IV. EXPERIMENTATION

A. Understanding the Stanford Dataset

Stanford Cars dataset has been widely used for model and car classification. The dataset was collected in 2013 and contained 196 different categories of cars (model, make, and year). The dataset is split into 8,144 pictures for the train set and 8,041 pictures for the test set. Fig. 7 shows an example of some quantitative car images in the Stanford dataset.

The files anno-test.csv and anno-train.csv are a table of six columns. The first column represents the name of the picture. From the second to the fifth column, we have four values of pixels that show the exact emplacement of the vehicle in the image. The last column contains information that classifies the car. The list of all classes is in the "classes.csv" file. Fig. 8 shows the dataset files structure.

Fig. 7. An Overview of the Diversity in the Stanford Dataset

File	Column 1	Column 2	Column 3	Column 4	Column 5

B. Model Implementation

Car classification is a challenging task in machine learning due to the variety of details in each car. Therefore, we used transfer learning on the EfficientNet model pre-trained on the ImageNet dataset and then fine-tuned the model to get better results. First, we started by adding layers to our base model, mainly the globalAveragePooling2D layer, to reduce the variance and complexity of calculations, two fully-connected layers with the activation function "relu," and the integration of dropout to reduce overfitting. Next, we trained our model on the Stanford cars database combined with MoVITS Dataset [27]. Finally, to get a higher accuracy rate, we fine-tuned the model by unfreezing our entire model and retraining it.

C. Training on the Stanford Dataset

We used adam as an optimizer and categorical cross-entropy as a loss function to train our model. The use of adam, in this case, is due to the quick convergence that the optimizer allows. Since the dataset is quite complex in term of diversity, adam will help reduce computation time and converges in a significantly lower period. Due to the different classes in the dataset, we chose categorical cross-entropy as our loss function. To evaluate our model, we minimize the loss and compute the accuracy of the training and validation data. Since this is a classification task, we also demonstrate a confusion matrix to help visualize the behavior of the network. We define the categorical cross-entropy loss function as follows:

$$\mathcal{L}(y, y') = \sum_{j=0}^M \sum_{i=0}^N (y_{i_j} * \phi) \quad (3)$$

where:

$$\phi = \log (y'_{ij}).$$

y' is the predicted value, y is the ground-truth value.

To compute the accuracy, we use the following principle:

$$A = \frac{TP + TN}{TP + TN + FP + FN} \quad (4)$$

where:

A represents the Accuracy.

TP + TN represents the number of correct predictions.

TP + TN + FP + FN represents the total number of predictions.

In summary, anytime the prediction is incorrect, the forecast is False. Otherwise, it is True. Therefore, the final objective is to maximize the prediction as True (True Positive and True Negative) and minimize the prediction as False (False Positive and False Negative).

V. RESULTS AND DISCUSSION

Compared with ResNet implementation in [11], we show that using EfficientNet has significantly enhanced the network's ability to extract more detailed features of the dataset. Adding data augmentation, the model learns to adapt to different image perspectives making it more robust on unseen data. Furthermore, in contrast to [12], using pointwise convolutional layers to extract fine-grained features, we incorporated scaling coefficients. This allowed the network to scale parameters for an optimal state. Adding MobileNet as a model architecture with mobile inverted bottleneck convolution reduced memory requirement compared to classical residual block.

We trained our model first using 44 epochs. Comparing the training and test loss, as shown in Fig. 9, the model started to find the optimal state using a grid search for the model's scaling coefficient at around 20 epochs. After 20 epochs, the model fluctuated, considering the complexity and deviation of the dataset combined with the augmented images. Finally, After 40 epochs, the model stagnates. Thus, we deduct that the model achieved an optimal state for the given parameters. We found an accuracy of 88% on the train set and 82% on the test set. Fig. 9 shows the results.

After the first experiment, we understood the behavior of our model, especially after 20 epochs where more fine-grained features are extracted due to the compound scaling of the optimal d, w , and r in the network. To enhance our model's accuracy, we fine-tuned it by retraining it to only 24 epochs where the network understands mostly essential image features. Compared to the previous experiment. We achieved an accuracy of 95% on the train set and 90% on the test. Fig. 10 shows the results.

To showcase the confusion of the network with respect to the predicted values, we generate a confusion matrix which is a summary of the results of predictions about a classification problem to visualize our prediction better. Fig. 11 shows the confusion matrix obtained. Correct and incorrect predictions are highlighted and broken down by class. The results are thus compared with the actual values. This matrix helps

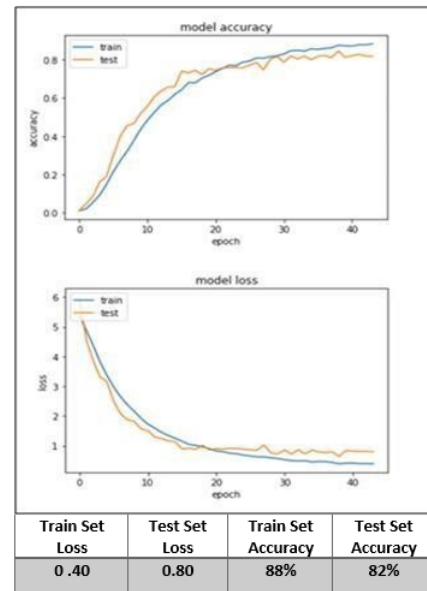

Fig. 9. Model Accuracy and Loss before Fine-Tuning

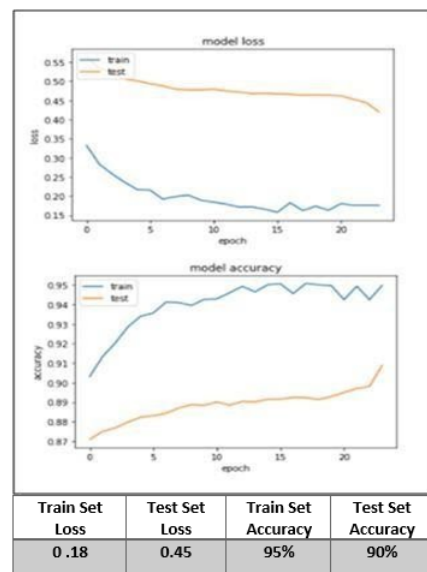

Fig. 10. Model Accuracy and Loss after Fine-Tuning

understand how the classification model is confused when making predictions.

The model accuracy on unseen data is significantly interesting, especially considering the use of augmented data. This allowed the model to understand different image perspective views and find similarities in fine-grained features to be then able to label the correct and incorrect predictions correctly. At this stage, our model's weight is ready to be used for real-time prediction.

Now that we have our model trained, we developed a friendly interface for real-time prediction using the FLASK API and the weighted model trained. The workflow of the API is described in Fig. 12.

Fig. 11. Confusion Matrix of the Classification Task

Fig. 12. FLASK API General Workflow

Our final interface is composed of an upload section where the user can freely upload a car image. Upon clicking on submit, the network uses the trained model to predict based on the model weights and outputs the predicted label of the given car image, describing the model and car make. Fig. 13 shows an example of the prediction mechanisms.

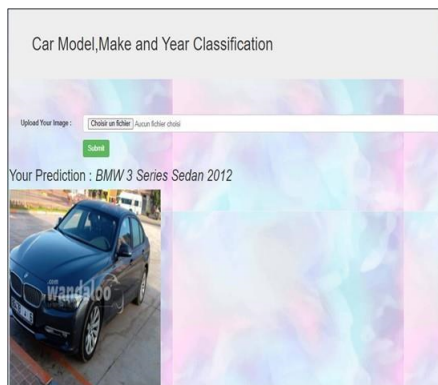

Fig. 13. An Example of Real Time Prediction in our Web Interface using Flask API

VI. CONCLUSION AND PERSPECTIVES

In this paper, we explored the use of transfer learning with EfficientNet compound scaling coefficients pre-trained on the ImageNet and the MobileNet model architecture to classify model and car make. The use of such a combination proved to be efficient in this task. We used the Stanford Cars dataset and fine-tuned the model to find an accuracy rate of 90%. Additionally, we have implemented a web interface to predict car images in real-time using Flask API. Extracting

fine-grained features is indeed a complex task, yet, we show that combining and fine-tuning the model can significantly enhance accuracy. Furthermore, we can improve the project prediction by building a system that identifies a car's plate number using Optical Character Recognition (OCR), which converts digital images to electronic text. The OCR output is an ASCII code that contains the text of the license plate and which can be compared to existing databases containing additional information on the car owner, such as his issuance badge, serial number, etc. These extracted features will then be used to improve the accuracy of the overall model.

ACKNOWLEDGMENT

Cache Complexity of Cache-Oblivious Approaches: A Review and Extension

Inas Abuqaddom, Sami Serhan, Basel A. Mahafzah
Department of Computer Science
King Abdullah II School of
Information Technology
The University of Jordan
Amman, Jordan

Abstract—The latest direction in cache-aware/cache-efficient algorithms is to use cache-oblivious algorithms based on the cache-oblivious model, which is an improvement of the external-memory model. The cache-oblivious model utilizes memory hierarchies without knowing memories' parameters in advance since algorithms of this model are automatically tuned according to the actual memory parameters. As a result, cache-oblivious algorithms are particularly applied to multi-level caches with changing parameters and to environments in which the amount of available memory for an algorithm can fluctuate. This paper shows the state of the art in cache-oblivious algorithms and data structures; each with its complexity concerning cache misses, which is called cache complexity. Additionally, this paper introduces an extension to minimize the cache complexity of neural networks by applying an appropriate cache-oblivious approach to neural networks.

Keywords—Cache complexity; cache-oblivious algorithm; memory hierarchy; neural network

I. INTRODUCTION

The processor speed is much faster than the main memory speed. The impact of this hole can be decreased by utilizing a hierarchy of multi-level caches in an effective way between the processor and the main memory [1]. Thus, modern computers have a memory hierarchy to speed up accessing memory, such that the speed of accessing a memory level becomes slower as its size becomes larger. Table 1 shows an example of a memory hierarchy. In most processors, the level 1 cache (L1) is on the same chip as the CPU, whereas the level 2 cache (L2) is on a separate chip [2], [3], [4].

TABLE I. MEMORY HIERARCHY

Memory level	Size	Response time
CPU registers	around 100B	around 0.5ns
L1 Cache	around 64KB	around 1ns
L2 Cache	around 1MB	around 10ns
Main memory	around 2GB	around 150ns
Hard disk	around 1TB	around 10ms

The response time increases as the memory size increases, as shown in Table I, consequently, there is an inverse relationship between memory size and its speed; as the memory level becomes larger, its speed becomes slower. Generally, each memory level communicates directly with the slower directly connected memory level. Additionally, data is transferred in blocks to reduce the effects of slow access [5]. For example,

to read one element of an array, the main memory will additionally transmit a "block" of consecutive words. Thus, accessing the other words of the transferred block is free in terms of memory transfers. The design of a multi-level memory hierarchy is more complex compared with single-level memory; such as extra design decisions are needed for each level of the memory hierarchy [6].

One performance metric of an algorithm is called memory performance, which measures the utilization of the memory hierarchy in an algorithm. Thus, algorithms have to know the memory hierarchy, memory size, and block size to achieve high memory performance; these algorithms are called cache-aware algorithms or cache-efficient algorithms. Nevertheless, cache-aware algorithms reduce running time up to 50% compared with other algorithms. On the other hand, algorithms, that worry about memory performance, have to be tuned according to the underlying cache size. The big question here is: "Can we design algorithms to efficiently utilize memory hierarchy, without knowing the underlying cache size?" The answer is yes by using cache-oblivious algorithms [7].

Neural networks greedily consume the memory hierarchy, hence there is a strong need to design neural network algorithms efficiently in terms of memory performance [8], [9]. In this paper, we show the recent direction of the memory model, which is the cache-oblivious model, and the state of the art in cache-oblivious algorithms and data structures. Furthermore, we applied the appropriate cache-oblivious approach to neural networks to improve their memory performances.

The rest of this paper is organized as follows: Sections II and III explain the cache-oblivious model and cache complexity, respectively. Section IV discusses a set of cache-oblivious algorithms, while Section V introduces the extension, which is cache-oblivious neural networks. Finally, we provide a summary of the best lately known cache-oblivious algorithms in Section VI.

II. CACHE-OBLIVIOUS MODEL

The literature discusses two memory-hierarchy models; the external-memory model and the cache-oblivious model. The memory hierarchy of the external-memory model consists of two levels; cache and disk. Such that, cache refers to the near memory to the CPU as disk refers to the far memory from the CPU. The basic unit of transferring data between two memory levels is a block, so the memory is divided into blocks of B

words (a certain number of bytes). At most, the memory of size M can store $\frac{M}{B}$ blocks from data of size N words [10], [11].

To reduce the number of transferring blocks, cache-aware algorithms are designed based on the external-memory model; such algorithms worry about the existence of two levels of memory and their parameters. Cache-aware algorithms perform efficiently with two levels of memory, in terms of memory transfers. But in reality, memory hierarchy is more than just two levels of memory. To cope with this fact, the cache-oblivious model is introduced as an extension to the external-memory model [12], [11].

The cache-oblivious model utilizes all cache levels efficiently without tuning, which means algorithms can utilize the memory without knowing its size M and block size B . Cache-oblivious model is the best choice for the environment that provides a fluctuation amount of available memory for an algorithm. Better algorithms for this model can be better for any possible values of M and B . Cache-oblivious algorithms are particularly helpful for multi-level caches and for caches with changing values of M and B . Recently, the direction of designing cache-efficient algorithms is cache-oblivious algorithms. The advantages of cache-oblivious algorithms are as follows [13], [14]:

- 1) Inclusion: As the cache-oblivious algorithms optimally progress between two adjacent levels of the memory hierarchy, which are cache referring to the near memory to the CPU and disk referring to the far memory from the CPU. Then, these algorithms are automatically adapted between any two adjacent memory levels with different values of M and B , because they are not fixed in cache-oblivious algorithms.
- 2) Constant optimal factor: Optimality means the minimum number of cache misses for an algorithm. There is no way to reduce the cache misses for an algorithm less than its optimal cache misses. When the number of memory transmissions or cache misses is optimal to a constant c between any two adjacent memory levels, then this optimality is kept within a weighted factor between the other two adjacent memory levels, such that the weighted mixture will be corresponding to the relative speeds of the memory levels. For example, assuming the optimal number of cache misses between two adjacent memory levels to traverse data of size N is $\left\lceil \frac{N}{B} \right\rceil$. Then, this factor is kept between the other two adjacent memory levels and is weighted by their relative speeds. Thus, algorithms in a two-level memory model can be designed and analyzed to gain outcomes for some levels of the memory hierarchy.
- 3) Self-tuning: Typical cache-aware algorithms need tuning to various cache parameters which are no longer on hand from the manufacturer and are often hard to extract automatically. Parameter tuning makes code portability difficult, while cache-oblivious algorithms perform well on all machines without modifications based on the cache parameters.

III. CACHE COMPLEXITY

Cache complexity is the number of cache misses that are incurred by an algorithm for a problem of input size N and denoted by $T(N)$. The transfer unit between two adjacent memory levels is a block of size B words to amortize the access time cost. Typically, the main goal of an algorithm is to minimize the cache complexity $T(N)$, which is bounded by N as the upper bound and $\frac{N}{B}$ as the lower bound. In other words, the number of memory transfers at most equals the input size when each operation incurs a cache miss, whereas storing related elements in the same memory block B , which is called locality, reduces the number of cache misses into $\frac{N}{B}$ as a lower bound. We are concerned about complexity for large problem N when it is greater than B or even greater than M [15].

Typical cache complexity is a function of N and B because the minimum unit of transferred data is B with one cost unit. Also, M is relevant in cache complexity especially for algorithms with recursion when data fits in the cache and has been loaded in it, then the accessing cost will be zero. Generally, to compute the cache complexity of divide and conquer algorithms, we have to enlarge the base case to fit either B or M sizes [16], [17].

IV. CACHE-OBLIVIOUS ALGORITHMS

Cache-oblivious algorithms are mainly concerned with the efficiency of fetching large data into memory, which needs many memory transfers. This Section shows various cache-oblivious algorithms and their lower bound of memory transfers. Generally, cache-oblivious algorithms provide the lower bound of memory transfers utilizing the ideal cache, which is based on the following assumptions [18], [19], [20]:

- Optimal page replacement, such as evicting the least-recently-used block (LRU) or evicting the oldest-used block (FIFO) [21].
- Full associativity, such that the transferred memory block B can be stored at any available block in the cache.
- Tall cache, which means the number of blocks $\frac{M}{B}$ is greater than the block size B .

A. Scanning Approach

Scanning algorithms access all data items to perform some tasks such as finding maximum element, getting the average of elements, classifying elements, etc. Therefore, scanning algorithms touch all data items once and in the same order as they are stored, consequently, scanning algorithms are not aware of the cache size M . The cache complexity of a scanning algorithm is shown in Equation 1, such that N items lay out in contiguous blocks of memory. The ceiling function indicates one more memory transfer than $\frac{N}{B}$, because either N is not divided by B , or N does not start to lay out items from the beginning of a block. In other words, data items of size B require one memory transfer, but sometimes they require two memory transfers according to the alignment of the data items. For example, if the size of N is 8 and the size of B is 4, then scanning N incurs 2 memory transfers. However, if we did

not start to lay out N items from the beginning of a block as shown in Fig. 1, where N items are displayed in gray color. Even though the N size is $2B$, scanning N incurs 3 memory transfers instead of 2 because of the alignment [10].

$$T(N) = O\left(\left\lceil \frac{N}{B} \right\rceil\right) \quad (1)$$

Fig. 1. Two Consecutive Blocks in Memory (the Gray Blocks Represent a Two-Block-Data item).

B. Divide and Conquer Approach

Divide and conquer algorithms recursively split problems into non-overlapping smaller sub-problems, solve them, and combine them. Divide and conquer algorithms recur down to the base case of constant size. In terms of memory transfers, we consider the base case that either fits one block B or fits within cache size ($\leq M$). Such a size is considered the critical place for memory transfers, where all the cost is. Because once data fits in the cache, the accessing cost will be zero. However, the base case below B is kind of trivial [6].

Nevertheless, the divide and conquer approach is a basic technique for designing cache-oblivious algorithms, which often afford optimal cache complexity within a constant factor among the levels of a memory hierarchy [6].

C. Search Tree Approach

Initially, we will discuss a binary search tree using a divide and conquer approach, where the base case is a sub-tree of size B [6]. Nevertheless, the cache-complexity of the binary search tree on a sorted array is:

$$T(N) = O(\lg N - \lg B) = O\left(\lg \frac{N}{B}\right)$$

Where $\lg N$ is the height of the binary tree, and $\lg B$ is the leaf height i.e. the base case height. However, B-tree can achieve the optimal cache-complexity i.e. $O\left(\frac{\lg N}{\lg B}\right)$ by making the branching factor value between B and $\frac{B}{2}$. The drawback of B-trees is that the branching factor cannot be tuned easily between any two memory levels. Nevertheless, if the branching factor is known for all levels of the memory hierarchy, then the optimal cache-complexity can be achieved by using a B-tree algorithm [6].

The authors of [22] introduced an efficient search tree algorithm that can be tuned easily between any two memory levels and their algorithm achieves the optimal cache complexity. This algorithm is the so-called cache-oblivious tree (or Van Emde Boas layout), which is a binary search tree, but each recursive sub tree is laid out in a single segment of memory. Accordingly, the tree is recursively split from the middle, so the height of the tree is $\lg N$, see Fig. 2. We keep splitting

each half recursively into two almost equal halves. At some point in this recursion, we reach halves of size less than or equal to B [22], [6].

Fig. 2. Layout of the Cache-Oblivious Tree.

For analysis, following a root-to-leaf path visits some sequence of triangles, where each of them fits in, basically one block. In other words, triangle size is, at most B and at least \sqrt{B} , which is generated from splitting $B+1$ sub-tree into two further sub-trees, each of size \sqrt{B} . Thus, the height of the smallest triangle i.e. the leaf belongs to $[\lg \sqrt{B}, \lg B]$. Then, at most the number of visited triangles for a root-to-leaf path of at most $\lg N$ height is as follows [22]:

$$\frac{\lg N}{\lg \sqrt{B}} = \frac{\lg N}{\frac{1}{2} \lg B} = 2 \log_B N$$

Each block requires one transfer, but sometimes a block requires two transfers because of the alignment of each block, as shown in Figure 1. Therefore, the cache-oblivious tree incurs at most $2 \times (2 \log_B N)$ memory transfers. As a result, the cache-oblivious tree performs INSERT, DELETE, and SEARCH operations through an optimal cache complexity, which is shown in Equation 2 [22].

$$T(N) = O(4 \log_B N) \quad (2)$$

D. Sorting Algorithms

Sorting algorithms take N elements of some arbitrary order and put them into a sorted order. Nevertheless, sorting is an essential algorithm in computer science, since it can decrease the complexity of a problem, especially in searching and database problems. There are many ways to sort elements using various algorithms, such as bubble, selection, insertion, merge, quick, heap, radix, bitonic, and bucket sort [23], [24], [25], [26].

The obvious and easiest way to sort elements is by doing N inserts into a regular B-tree, which incurs $O(N \log_B N)$. B-trees are efficient for searches but are not efficient for very frequent updates [27]. To get a better result, an efficient sorting algorithm can be used such as merge sort, which uses a divide and conquer approach.

Merge sort divides the problem into two parts, recursively sorts each part, and recursively merges the two parts. Thus, merge sort requires three parallel scans; one for the first portion, another for the second portion, and the third scan for the merged array, i.e. the sorted array. Such that, we compare the first elements of both unsorted portions, output one of them into the merged array, and move the unsorted portion pointer to the next element, then compare, output one of them, and so on till reaching the end of both unsorted portions [28]. Accordingly, the whole block is scanned, kicked out, and then the next one is read, so the three parallel scans can be afforded, as long as, $\frac{M}{B} \geq 3$.

Nevertheless, we always have to be careful with the base case, whose best size is $\leq M$, because when a sub-array of size M is reached, the whole thing is read without incurring any more cost as long as, the sub-array stays within a region of size M . Figure 3 shows the recursion tree of merge sort, which is better than B-trees and incurs $O\left(\frac{N}{B} \lg \frac{N}{M}\right)$. In terms of memory transfers, $\frac{N}{B}$ is the number of sorted elements and $\lg \frac{N}{M}$ is the longest path through the recursion tree to sort an element [29].

Fig. 3. The Recursion Tree of Binary Merge Sort.

Furthermore, to do a multi-way merge sort such as $\frac{M}{B}$ -way merge sort, then we can mimic the binary merge sort but with $\frac{M}{B}$ portions instead of two portions [30]. In other words, $\frac{M}{B}$ parallel scans are needed, so we have to lay out in cache the first blocks of these $\frac{M}{B}$ sub-arrays, whose size for each of them is $(N/\frac{M}{B})$. As a result, the same solution as binary merge sort is achieved but with a shorter longest path through the recursion tree as $\left(\log_{\frac{M}{B}} \frac{N}{M} + 1\right)$, such that:

$$\begin{aligned} \log_{\frac{M}{B}} \frac{N}{M} + 1 &= \log_{\frac{M}{B}} \left(\frac{N}{B} \frac{B}{M}\right) + 1 \\ &= \log_{\frac{M}{B}} \frac{N}{B} + \log_{\frac{M}{B}} \frac{B}{M} + 1 \\ &= \log_{\frac{M}{B}} \frac{N}{B} - \log_{\frac{M}{B}} \frac{M}{B} + 1 \\ &= \log_{\frac{M}{B}} \frac{N}{B} - 1 + 1 \\ &= \log_{\frac{M}{B}} \frac{N}{B} \end{aligned}$$

Accordingly, Equation 3 shows the cache complexity of sorting N elements using an $\frac{M}{B}$ -way merge sort, which is optimal. Also, an $\frac{M}{B}$ -way merge sort is the so-called cache-

oblivious sorting algorithm [29].

$$T(N) = O\left(\frac{N}{B} \log_{\frac{M}{B}} \frac{N}{B}\right) \quad (3)$$

E. Priority Queue Data Structure

A priority queue is a queue, where every item is associated with a priority. An item with the highest priority is dequeued before any other item. The main operation associated with the priority queue is getting the highest priority item at any given time. Priority queue provides INSERT and DELETE-MIN operations, to add an item to a queue and to dequeue the highest priority item from it, respectively, as the highest priority item corresponding to the minimum number. Literature introduces priority queues supporting a different set of operations. In this section, we discuss the cache-oblivious priority queue supporting INSERT and DELETE-MIN operations [31], [32], [33].

The cache-oblivious priority queue uses a bunch of arrays in a linear order instead of a bunch of B-trees. Because priority queue using arrays is simpler and incurs fewer memory transfers than priority queue using B-trees, which are the best choice for searching operations. The cache-oblivious priority queue using the divide and conquer approach is arranged in levels, as each level is decomposed of two types of buffers; one “up buffer” and a set of “down buffers” such that each buffer is of a certain size. In other words, the cache-oblivious priority queue levels are recursive smaller priority queues, where the highest priority item exists in the smaller priority queue, i.e. the smaller level, in the cache [34].

The cache-oblivious priority queue for N items has $\lg \lg N$ levels, whose sizes are arranged from top to bottom as $N, N^{2/3}, N^{4/9}, \dots, X^{9/4}, X^{3/2}, X, X^{2/3}, \dots, C$, respectively, as shown in Fig. 4. C is a constant size level, and X is a size between N and C . At the same level, the total size of its “down buffers” at most equals the size of its “up buffer”. For example, Level $X^{3/2}$ in Figure 4 has one “up buffer” of size $\Theta(X^{3/2})$ and at most $X^{1/2}$ of “down buffers” each of size $\Theta(X)$. At most, the total size of the “down buffers” at level $X^{3/2}$ is $(X^{1/2} \times X = X^{3/2})$, which matches the size of the “up buffer” at level $X^{3/2}$. For any two consecutive levels, a “down buffer” at the larger level matches the size of the “up buffer” at the smaller level. For example, $X^{3/2}$ and X are consecutive levels as shown in Fig. 4, the size of a “down buffer” at level $X^{3/2}$ (i.e. the larger level) is X , which matches the size of the “up buffer” at level X (i.e. the smaller level) [34].

Generally, minimum and maximum items are corresponding to the highest priority item and the least priority item, respectively. At a level, items of its “up buffer” are disordered and their priorities are less than all items in the “down buffers” at that level. Items of a “down buffer” are disordered and their priorities are greater than items of the next “down buffer” at the same level. However, items of the “down buffers” at the very small levels are ordered and have the minimum item, i.e. the highest priority item. The priority queue algorithm knows the maximum item, which is corresponding to the least priority item, of each “down buffer” at all levels [31], [34], [29].

INSERT operation appends the new item i to the “up buffer” of the smallest level in the cache. Then the algorithm

Fig. 4. Cache-Oblivious Priority Queue Levels.

locates i in an appropriate “down buffer” of the smallest level by comparing i to maximum items of the “down buffers” sequentially. If the selected “down buffer” has space, i is just added to it, otherwise, the “up buffer” swaps i with the maximum item in the selected “down buffer”. When the “up buffer” overflows, the algorithm performs the push operation[29].

To describe push operation, assume the “up buffer” of level X overflows, then the algorithm pushes X items of the level X “up buffer” into level $X^{3/2}$ “up buffer”. After that, the algorithm sorts X items and distributes them among the “down buffers” at level $X^{3/2}$ and possibly the “up buffer” at level $X^{3/2}$. Such that to allocate every item in its appropriate buffer, the algorithm scans the X items sequentially and visits “down buffers” at level $X^{3/2}$ in order. When the selected “down buffer” overflows, it is split in half to spawn a new “down buffer” at level $X^{3/2}$. However, if the number of allowed “down buffers” overflows, according to our example, the number of “down buffers” at level $X^{3/2}$ exceeds $X^{1/2}$, then the last “down buffer” at level $X^{3/2}$ is moved into the “up buffer” at level $X^{3/2}$. When this “up buffer” overflows, the algorithm pushes recursively $X^{3/2}$ items of the level $X^{3/2}$ “up buffer” into the level $X^{9/4}$ “up buffer” [29].

DELETE-MIN operation reverses the INSERT operation, therefore the algorithm deletes and pulls instead of inserts and pushes. The pull operation is a sort of reverse distribution step. Usually, “down buffers” of the smallest level are kept sorted in the cache and have the minimum item all the time, so the highest priority item is touched with zero memory transfers. However, there is no need to sort items in “down buffers” of the larger levels, we just need to keep track of the maximum items for the “down buffers” of larger levels. The smallest level in external memory is called the key level, where the algorithm consumes memory transfers to touch any item there.

In the cache-oblivious priority queue, most memory transfers are consumed to sort items. Consequently, the cache-oblivious priority queue provides INSERT and DELETE-MIN operations for one element with the cost of sorting, as shown in Equation 4 [29].

$$T(N) = O\left(\frac{1}{B} \log_{\frac{M}{B}} \frac{N}{B}\right) \quad (4)$$

F. Matrix Multiplication Algorithm

Matrix multiplication is the most essential matrix operation since it has significant applications in various fields. Examples are cryptography, wireless communication, computer graphics, computations in linear algebra, solution of linear systems of equations, the transformation of coordinate systems, and computational modeling [35], [36], [37], [38], [39].

Multiplying two matrices of size $N \times N$ using the standard matrix-multiplication algorithm incurs $O\left(\frac{N^3}{B}\right)$ memory transfers. However, the cache-oblivious algorithm uses the divide and conquer approach to solve matrix-multiplication problems. For simplicity, assume that A, B, and C are square matrices of size $N \times N$ for each. The cache-oblivious algorithm recursively partitions these matrices into quadrants, as shown in Fig. 5 [40], [41], [42].

Fig. 5. Cache-Oblivious Algorithm Recursively Divides Matrices into quadrants.

The algorithm performs eight recursive matrix multiplications to update the four quadrants of C. At some point in this recursion, we get a base case, that the three sub-matrices fit in a certain number of B's, or for the best base case when the three sub-matrices fit in the cache M . For cache complexity analysis, the recursion stops at the best base case, when the three sub-matrices of size $c\sqrt{M} \times c\sqrt{M}$, such that, c is a constant due to dividing cache into three sub-matrices. Then, the three sub-matrices fit in the cache, and accessing any element of them is free [43].

Nonetheless, this recursion is dominated by its leaves, so its cache complexity is the total number of leaves times the cache misses per leaf. Accordingly, each leaf of this recursion incurs $O\left(\frac{M}{B}\right)$ memory transfers, as the total number of leaves is:

$$8^{\lg N - \lg c\sqrt{M}} = 8^{\lg \frac{N}{c\sqrt{M}}} = \left(\frac{N}{c\sqrt{M}}\right)^{\lg 8} = \frac{N^3}{cM^{\frac{3}{2}}}$$

So, the total number of memory transfers is $\frac{M}{B} \times \frac{N^3}{cM^{\frac{3}{2}}}$. Consequently, Equation 5 shows the cache complexity of the

cache-oblivious matrix-multiplication algorithm using recursive block matrices, which is the optimal cache complexity for matrix-multiplication problems [40], [41], [42].

$$T(N) = O\left(\frac{N^3}{B\sqrt{M}}\right) \quad (5)$$

V. EXTENSION: CACHE-OBLIVIOUS NEURAL NETWORKS

Generally, a neural network iteratively learns by datasets, such that a neural network passes the whole dataset several times to learn correctly, as the neural network gets better performance in terms of mean squared error and accuracy [44]. The number of passes through the entire dataset is called epochs. To speed up the learning process, a dataset of size N is divided into mini-batches as a minimum learning unit, where a neural network updates its parameters after passing each mini-batch. Consequently, every epoch consists of several mini-batches, each of them having a size between 1 and N . For brevity, mini-batches are commonly called batches [8], [45], [46].

During the learning process, the neural network must be kept in the cache, but mini-batches are loaded and kicked out as needed. For the cache-oblivious neural network, the dataset must lay out in contiguous segments of memory, in any order, so the neural network scans the dataset in the same order it is stored [6]. The mini-batch size interacts with other hyper-parameters and must be optimized at the end to find the optimal size. However, if the size of a neural network is P , then the mini-batch size equals a multiple of B , as the selected multiple of B is recommended to be $\leq (M - P)$ to avoid incurring a memory transfer within a learning unit. In other words, it is recommended to select the mini-batch size as a power of two, that does not exceed $(M - P)$.

Accordingly, if a neural network of size P , using a dataset of size N , and a number of epochs E , then the cache complexity of this problem is described in Equation 6. As the number of epochs increases to get better results, the cache complexity of a neural network for a large problem (i.e. $P + N > M$) increases by at most the same factor. However, the number of epochs does not incur any memory transfer for a small problem (i.e. $P + N \leq M$).

$$T(N) = \begin{cases} O(\lceil \frac{P}{B} \rceil + \lceil \frac{N}{B} \rceil), & \text{if } P + N \leq M \\ O(\lceil \frac{P}{B} \rceil + E \times \lceil \frac{N}{B} \rceil), & \text{if } P + N > M \end{cases} \quad (6)$$

Neural networks greedily access memories, consequently, if N does not lay out in contiguous segments of memory, the cache complexity of a neural network will expand by a factor of N . Another extreme case that expands the cache complexity of a neural network, is when the N element is larger than B , so accessing any of the N elements initiates a memory transfer, too.

A. Experimental Results

To examine cache-oblivious neural networks, we implemented a cache simulator based on Intel i7 CPU and a memory hierarchy as described in Table II. Our cache simulator using

Python 3.6 is concerned with the L1 cache, whose block size is $8KB$, consequently, $M = 8MB$ and $B = 8KB$. Additionally, the simulator uses a tall full associative cache and the LRU as a page replacement policy.

TABLE II. EXPERIMENTAL MEMORY HIERARCHY

Memory level	Size
L1 Cache	8MB
L2 Cache	1GB
Main memory (RAM)	8GB

Furthermore, a 6-layer-stacked auto-encoder (SAE) model is used to classify the MNIST dataset as being created according to the authors of [8]. The experimental 6-layer SAE of 1139710 parameters occupied a $4.35MB$ of M . We examined two factors, the dataset sizes $\{0.63, 1.59, 3.18, 6.36, 9.69, 13.02, 16.36\}$ in MB and the number of epochs $\{0, 10, 20, \dots, 100\}$. Table III shows the experimental results, which are the total cache misses per epoch using different dataset sizes.

The available cache space for a dataset is $3.65MB$ because the experimental SAE occupied $4.35MB$ of M (i.e. $8 - 4.35$). Thus, three dataset sizes fit the free space of M as the rest dataset sizes are larger than the free space of M . Accordingly, we split the results into two figures; Fig. 6 shows the cache misses of the experimental SAE using small dataset sizes (i.e. $P + N \leq M$), and Fig. 7 shows the cache misses of the experimental SAE using large dataset sizes (i.e. $P + N > M$). Epoch zero represents the initial step when the SAE model is loaded to M without the dataset. Therefore, all experiments using any dataset size have the same number of cache misses at zero epoch, which equals 557 cache misses i.e. $\lceil \frac{\text{modelsize}}{B} \rceil = \lceil \frac{4.35MB}{8KB} \rceil$, as illustrated in Table III.

Fig. 6 shows that increasing dataset size increases the cache misses. However, increasing the number of epochs does not perform any additional cache misses. Because the experimental SAE and the dataset fit M . Fig. 7 shows that increasing dataset size increases the cache misses too. Additionally, increasing the number of epochs increases the cache misses by the same factor. Because the experimental SAE and the dataset are larger than M , consequently, every dataset access performs a cache miss. For example, the dataset size of $6.36MB$ in addition to the model size of $4.35MB$ needs $10.71MB$, which is greater than M . Therefore, the cache misses based on Equation 6 are $557 + E \times \lceil \frac{6.36MB}{8KB} \rceil$, as shown in Table III. However, if the dataset size is 3.18 , then the total needed space is $(3.18MB + 4.35MB = 7.53MB)$. Thus, the problem fits M , and the cache misses based on Equation 6 are $557 + \lceil \frac{3.18MB}{8KB} \rceil$, which is independent of E , as illustrated in Table III.

VI. SUMMARY

Cache-oblivious algorithms utilize all levels of memory hierarchy efficiently, without knowing their parameters or even the existence of memory hierarchy levels. Thus, cache-oblivious algorithms support portability and better memory performance. Cache complexities of cache-oblivious algorithms are denoted by the cache parameters i.e., the cache size M and the block size B , even though M and B are unknown for cache-oblivious algorithms in reality.

Fig. 6. Cache Misses of SAE using Small Datasets.

Fig. 7. Cache Misses of SAE using Large Datasets.

This paper discusses the cache complexities of the optimal recently known cache-oblivious algorithms for most essential problems, as summarized in Table IV. Notice that, the same input size N for all algorithms, but each of them incurs a

different number of cache misses according to the algorithm target. Generally, cache-oblivious algorithms utilize a divide and conquer approach with a base case based on the algorithm behavior. However, their cache complexities are calculated on different base cases that are proportional to either the block size B or the cache size M .

TABLE IV. CACHE-COMPLEXITY BASED ON CACHE-OBVIOUS MODEL

Cache-oblivious algorithm and data structure	Cache-complexity
Scanning	$\lceil \frac{N}{B} \rceil$
Binary search tree	$4 \log_B N$
$\frac{M}{B}$ -way merge sort	$\frac{N}{B} \log \frac{M}{B} \frac{N}{B}$
Priority queue	$\frac{1}{B} \log \frac{M}{B} \frac{N}{B}$
Recursive block-matrix multiplication	$\frac{N^3}{B\sqrt{M}}$
Small neural network ($P + N \leq M$)	$\lceil \frac{P}{B} \rceil + \lceil \frac{N}{B} \rceil$
Large neural network ($P + N > M$)	$\lceil \frac{P}{B} \rceil + E \times \lceil \frac{N}{B} \rceil$

Moreover, we introduce an extension that applies the cache-oblivious scanning approach to neural networks. In other words, to minimize the cache complexity of a neural network, the dataset must lay out in contiguous blocks of memory. When a neural network and its dataset are within cache size, the cache complexity is $\leq \frac{M}{B}$. Otherwise, cache complexity is growing by a factor that at most equals the number of epochs, as shown in Fig. 7. Nevertheless, if the dataset does not lay out in contiguous blocks of memory, then the cache complexity of a neural network expands, consequently, its learning process consumes unreasonable time.

Abstract—Overlapping Snowball Chain is an extension to Snowball Chain, which is based on the concept of community formation in line to the snowball chaining process. The inspiration behind this approach is from the snowball sampling process, wherein a snowball grows to form chain of nodes, leading to the formation of mutually exclusive communities in Snowball Chain. In the current work, the nodes are allowed to be shared among different snowball chains in a graph, leading to the formation of overlapping communities. Unlike its predecessor Snowball Chain, the proposed technique does not require the use of any hyper-parameter which is often difficult to tune for most of the existing methods. The proposed algorithm works in two phases, where overlapping chains are formed in the first phase, and then they are combined using a similarity-based criteria in the second phase. The communities identified at the end of the second phase are evaluated using different measures, including *modularity*, *overlapping NMI* and *running time* over both real-world and synthetic benchmark datasets. The proposed Overlapping Snowball Chain method is also compared with eleven state-of-the-art community detection methods.

Keywords—Clustering coefficient; community detection; overlapping communities; snowball sampling; social graph

I. INTRODUCTION

In recent years, there has been a tremendous growth in the study of linked data in the form of networks, such as Internet, World Wide Web, and social networks. The relationships among the entities existing in these networks provide rich insights pertaining to various dynamic interactions and might prove to be beneficial in various applications [1]. To analyse and study these networks, graph is used as a data structure, which consists of a set of nodes joined by links or edges that can be labelled/unlabelled, directed/undirected, or signed/unsigned. The representation of an online social network is termed as *social graph*, which provides a good visualization and eases the interpretation of the network.

One of the emerging research areas in social network analysis is community detection, which digs deep into the social graph and mines the most dense subgraphs that are highly cohesive in nature. A community in a network is represented by a set of nodes with high density links among themselves, but low-density links among inter-community connections [2]. These subgraphs are called communities or modules. Community detection in a social graph mainly involves splitting it into its constituent functional groups. The task has

largely been addressed in a distinct community context wherein the communities are considered to be mutually exclusive. However, in case of real-world networks, community structures can be overlapping wherein a node belongs to multiple communities. A density-based approach called CMiner in [3], aims to find similarity among nodes and defines a distance function. Overlapping communities are identified based on this distance function. Another work in [4], detects overlapping communities along with their evolution, called as OCTracker. A similar work in [5], identifies hierarchical communities called HOCTracker which works for dynamic social networks.

The work in this paper aims to address this issue by proposing a novel overlapping community detection algorithm which extends the existing *SbChain* algorithm. The proposed method, named *OvSbChain*, starts with identification of the seed or core nodes in a social graph based on a node parameter, called *normalized degree*. The nodes in the entire social graph are ranked on this parameter and processed in a non-increasing order of their ranks. The method works in two phases. In the first phase, every node is paired with its best suited neighbor in accordance to a score value in each iteration. After several iterations, chains of nodes are formed that may share nodes with each other, i.e., there could be overlapping nodes among different chains. Therefore, the proposed technique is called overlapping snowball chains. The second phase tries to combine chains based on a similarity criteria as discussed in Section III, which finally leads to the formation of overlapping communities. Therefore, the technique focuses on resolving the problem in hand, i.e., community detection using an uncomplicated and elementary strategy. The major enhancements in this work can be summarized as follows:

- 1) *OvSbChain* introduces overlapping communities unlike *SbChain*, which produces only crisp communities.
- 2) There is no hyper-parameter tuning required in *OvSbChain*, hence, it always produces the same set of communities every time it is run.
- 3) *SbChain* uses a maximum common neighbor criteria for finding its best neighbor. Whereas, *OvSbChain* uses normalized degree function to find its best neighbor. Also, both the techniques differ in the way they find the seed nodes. This is discussed in detail in Section III.
- 4) The results are evaluated and compared based on

Nicosia modularity measure [6], two types of *ONMI* [7], [8] and their *running time*, as discussed in Section IV.

The proposed *OvSbChain* method is compared with eleven state-of-the-art community detection methods, including CFinder [9], LAIS [10], CONGA [11], PEACOCK [11], COPRA [12], SLPA [13], Demon [14], BIGCLAM [15], MULTICOM [16], Lemon [17] and ANGEL [18]. The results from all these methods are evaluated on different parameters including *modularity*, *ONMI* and *running time*, as discussed in Section IV.

The rest of the paper is organized as follows. Section II presents a brief review of the existing literatures on overlapping community detection. Section III presents the preliminary concepts, along with the proposed approach. This section also presents the functional details of the *OvSbChain* method. Section IV describes the details about the datasets, evaluation parameters, experimental settings, and analysis of the results. Section V concludes the paper and finally, Section VI provides future directions of research.

II. RELATED WORK

This section presents a brief description of the state-of-the-art in the area of overlapping community detection. A review of the current community detection methods is described in [19]. It segregates the detection methods into probability-based and deep learning-based. The classical methods use probability-based models for community identification. Whereas, complex networks are generally converted to lower dimensional data using deep learning methods so as to ease the process. A few other works like [20], [21], [22], discuss various community detection algorithms based on their weakness and strengths, performance of algorithm and other domains. We mainly discuss all the traditional approaches for overlapping community detection and compare them with *OvSbChain* in Section IV.

CFinder is an overlapping community detection technique that makes use of the Clique Percolation Method (CPM) [23] to identify the k -cliques in a network. A k -clique is a complete subgraph consisting of k nodes. This method finds dense groups of overlapping nodes in a network [9].

LAIS [10] is an algorithm that combines two functions List Aggregate (LA) and Improved Iterative Scan (IS^2). The LA procedure initializes the clusters, and the IS^2 procedure improves upon these set of clusters in an iterative manner. The IS procedure starts with a seed node and processes clusters by expanding or shrinking them according to a metric value, and IS^2 improves upon this by focussing on nodes within a cluster and its neighboring nodes, instead of considering the entire graph. The overall algorithm detects overlapping community in a network.

CONGA (Cluster-Overlap Newman Girvan Algorithm) [11] is an overlapping community detection algorithm that uses the concept of split-betweenness, i.e., it counts the shortest paths that exist between all pairs of nodes in the network. It keeps removing edges with high betweenness, and thus, keeps splitting the network into singleton clusters. The partition with the desired number of clusters is picked up. However, it requires number of communities as an input for the algorithm.

PEACOCK algorithm [11] consists of two phases; the first phase is similar to CONGA, where the network is split using split betweenness. The altered network is processed by a disjoint community detection algorithm, called centrality of detecting communities based on node centrality or CNM.

COPRA [12] technique extends the previous work on the label propagation by Raghavan, Albert, and Kumara [24], and it is able to detect overlapping communities in a social network. The main extension is to make the label and propagation step to include information about more than one community. Therefore, it allows each node to belong to up to v communities, where v is a hyper-parameter.

In SLPA (Speaker-listener Label Propagation algorithm) [13], the nodes store multiple labels, and act either as the provider or consumer of information. A node keeps gathering information about the observed labels without removing the previously stored label. The frequency of observation of a label by a node is directly related to the spreading of the label among other nodes. It requires a threshold input parameter that gives the minimum probability of occurrence of a label, before it is deleted from the memory of the node.

Demon (Democratic Estimate of the Modular Organization of a Network) [14] is a simple approach for community detection which works on the modular structure of networks. Firstly, each node finds and votes the communities present in its local neighborhood, using a label propagation algorithm. These local communities are merged to form a global collection by combining all the votes, leading to the formation of overlapping modules. However, this algorithm requires a minimum threshold parameter.

BIGCLAM (Cluster Affiliation Model for Big Networks) [15] is a model-based community detection algorithm that allows for identification of dense overlapping, hierarchical communities in massive networks. Each node-community pair is assigned a non-negative latent factor that decides the degree of membership between them. The probability of a connection between a pair of nodes in the network is modeled as a function of the shared community affiliations. Further, the communities are identified using non-negative matrix factorization methods and block stochastic gradient descent.

MULTICOM is another community detection technique that produces overlapping communities starting with an initial seed set. Local community is detected around the seed nodes using a transformation function. After this step, each node belongs to a single community. Thereafter, the transformation function is used to transform a node into its respective vector, that is clustered using a local clustering technique. For each cluster produced in the previous step, a ratio value is calculated using a function mentioned in [16]. The clusters having ratio value less than a pre-defined threshold are considered for further exploration. The process keeps repeating until the number of communities is greater than the set value or if there is no new seed.

In [17], the technique called Lemon (Local Expansion via Minimum One Norm) detects overlapping communities by finding a sparse vector in the local spectra span, such that all the seeds are in its support. The span of vector dimensions produced by random walk is used as an approximate invariant subspace, called the local spectra. However, this local spectral

approach is used for community detection from a small seed set.

ANGEL [18] is a faster successor of Demon that uses a bottom-up approach to find overlapping communities. It works in two phases, where the first phase produces local communities using ego network of the nodes. The second phase merges communities until convergence or a threshold value is met.

The work in [25], develops a PageRank algorithm with constraints so as to obtain tightly packed overlapping communities. Using probability-based methods, a walker avoids irrelevant communities. Therefore, it results in communities with good fitness score. In [26], a method called Adjacency Propagation Algorithm (APA) is developed using adjacent nodes as seed nodes. It uses a threshold parameter to identify subgraphs based on their intraconnectivity. Another work in [27], can produce disjoint as well as overlapping communities in a two-step process that uses genetic algorithm. In the first step, mean path length of a community is calculated in relation with its respective ER random graph. And the second step shrinks the search space by selecting a subset of nodes. Another work in [28], influential nodes are identified to form local communities. These communities expand as nodes join these local communities. Overlapping communities are merged and evaluated on a model.

An application-based work in [29], exploits community detection to protect the privacy of individuals on social platforms. It discusses community detection attacks and rewiring of connections for development of effective attack approach.

OvSbChain approach focuses on local community detection using graph parameters such as degree and global clustering coefficient. If these local communities are identical they are merged. The motivation behind this work is that it exploits simple topological features of the graph to detect communities without any expensive overhead in two simple levels, (i) formation of local communities, and (ii) combining local communities based on two criteria.

III. PROPOSED APPROACH

The OvSbChain approach discussed in this section is an extension to the previously developed SbChain [30] method. It detects overlapping communities, i.e., nodes are allowed to be shared among more than one community. The approach works on two levels. In the first level, it starts with finding the best suited pairs of nodes according to an initial criterion. This level ends up with formation of overlapping snowball chains. In the second level, these chains are merged to form the larger chains, and eventually form communities based on global clustering coefficient or majority overlapping criteria.

A. Preliminaries

For a graph $G(V, E)$, V represents the set of vertices or nodes in the graph, i.e. $\{v \in V\}$, where n is the number of nodes. And E is the set of edges, i.e., $\{e_{uv} = (u, v) : u, v \in V\}$. This section presents the details about frequently used terms and their meanings, as mentioned in table I.

OvSbChain works at two levels that are described in the following paragraphs:

TABLE I. NOTATIONS AND THEIR DESCRIPTIONS

Notation	Description
$\mathcal{N}(v)$	Set of immediate neighbors of a node v
$k(v) = \mathcal{N}(v) $	Degree of a node v
k_{max}	Maximum degree value in the graph
$\mathcal{N}_{best}(v)$	Best scoring neighbor of node v
$s^{(n)}$	n^{th} snowball chain
$GCC(s^{(n)})$	Global clustering coefficient of a snowball chain $s^{(n)}$

1) *Level-I*: It starts by finding the seed nodes and sorting them in non-increasing order, based on the following criteria so as to begin the processing.

- 1) Seed function - A seed v can be identified by sorting nodes according to their normalized degree value function, given by equation 1. This also represents the score $score(v)$ of a node v .

$$score(v) = k(v)/k_{max} \quad (1)$$

These sorted nodes are processed in non-increasing order of this function value. It should be noted that SbChain used a combination of normalized degree and normalized local clustering coefficient for sorting of nodes.

- 2) $\mathcal{N}_{best}(v)$ function - The best suited neighbor for a seed v is identified using the same score value, i.e., the normalized degree. This neighbor further combines with the seed v to form a snowball chain. Whereas, SbChain used maximum number of overlapping neighbors for finding its best neighbor.

It should be noted that these functions have been chosen and designed empirically.

2) *Level-II*: The second level starts with the chains formed in the first level. These chains are merged to form communities, so as to eliminate almost similar chains. The snowball pairs/chains formed in first level are combined based on global clustering coefficient (GCC) or majority overlapping criteria to form a community. GCC signifies the number of closed triangles to the number of triplets in a graph. Therefore, the technique focuses on finding higher values of GCC for a community, so as to find coherent communities. The first criteria involves calculation of GCC of the formed community, along with GCC of each individual snowball chain. If the combined GCC is higher than the GCC of each chain, then their combination is permitted, otherwise it is discarded, i.e., the chains remain undisturbed. Communities can also be combined as per the second criteria of majority overlapping. This allows communities to get merged if they have atleast 70% overlapping nodes. This percentage is decided empirically, as the value of communities do not change after this point. Also, the minimum percentage overlap was decided to be above 50% so as to form coherent communities. The majority overlapping test prevents the existence of two or more similar communities.

It should be noted that OvSbChain creates overlapping communities because it does not follow *non-redundant node strategy*, previously used by SbChain. According to this

Algorithm 1: bestNeighbor($v, \mathcal{N}(v)$)

Input : Node v , neighbor list $\mathcal{N}(v)$
Output: Best neighbor of v i.e, $\mathcal{N}_{best}(v)$

```

1  $maxWeight \leftarrow 0$ 
2 foreach  $v \in \mathcal{N}(v)$  do
3   if  $score(v) \geq maxWeight$  then
4      $maxWeight \leftarrow score(v)$ 
5      $\mathcal{N}_{best}(v) \leftarrow v$ 
6   end
7 end
8 return  $\mathcal{N}_{best}(v)$ 

```

strategy, a node could join with a single node per iteration which creates mutually exclusive communities. The focus of *OvSbChain* is to develop communities that share nodes among themselves. Therefore, it discards this strategy and allows a node to be a part of multiple chains within a single iteration itself.

TABLE II. DIFFERENT TYPES OF REAL-WORLD DATASETS

Dataset	Nodes	Edges

Blogs [38]	3982	6803
Protein [39]	2445	6265

TABLE III. PARAMETERS USED TO GENERATE LFR-1K NETWORK

Parameter	Value
Nodes (N)	1000
Average degree ($\langle k \rangle$)	15
Minimum community size (c_{min})	20
Maximum community size (c_{max})	50
Maximum degree (k_{max})	50
Number of overlapping nodes (o_n)	100
Number of memberships of the overlapping nodes (o_m)	30
Mixing parameter (μ)	[0.1, 0.5]

B. Algorithm

As discussed in the algorithm 2, *OvSbChain* starts with the pre-processing, i.e., it calculates neighbor list $\mathcal{N}(v)$, degree list $k(v)$ and $score(v)$ (equation 1) for each node v in the social graph. These nodes are then sorted in non-increasing order of their respective $score$ and processed one at a time. Snowball chains are formed by finding the best neighbor (algorithm 1) for each node on the basis of this $score$ value itself, i.e., for a given node v , the best neighboring node $\mathcal{N}_{best}(v)$ with highest value of $score$ parameter is chosen.

In the first iteration, best suited node pairs are combined. The snowball chains $s^{(n)}$ so formed grow internally and new chains are also formed in each iteration, as the nodes find their matches. This sums up the level-I of the proposed technique.

The level-II starts with calculation of global clustering coefficient $GCC(s^{(n)})$ for each snowball chain $s^{(n)}$ formed in level-I. These chains are combined and added to community list C if the GCC of the union of two chains $GCC(s^{(j)} \cup s^{(k)})$

Algorithm 2: OvSbChain(G)

Input : A graph $G(V, E)$
Output: Community list C

```

1 Pre-processing calculates  $\mathcal{N}(v)$ ,  $k(v)$ , and  $score(v)$  for each node  $v$

is greater than either of their individual GCC or if majority of their nodes overlap (i.e., $\geq 70\%$) as mentioned in step 36 of the algorithm. The chains keep combining until both of the criteria fail. If the chains do not combine with other chains, they are directly added to C . The end result is the final set of communities C .

IV. EXPERIMENTAL SETUP AND RESULTS

In this section, the performance of the *OvSbChain* algorithm is evaluated over different datasets using various parameters. The *OvSbChain* is compared with several other overlapping community detection techniques. The following

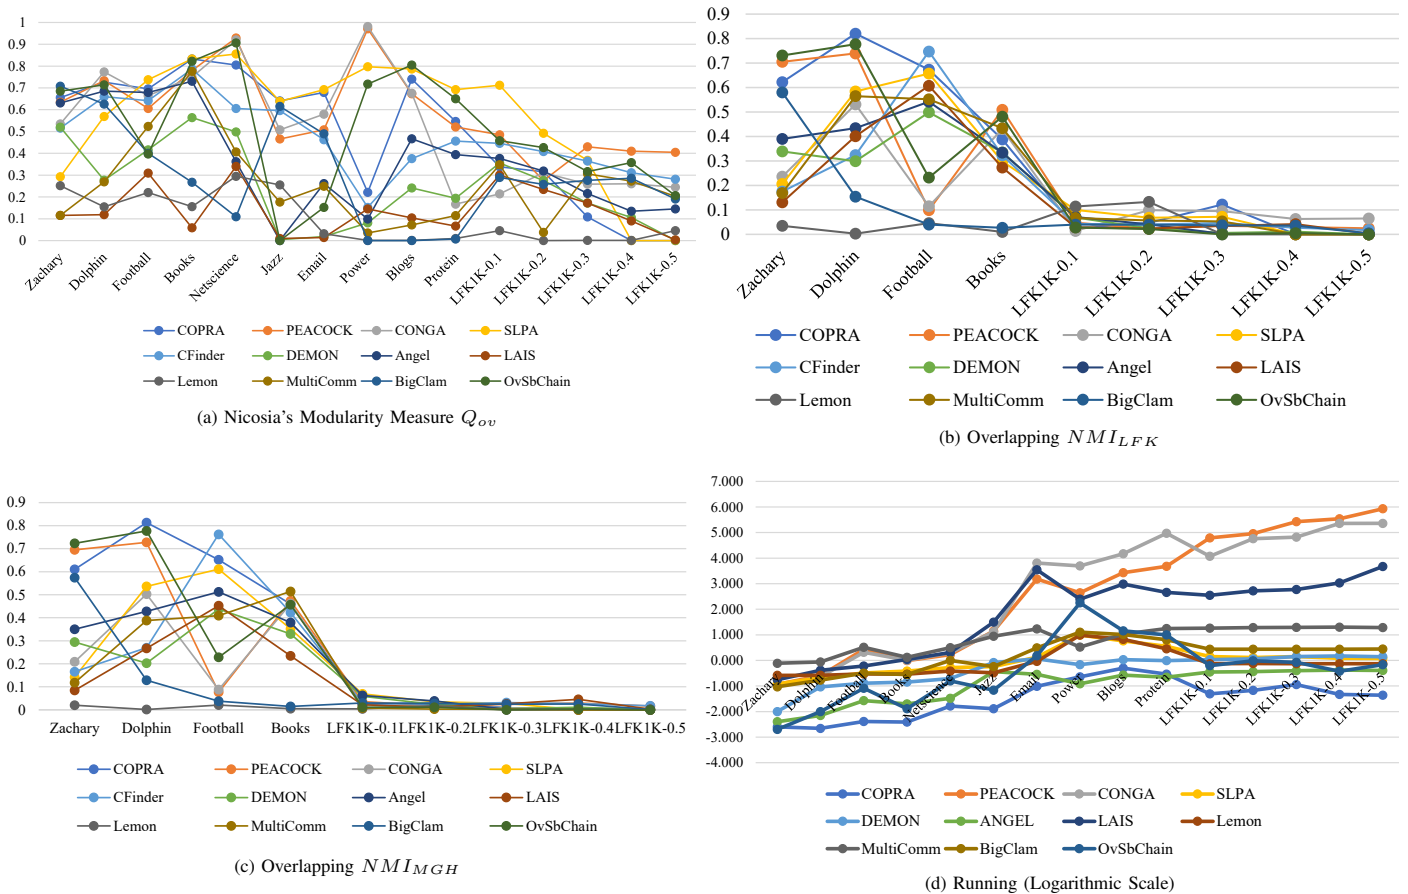

Fig. 1. Comparison of *OvSbChain* with Various Techniques on different Evaluation Metrics

subsections discuss the various datasets used in our experimental evaluations and all the parameters used for assessment of the identified communities.

A. Dataset

The efficacy of *OvSbChain* and other techniques is evaluated over ten real-world datasets and five computer-generated Lancichinetti Fortunato Radicchi (LFR) benchmark datasets [40], as discussed in Tables II and III. The LFR benchmark datasets consists of 1000 nodes with value of the mixing parameter (μ) varying from 0.1 to 0.5. Hence, the datasets are named as LFR1K-0.1, LFR1K-0.2, ..., LFR1K-0.5, respectively.

B. Evaluation Metrics

The communities identified as a result of algorithm 2 are analyzed by an overlapping *modularity* measure given by [6], two types of *ONMI* (Overlapping Normalized Mutual Information), and their *running time*.

It should be noted that the modularity measure given by [6] is represented as Q_{ov} . By definition, $Q_{ov} = 0$, for singleton communities or if all nodes belong to a community. Q_{ov} uses a belonging coefficient for each node which defines the percentage contribution of a node in a community. The sum of this coefficient in 1, for each node.

ONMI is an extension of the NMI score that accommodates overlapping partitions within a network. There are two types of ONMI used in this section; one is LFK (Lancichinetti Fortunato Kertesz) [7], which is referred as NMI_{LFK} , but it overestimates the similarity of two clusters in some cases. To fix this, another ONMI called MGH (McDaid Greene Hurley) is used. This version uses a different normalization than the original LFK based ONMI [8], and it is represented as NMI_{MGH} .

C. Results

Techniques like COPRA, PEACOCK, CONGA, SLPA, CFinder, Demon, and ANGEL use a parameter for tuning. Hence, the values represented in this paper are the best values for Q_{ov} . Fig. 1a shows the results of various overlapping techniques compared with *OvSbChain* on Q_{ov} , respectively. The same is also represented via Table IV. Also, Fig. 2a represents the number of datasets for each technique that have their respective value greater than or equal to 80% of the maximum Q_{ov} that exists for all the techniques. It can be observed that *OvSbChain* has an above average performance in terms of Q_{ov} . Though other techniques are seen to show a better value in terms of Q_{ov} , it is seen that the respective ONMI values drops. Hence, high modularity does not necessarily guarantee good partitions.

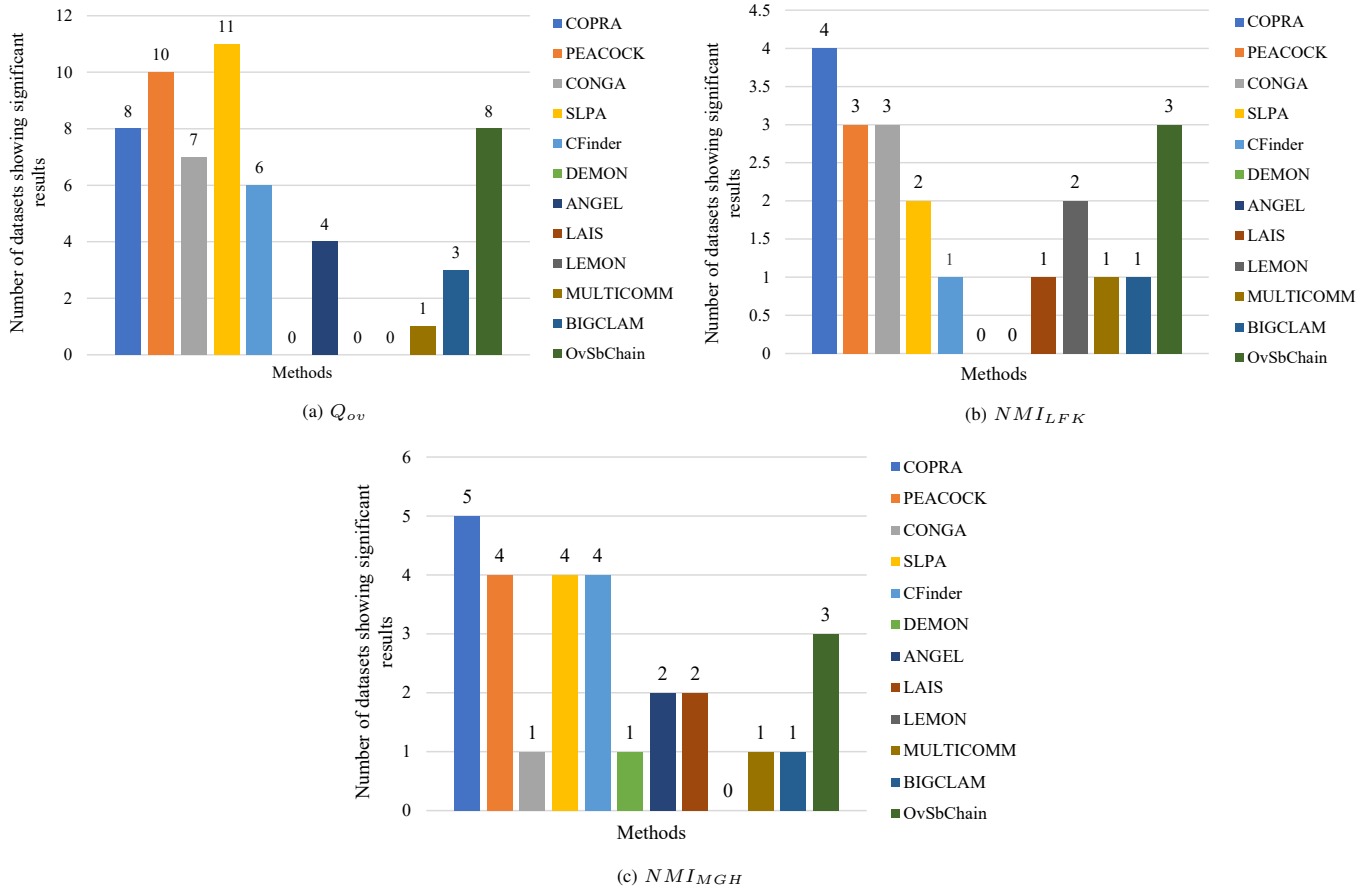

Fig. 2. Comparison of Various Techniques on the Number of Datasets having Values Greater than or Equal to 80% of the Maximum Existing Value of Different Evaluation Metrics

It can be seen that although modularity values are comparable or average in comparison to existing techniques, the ONMI values are promising. As an example, SLPA has the highest modularity among all techniques, it does not produce high ONMI values. *OvSbChain* is faster for smaller datasets and produces comparable or better results for certain cases in terms of both NMI_{LFK} and NMI_{MGH} .

Both NMI_{LFK} and NMI_{MGH} are calculated and compared on both real-world and LFR datasets, as shown in Fig. 1b and 1c for *OvSbChain* and other techniques. *OvSbChain* is seen to perform well in most of the cases. Fig. 2b and 2c also show the comparison of the number of datasets that have NMI values greater than or equal to 80% of the maximum existing value of NMI (among all the given datasets). Tables VI and VII show both the ONMI values. It can be observed that the performance of *OvSbChain* is above average for both NMI_{LFK} and NMI_{MGH} measures.

A comparison of the running time of all the techniques is presented in Fig. 1d. Logarithmic scale is used for this comparison because it provides a better visualization. CFinder technique is excluded from this comparison because it does not mention the time it takes to evaluate the communities so formed. It can be observed that *OvSbChain* works fast on smaller datasets, and it is comparable to other techniques on

larger datasets. The same can be seen through table V. As mentioned before, a few techniques use a parameter which needs to be defined every time they are executed. Therefore, in our experimental evaluation, these techniques were run for different parameter values and the best value for Q_{ov} was chosen and the corresponding ONMI and run time values are represented. On the other hand, our proposed *OvSbChain* approach does not need any parameter value to be set, hence, produces the same result every time it is run.

V. CONCLUSION

It can be seen that the technique *OvSbChain* discussed in the current article works well on real-world datasets with good results in terms of NMI_{LFK} and NMI_{MGH} . It gives comparable results on a few benchmark datasets as well. It should be noted that the running speed of the algorithm was at par with other techniques, or even better in a few cases. The experiments show average results on modularity measure as well. *OvSbChain* does not use any external parameter like most of its counterparts. Also, it produces the same results every time it is run, unlike the other techniques, e.g., COPRA. It gives different results each time it is run (for same parameter value). Hence, it is run for ten times, and the results are averaged. Therefore, it can be established that our technique works well without any parameter tuning, unlike the other

approaches. The overhead of calculations involved in the technique slows it down, but that can be resolved using better hardware options.

VI. FUTURE WORK

The future scope of improvement includes extension of the technique to directed graphs as real-world networks are generally directed in nature. OvSbChain can be improvised to find faster and high coverage seed nodes for snowball chains formation and eventually communities.

Improving the Computational Complexity of the COOL Screening Tool

Mohamed Ghalwash
IBM Research, NY, USA
Ain Shams University, Cairo, Egypt

Abstract—Autoimmune disorder, such as celiac disease and type 1 diabetes, is a condition in which the immune system attacks body tissues by mistake. This might be triggered by abnormality in the development of biomarkers such as autoantibodies, which are generated by unhealthy beta cells. Therefore, screening of such biomarkers is crucial for early diagnosis of autoimmune diseases. However, one of the fundamental questions of screening is when to screen subjects who might be at a higher risk of autoimmune disorder. This requires an exhaustive search to find the optimal ages of screening in retrospective cohorts. Very recently, a comprehensive tool was developed for screening in autoimmune disease. In this paper, we improved the computational time of the algorithm used in the screening tool. The new algorithm is more than 100 times faster than the original one. This improvement would help to increase the utility of the tool among clinicians and research scientists in the community.

Keywords—Software engineering; screening tool; autoimmune disorder

I. INTRODUCTION

Autoimmune disorder is a condition in which the immune system mistakenly attacks healthy body tissues in different organs of the body. For example, in type 1 diabetes, the immune system destroys the insulin-producing cells of the endocrine pancreas, which leads to insulin deficiency [1]. In celiac disease, eating gluten – a protein found in wheat, rye, and barley – causes the autoimmune system to damage the small intestine [2]. There are many factors involved in causing such diseases such as genes, environmental factors, drugs and/or chemicals. However, autoimmune disorder is often associated with a few circulating autoantibodies, which are abnormal antibodies generated by pathogenic β -cells, when targeting a tissue [3]. Autoantibodies are often precede the onset of the disease and, therefore, considered as a clinical biomarker of the autoimmune disorder. In type 1 diabetes and celiac diseases, there are four or five autoantibodies that are often used to assess the risk of developing the disease [4], [5].

Screening for autoantibodies – a group of serum tests to assess the presence of autoantibodies – is usually performed to detect the disease as early as possible so that a proper treatment or intervention can be administered. Therefore, frequent screening is of utmost importance to detect potential autoimmune disorder in subjects who in an apparently healthy population [6], [7]. Although frequent screening is beneficial for detecting subjects who are at a higher risk of the disease, it is cost inefficient and may also introduce harm for those who do not have the diseases by increasing the risk of overdiagnosis [8]. Therefore, one needs to find the *optimal*

ages for screening in order to balance between the benefit and the harm of multiple screening.

To find a proper screening schedule, one needs to do cross-sectional experiments on retrospective cohort to find the optimal ages for screening. The authors of a recent paper [9] proposed a tool, called the Collaborative Open Outcomes tool (COOL), that can be used to compute the quality performance of a given proposed screening schedule according to some measures that can be used to balance between the benefit and the harm of the screening schedule. However, computing these measures for a given schedule is a very time consuming task. In this paper, we propose to make these computations much faster. This proposed enhancement will increase the utility of the tool to compare multiple schedules to find the optimal (according to the given measures) screening schedule much faster.

II. METHOD

A. Data Structure

We explain the structure of the data used for defining the screening schedule. The data has biomarkers information for each subject. Each subject may visit the clinic multiple times and each time a blood sample is taken from the subject to assess the development of biomarkers. The value of each biomarker is either positive (the autoantibody is developed) or negative. It is worth mentioning that each subjects may have a different number of visits.

Notations: We use the upper case letter to define a matrix – a two dimensional array –, e.g. X , a boldface letter to define a vector, e.g. \mathbf{x} , and a italic letter to define an entry or element, e.g. x . $\mathbf{x}[i]$ represents the entry i of the vector \mathbf{x} . $X[i]$ represents the i^{th} row of the matrix X , and $X[i][j]$ represents the entry in the row i and column j .

Mathematically, let us define the data for a subject i as $\mathbf{x}_i = [(t_i^1, \mathbf{x}_i^1), (t_i^2, \mathbf{x}_i^2), \dots, (t_i^{T_i}, \mathbf{x}_i^{T_i})]$ where T_i is the number of visits for the subject i , t_i^j is the subject's age at the visit j , and $\mathbf{x}_i^j \in \{0, 1\}^M$ is the list of M biomarkers for the visit j . In addition, the information about whether and when the disease was developed is recorded. For simplicity, we assume that each subject either developed the disease within a predefined period of time from birth or the subject has been observed for the full period but has not developed the disease¹. If the subject has

¹The other case where the subject is partially observed and has not developed the disease (right censored subjects) can be handled using inverse probability censoring weights [10] but it is outside the scope of this paper.

developed the disease, the subject is not followed afterwards. y_i is the age when the disease was developed and -1 otherwise.

Example II.1. Let us assume that there are four subjects, 1, 2, 3, and 4. The data for these four subjects can be represented as

- $\mathbf{x}_1 = [(1, [0, 1, 0, 1]), (2.3, [1, 1, 0, 0]), (5.8, [0, 1, 0, 1]), (7.1, [1, 0, 1, 0]), y_1 = 9]$
- $\mathbf{x}_2 = [(2.4, [0, 0, 0, 1]), (6, [1, 0, 0, 1]), (9.2, [0, 0, 0, 1]), y_2 = -1]$
- $\mathbf{x}_3 = [(1.9, [0, 0, 0, 0]), (7.4, [0, 0, 1, 1]), y_3 = 8]$
- $\mathbf{x}_4 = [(0.6, [0, 1, 0, 0]), (4.7, [0, 0, 0, 1]), (6.4, [0, 0, 1, 1]), (10, [0, 0, 0, 0]), y_4 = -1]$

Subject 1 has a sequence of $T_1 = 4$ visits. Each visit has measurements for $M = 4$ biomarkers. The first visit was measured at age $t_1^1 = 1$ year and the second and the fourth biomarkers were positives while the other two biomarkers were negatives. The second visit was sampled at age $t_1^2 = 2.3$ years. We can see that the fourth biomarker turned to negative in the second visit while the first biomarker became positive. The subject has developed the disease at age $y_1 = 9$ years. The second subject has $T_2 = 3$ visits at ages 2.4, 6, and 9.2 years and has not developed the disease, i.e. $y_2 = -1$. We clearly see that each subject may have a different number of visits and these visits might be sampled at different ages. A graphical representation of these data is shown in Fig. 1.

Fig. 1. A Graphical Representation for the given Data in the Example. The Green Points Represent Visits while the Red Stars Represent the Age at which the Subjects Developed the Disease. E.g., Subject 3 has 2 Visits and Developed the Disease at Age 8.

One simple data structure that can be used to store the data for all subjects is a 3-dimensional array, where the first dimension is the number of subjects N , the second dimension is the maximum number of visits $S = \max_i\{T_i\}$, and the third dimension is the number of biomarkers M , i.e. $\mathbb{R}^{N \times S \times M}$. However, there are two challenges to store the data in a three-dimensional array. The first challenge is that each subject may have a different number of visits. The second challenge is the irregularity in the biomarkers collections. As seen from the example, the biomarkers are collected at different and irregular time stamps. These two issues pose a challenge to store the data for all subjects in a 3-dimensional array, which assumes that the data are time-aligned. A better data structure for storing such information would be a 2-dimensional array (matrix) with a special structure.

Let us assume that $T = \sum_{i=1}^N T_i$ is the total number of

visits across all N subjects. We construct a matrix X with dimensions $T \times M + 2$, where each row represents one visit for a particular subject. The first column in the matrix represents the subject index, the second column is the age of the subject at the current visit, the other M columns are the values of the biomarkers. Data is sorted in ascending order by subject index and age. An additional array \mathbf{y} stores the age at which the subject developed the disease, i.e. $\mathbf{y}[i]$ is the age when the subject i developed the disease and -1 otherwise.

Example II.2. The matrix for the data in Example II.1 can be represented as

$$X = \begin{bmatrix} 1 & 1.0 & 0 & 1 & 0 & 1 \\ 1 & 2.3 & 1 & 1 & 0 & 0 \\ 1 & 5.8 & 0 & 1 & 0 & 1 \\ 1 & 7.1 & 1 & 0 & 1 & 0 \\ 2 & 2.4 & 0 & 0 & 0 & 1 \\ 2 & 6.0 & 1 & 0 & 0 & 1 \\ 2 & 9.2 & 0 & 0 & 0 & 1 \\ 3 & 1.9 & 0 & 0 & 0 & 0 \\ 3 & 7.4 & 0 & 0 & 1 & 1 \\ 4 & 0.6 & 0 & 1 & 0 & 0 \\ 4 & 4.7 & 0 & 0 & 0 & 1 \\ 4 & 6.4 & 0 & 0 & 1 & 1 \\ 4 & 10.0 & 0 & 0 & 0 & 0 \end{bmatrix} \in \mathbb{R}^{T \times M + 2},$$

$$\mathbf{y} = \begin{bmatrix} 9 \\ -1 \\ 8 \\ -1 \end{bmatrix}$$

As it can be seen, subject 1 has 4 rows in the matrix representing 4 visits, and subject 3 has two rows.

B. Single-Age Screening

Problem 1 (Single-age screening). At which age a , subjects with a positive test at that age will likely develop the disease within the observation period?

The objective of screening at a single age is to assess the likelihood that a subject has the disease. Let us assume that the screening test is whether any biomarker is positive. The question would be how likely subjects with any positive biomarker at a given age will develop the disease within the observation period (e.g. within 10 years from birth). In order to compute the quality performance of the screening at a single age, we need to compute the following Table I:

TABLE I. SUMMARY OF THE SCREENING TEST RESULTS

Screening test	Developed the disease	Not developed the disease
Positive	# true positives (TP)	# false positives (FP)
Negative	# false negatives (FN)	# true negatives (TN)
No test	# no test and positives (NP)	# no test and negatives (NN)

Each subject will be placed in one of these six cells. If the subject was tested positive and developed the disease, the subject will be counted in the TP cell. FP is the number of subjects who were tested positive and have not developed the disease. Similarly, FN (TN) is the number of subjects

who were tested negative and developed (not developed) the disease, respectively. Finally, since not all subjects may not necessarily have a visit at a particular age, some subjects may have no screening test and therefore will be missing from the screening test. This is accounted for in the last row of Table I.

Using the information provided in Table I, the screening test is usually evaluated using the sensitivity and the specificity measures [11]. The sensitivity is the probability that the screening test is positive among those who have the disease. Specificity is the probability that the screening test is negative among those who do not have the disease [12]. These two measures can be computed as:

$$Sen = \frac{TP}{TP + FN} \quad (1)$$

$$Spc = \frac{TN}{TN + FP} \quad (2)$$

Example II.3. If the sensitivity is 80%, it means that 80% of diseased subjects are identified as diseased (have a positive test). If the specificity is 90%, it means that 90% of non-diseased subjects have a negative test (correctly identified as non-diseased).

These two measures are important as they measure the percentage of diseased individuals who have positive test results and the percentage of non-diseased individuals who have negative test results, respectively. Nevertheless, these two measures assume that the test result for each subject is known, i.e. they do not account for subjects with missing tests. Cumulative sensitivity ($CSen$) and dynamic specificity ($DSpc$) address this issue [13]:

$$CSen = \frac{TP}{TP + FN + NP} \quad (3)$$

$$DSpc = \frac{TN}{TN + FP + NN} \quad (4)$$

As it can be seen, $CSen$ and $DSpc$ require all subjects who do/do not have the disease, respectively. However, from the subject's perspective, these two measures do not give insights about the likelihood to develop the disease if the test results is positive or negative. Positive predictive value (PPV) and negative predictive value (NPV) answer this question.

$$PPV = \frac{TP}{TP + FP} \quad (5)$$

$$NPV = \frac{TN}{TN + FN} \quad (6)$$

PPV is the probability of having the disease among those subjects who tested positive. NPV is the probability of not having the disease among those subjects who tested negative.

So, in order to evaluate the performance of a screening test, we need to compute 4 measures $CSen$, $DSpc$, PPV and NPV . Algorithm 1 evaluates the performance of a screening at a given age a by computing these four measures.

Algorithm 1 takes as parameters the age a at which the screening will be evaluated, the data matrix X that encodes the age and the biomarkers information, and the label array y that encodes the age at which the disease was developed. The algorithm utilizes an array $found$ to mark whether the subject

Algorithm 1: Single-Age Screening (SS)

Input: Age a , encoding data matrix X , label array y
Return: $CSen$, $DSpc$, PPV , and NPV .
// list for all N subjects
1 Initialize all N entries of the $found$ list with false
Initialize TP , TN , FP , FN , NP , and NN with zeros.
2 **for** each row in X **do**
 // row is a list of $M+2$ entries
3 $id = row[1]$
4 $age = row[2]$
5 $biomarkers = row[3 : M + 2]$
 / if the age is within 6 months of a */*
6 **if** $a - .5 \leq age < a + .5$ **then**
 // found a visit for the current subject
7 $found[id] = true$
8 **if** $IsPos(biomarkers)$ **then**
9 $PositiveTest(y[id])$
10 **else**
11 $NegativeTest(y[id])$
 / loop over subjects with a missing screening test to compute NN and NP . */*
12 **for** each subject id **do**
 // if the test is missing
13 **if** $found[id]$ is false **then**
14 $MissingTest(y[id])$
15 Compute $CSen$, $DSpc$, PPV , NPV using equations 3-6

Algorithm 2: Helper Functions

1 **Function** $PositiveTest(label)$:
2 **if** $label \geq 0$ **then**
3 $TP = TP + 1$ *// diseased subject*
4 **else**
5 $FP = FP + 1$ *// non-diseased subject*
6 **return**
7 **Function** $NegativeTest(label)$:
8 **if** $label \geq 0$ **then**
9 $FN = FN + 1$ *// diseased subject*
10 **else**
11 $TN = TN + 1$ *// non-diseased subject*
12 **return**
13 **Function** $MissingTest(label)$:
14 **if** $label \geq 0$ **then**
15 $NP = NP + 1$ *// diseased subject*
16 **else**
17 $NN = NN + 1$ *// non-diseased subject*
18 **return**
19 **Function** $IsPos(biomarkers)$:
20 **return**

has a screening test at the given age a , i.e. $found[i] = 1$ if the subject i has a visit at the given age a , and 0 otherwise.

In line 1, the algorithm initializes the boolean array *found* with false. In line 2, it initializes all counts with zero. Then, it loops over all rows in the data matrix *X* (line 3), and for each row it checks whether the age of the current visit is within a specified window of 6 months around the given age (line 7). If yes, it marks that the subject has been tested (line 8) and checks the results for the screening test (line 9) using the function *IsPos*. If the test result is positive (line 10), the algorithm calls the function *PositiveTest* in Algorithm 2, which updates the number of true positives or false positive depending on whether the patient has developed the disease. Otherwise, it updates the number of false positives (line 12). If the test result is negative (line 11), the algorithm calls the function *NegativeTest* which updates either false negatives if the patient developed the disease or true negatives if the patient has not developed the disease.

Finally, after iterating over the entire matrix *X*, the algorithm iterates over the *found* array (line 13) to find those who have not been tested at the given age (line 14) and calls the function *MissingTest* in line 15 to compute the number of subjects who missed the screening test and developed (*NP*) or did not develop the disease (*NN*). After computing *TP*, *TN*, *FP*, *FN*, *NP*, and *NN* counts, the algorithm uses equations (3-6) to compute *CSen*, *DSpc*, *PPV*, and *NPV* for the single-age screening at age *a*.

Time Complexity: The for loop in line 3 has $O(T)$ iterations. Let us assume that the function *IsPos* in line 9 takes $O(M)$. The loop in line 18 takes $O(N)$. Hence, the total time complexity of Algorithm 1 is $O(T.M + N)$.

Example II.4. We compute the quality performance of screening for any biomarker (if any biomarker is positive, the result of the test is positive) at age 2 using data provided in Example II.2. The summary statistics of screening at age 2 is given in the following Table II:

TABLE II. SUMMARY STATISTICS FOR SCREENING OF ANY BIOMARKER AT AGE 2. THE SUBJECT ID COLUMNS INDICATES THE SUBJECTS USED FOR COMPUTING THE MEASURE OR THE COUNT

Screening test	Count	Subject ids
<i>TP</i>	1	1
<i>FP</i>	1	2
<i>TN</i>	0	
<i>FN</i>	1	3
<i>NP</i>	0	
<i>NN</i>	1	4
<i>CSen</i>	0.5	1,3
<i>DSpc</i>	0	2,4
<i>PPV</i>	0.5	1,2
<i>NPV</i>	0	3

The screening at a single age might not perform good as some subjects might miss the screening test and that will reduce the sensitivity and/or specificity of the test. To increase the quality performance of a screening, one can screen twice so that those subjects who missed the first screening can be

covered by the second screening. This is discussed in the next section.

C. Two-Age Screening

Problem 2 (Two-age screening). How likely subjects with a positive test at either one of a pair of ages *a* and *b* will develop the disease within the observation period?

The screening test can be performed at the first age *a*. If the result is positive then no need to screen again and the final result is positive. If the screening test is negative or the subject missed the first screening then another screening is required at the second age and the result of the second screening determines the final result. If the subject missed both screening then it will be counted either in *NN* or *NP* depending whether the subject developed the disease. The two-age screening can be visualized as in Fig. 2.

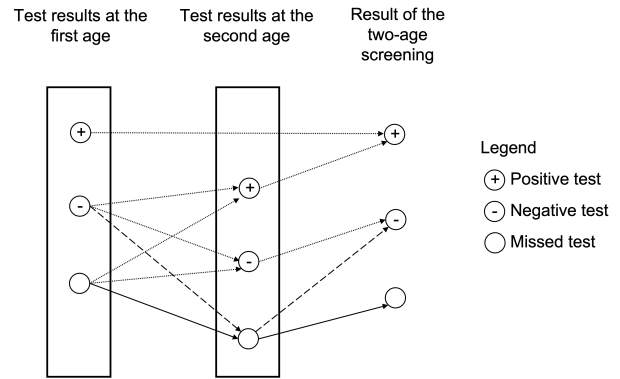

Fig. 2. Visualization of the Two-Age Screening Process. The Final Result of the Screening is Positive if and only if One of the Screenings at the First or the Second Age is Positive. The Final Result is Missing if both Screenings are Missing. Otherwise, the Final Result is Negative.

Algorithm 3 describes the two-age screening process. The algorithm takes a pair of ages *a* and *b* to compute the screening results where $a < b$. For each row in *X*, it tests whether the current visit are within the window of 6 months of age *a* (line 7). If the subject has a visit within that window, the algorithm applies the screening test (line 8) and if the result is positive, it marks that the subject *id* has a positive test at age *a* (line 9) and then updates *TP* and *TN* in line 10. If the result is negative, it marks that the subject has a negative first screening (line 12).

If the current visit is not within the window of 6 months around *a*, the algorithms checks for the second screening (note that the matrix *X* is sorted in ascending order by age). If the visit is within the window of 6 months around the second age *b* and if the subject has no positive results in the first screening (line 13), then it checks the results of the screening at the second age (line 14). If the screening at the second age is positive, the algorithm marks that the second screening is positive (line 15) and updates the counts *TP* and *FP* (line 16). If the second screening is negative, it marks that the second screening is negative (line 18).

After iterating over all rows in *X*, the algorithm iterates over all subjects who missed the first and the second tests (line

Algorithm 3: Two-Age Screening (TS)

Input: Ages a, b where $a < b$, encoding data matrix X , label array \mathbf{y}
Return: $CSen, DSpc, PPV$, and NPV .
// assume all subject missed both screenings

- 1 Initialize all N entries of $found1$ and $found2$ with -1
- 2 Initialize TP, TN, FP, FN, NP , and NN with 0
- 3 **for** each row in X **do**
- 4 $id = row[1]$
- 5 $age = row[2]$
- 6 $biomarkers = row[3 : M + 2]$
- 7 */* if the age is within the window of a */*
- 8 **if** $a - .5 \leq age < a + .5$ **then**
- 9 *// found a visit for the current subject*
- 10 **if** $IsPos(biomarkers)$ **then**
- 11 $found1[id] = 1$ *// 1st test is positive*
- 12 $PositiveTest(\mathbf{y}[id])$
- 13 **else**
- 14 $found1[id] = 0$ *// 1st test is negative*
- 15 **else if** $b - .5 \leq age < b + .5 \wedge found1[id] \neq 1$ **then**
- 16 **if** $IsPos(biomarkers)$ **then**
- 17 $found2[id] = 1$ *// test is pos*
- 18 $PositiveTest(\mathbf{y}[id])$
- 19 **else**
- 20 $found2[id] = 0$ *// test is neg*
- 21 */* loop over subjects with a missing test */*
- 22 **for** each subject id **do**
- 23 *// if both tests are missing*
- 24 **if** $found1[id] = -1 \wedge found2[id] = -1$ **then**
- 25 $MissingTest(\mathbf{y}[id])$
- 26 *// if 1st test is neg and 2nd is missing*
- 27 **else if** $found1[id] = 0 \wedge found2[id] = -1$ **then**
- 28 $NegativeTest(\mathbf{y}[id])$
- 29 Compute $CSen, DSpc, PPV, NPV$ using equations (3-6)

20) to update the counts NN and NP (line 21) and iterates over subjects who tested negative in the first screening and missed the second screening (line 22) to update the FN and TN counts (line 23). Finally, the screening quality measures are computed in line 24.

Time Complexity: The time complexity of Algorithm 3 is $O(TM + N)$.

Although the time complexity of Algorithm 3 is $O(TM + N) \approx O(T)$, but the actual running time is very large, especially if the algorithm needs to be executed multiple times. For example, in almost all cases in medical context, a confidence interval for each measure (sensitivity, specificity, PPV and NPV) is required. To compute the confidence interval [14], the algorithm needs to be run thousands of times on different samples of the matrix X . In addition, to compare different screening schedules, we compute the confidence interval for

each schedule and compare them to see how statistically significant the difference between the screening schedules is [15]. Therefore, it is preferred that the algorithm that computes the quality performance of the screening needs to be fast enough so that all these experiments can be run in a reasonable time.

To do that, we perform a data pre-processing that needs to be done only once, and then we will devise Algorithm 3 to make it faster which can be run multiple times and obtain the results much faster than using Algorithm 3.

D. Improved Two-Age Screening

We start with the improved algorithm for the two-age screening which can be easily modified for single-age screening. To improve the computational time of the two-age screening algorithm, we preprocess the data in a different data structure so that the computation becomes faster. The preprocessing step needs to be executed only once for the data and then each application of the two-age screening uses the preprocessed data and returns the results faster than the original algorithm.

For now, let us assume that we have already constructed a matrix B that contains the biomarker information, which will be used by the screening schedule algorithm (the construction of this matrix is explained in Section II-E). $B \in \mathbb{Z}^{N \times A}$ where A is the number of all possible distinct ages in the data that the screening are to be evaluated at, and N is the number of subjects. The entry $B[id][a] \in \{-1, 0, 1, 2, \dots, 2^M\}$ has the encoding of the biomarkers for the subject id at age a . Since the biomarkers are binary, then the number of all possible cases of biomarkers values is 2^M (note that the number of biomarkers is usually small in these applications as explained in the introduction section). The value -1 indicates that the subject id missed the test at age a .

Example II.5. Given Example II.2, there are $2^4 + 1 = 17$ possible values for each entry in the matrix B . The encoding matrix B is shown here:

$$B = \begin{bmatrix} 10 & 3 & -1 & -1 & -1 & 10 & 5 & -1 & -1 & -1 \\ -1 & 8 & -1 & -1 & -1 & 9 & -1 & -1 & 8 & -1 \\ -1 & 0 & -1 & -1 & -1 & -1 & 12 & -1 & -1 & -1 \\ 2 & -1 & -1 & -1 & 8 & 12 & -1 & -1 & -1 & 0 \end{bmatrix}$$

Column j encodes the biomarker information at age j . For example, the entry $B[2][6]$ encodes the biomarker information for subject $id = 2$ at age 6. The biomarker for subject 2 at age 6 were $[1, 0, 0, 1]$ which can be encoded as $2^1 + 2^0 + 2^0 + 2^1 = 9$. Similarly, the biomarker of subject 3 at age 2 is encoded as $B[3][2] = 2^0 + 2^0 + 2^0 + 2^0 = 0$. All entries with -1 indicate that the subject has no visit at that age, e.g. $B[2][5] = -1$ because the subject 2 has no visit at age 5.

Note that all ages are rounded given the window of interest. For example, visits at ages 2.4 are considered at age 2 (this is similar to line 6 in Algorithm 1)²

Given the matrix B , the improved algorithm for two-age screening is re-written in Algorithm 4. The algorithm iterates over all subjects (line 1), and for each subject id it checks if screening at age a and age b are missing (line 2) then it marks

²If there are multiple visits within the window around the given age, we can consider either the closest visit, the first visit, the last visit, or any other visit based on the application. This is outside the scope of this paper.

that the final result is missing (line 3). If one of the tests is positive (line 4) it marks that the final result is positive (line 5). Otherwise, it marks that the final results is negative (line 7).

Algorithm 4: Improved Two-Age Screening (ITS)

Input: Ages a, b where $a < b$, biomarkers matrix B , label array \mathbf{y}
Return: $CSen, DSpc, PPV$, and NPV .
 /* loop over all subjects */
 1 **for** each subject id **do**
 // if both tests are missing
 2 **if** $B[id][a] = -1 \wedge B[id][b] = -1$ **then**
 3 $MissingTest(\mathbf{y}[id])$
 // one of tests is positive
 4 **else if** $IsPos(B[id][a]) \vee IsPos(B[id][b])$ **then**
 5 $PositiveTest(\mathbf{y}[id])$
 // (both tests are negative) or (one is
 negative and the other is missing)
 6 **else**
 7 $NegativeTest(\mathbf{y}[id])$
 8 Compute $CSen, DSpc, PPV, NPV$ using equations (3-6)

Time Complexity: The running time for Algorithm 4 is $O(N)$.

E. Data Preprocessing for ITS

We preprocess the data only once to construct the biomarker encoding matrix B which makes the algorithm runs faster as evident by our experiments. The algorithm for constructing the matrix B is shown in Algorithm 5. The algorithm iterates over all rows of the matrix X (line 2). For each row, it maps the age to the closest age (line 6), encodes the biomarkers (line 7), and stores the value in the matrix B (line 8). To encode the biomarker information into one integer value (line 9), we multiple the biomarker vector into the encoding vector (line 10) to obtain the code value (line 11).

Algorithm 5: Biomarker Matrix

Input: matrix X
Return: biomarkers matrix B
 1 Initialize all entries of B with -1
 /* loop over all subjects */
 2 **for** each row in X **do**
 3 $id = row[1]$
 4 $age = row[2]$
 5 $biomarkers = row[3 : M + 2]$
 6 $a = Round(age)$ // map it to the closed age
 7 $code = encode(biomarkers)$
 8 $B[id][a] = code$
 9 **Function** $encode(biomarker)$:
 10 $e = [1 \ 2 \ 4 \ 16 \ \dots \ 2^M]^T$ // column
 vector
 11 $code = biomarker \times e$ // matrix
 multiplication
 12 **return** code

Time Complexity: The time complexity of Algorithm 5 is $O(T)$ but this process is executed only once not for each application of screening.

F. Improved Single-Age Screening

The improved algorithm for a single-age screening is shown in Algorithm 6.

Algorithm 6: Improved Single-Age Screening (ISS)

Input: Ages a , biomarkers matrix B , label array \mathbf{y}
Return: $CSen, DSpc, PPV$, and NPV .
 /* loop over all subjects */
 1 **for** each subject id **do**
 // if the test is missing
 2 **if** $B[id][a] = -1$ **then**
 3 $MissingTest(\mathbf{y}[id])$
 // the test is positive
 4 **else if** $IsPos(B[id][a])$ **then**
 5 $PositiveTest(\mathbf{y}[id])$
 // (the test is negative)
 6 **else**
 7 $NegativeTest(\mathbf{y}[id])$
 8 Compute $CSen, DSpc, PPV, NPV$ using equations (3-6)

III. EXPERIMENTS

We evaluated the performance of the SS, TS, ISS and ITS algorithms on datasets with different number of subjects and visits. The description of the datasets is shown in Table III. The experiments were run on a Mac laptop with processor 2.7 GHz Quad-Core Intel Core i7 and 16 GB of memory. The screening test used for these experiments is to test for any positive biomarker, i.e. if any biomarker is positive the result of the screening test is positive. The code is written in Python [16]. Python has a data structure called pandas dataframe [17] which can be used store information in the matrix X . Using the dataframe, the SS and TS algorithm can be even run faster if we filter the dataframe on rows where the age is within the 6 months window of the given age a . This is done using the command

$df[(df['age'] \geq a-0.5) \ \& \ (df['age'] < a+0.5)]$

In all our experiments for the SS and the TS algorithms we used the above command.

TABLE III. EACH SUBJECT HAS ON AVERAGE 30 VISITS. THERE ARE 3 BINARY BIOMARKERS. SUCH AS DISTRIBUTION OF VISITS, NUMBER OF SUBJECTS, ETC

# subjects	# total visits	average # visits
9.170	169,530	19
13.383	219,276	16
15.747	240,917	15
18.984	262,233	14

A. Single Age Screening

We compared the running time for the single-age screening algorithms SS and ISS on different datasets. The experiments were run multiple times and the median and quartiles of the running times are reported as shown in Fig. 3.

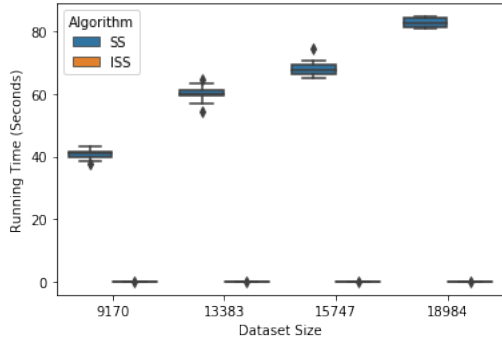

Fig. 3. Running Time Comparison between SS and ISS.

It is clear that the running time of the SS algorithm increases linearly with the dataset size. It takes about 80 seconds for Algorithm 1 to compute the quality performance of screening at a single age on data that has about 19,000 subjects, while the improved algorithm ISS takes only a fraction of a second to get the results. The running time for the ISS algorithm is shown in Fig. 4.

Fig. 4. Running Time for the ISS Algorithm.

B. Two Ages Screening

We compared the running time for the TS and ITS algorithms to compute the performance of the two-age screening. The results are shown in Fig. 5. A very similar behavior is observed. The TS algorithm scales linearly with the dataset size. The ITS algorithm is much faster than the TS algorithm. The running time for the ITS algorithm is shown in Fig. 6. ITS takes only 0.1 seconds to compute the quality performance of screening at a given two ages while TS takes 175 seconds.

C. Data Preprocessing for ISS and ITS

The additional overhead that the improved algorithms add on top of the original algorithms is the data preprocessing, i.e. the construction of the biomarkers encoding matrix B . This

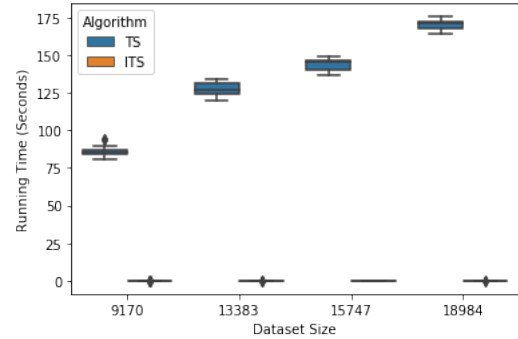

Fig. 5. Running Time Comparison between TS and ITS.

Fig. 6. Running Time for the ITS Algorithm.

step is required only once for each dataset. The running time for Algorithm 5 is shown in Table IV.

TABLE IV. RUNNING TIME FOR CONSTRUCTING THE MATRIX B

Dataset size (# subjects)	Time (mins)
9170	5.3
13383	6.7
15747	7.5
18984	8.4

IV. CONCLUSION

Screening of biomarkers is of utmost importance to assess the risk of developing autoimmune diseases such as type 1 diabetes and celiac diseases. To improve the quality performance of the screening test, screening more than one time is required. Algorithms to compute the quality performance of a screening schedule were developed as part of a screening tool. However, the running time of these algorithms are large which hinders the utility of the tool on large applications. We improved the running time of the screening algorithms by more than 800 times at an additional cost of preprocessing the data only once. We evaluated the running time of these screening algorithms on datasets with different sizes.

Abstract—Verifiable Secret Sharing (VSS) is a fundamental tool of cryptography and distributed computing in Internet of Things. Since network bandwidth is a scarce resource, minimizing the number of verification data will improve the performance of VSS. Existing VSS schemes, however, face limitations in meeting the number of verification data and energy consumptions for low-end devices, which make their adoption challenging in resource-limited IoTs. To address above limitations, we propose a VSS scheme according to Nyberg’s one-way Accumulator for one-way Hash Functions (NAHFs). The proposed VSS has two distinguished features: first, the security of the scheme is based on NAHFs whose computational requirements are the basic criteria for known IoT devices and, second, upon receiving only one verification data, participants can verify the correctness of both their shares and the secret without any communication. Experimental results show that, compared to the Feldman scheme and Rajabi-Eslami scheme, the energy consumption of a participant in the proposed scheme is respectively reduced by at least 24% and 83% for a secret.

Keywords—Verifiable secret sharing; one-way function; internet of things; security

I. INTRODUCTION

The Internet of Things (IoT) is moving at such a rapid pace that there is rising demand for transforming our physical world into a complex and dynamic system of connected devices. These IoT devices will be widely used in smart homes, body/health monitoring, environmental monitoring, condition-based maintenance, among many others. IoT is not a single technology. It is a combination of sensors, devices, networks, and software that works on a collaborative basis to achieve a common goal. Secure and reliable group communication has become critical in the IoT system. Group key agreement is widely employed for secure group communications in modern collaborative and group-oriented applications. The central challenge is secure and efficient group key management [1, 2]. This is because these IoT devices have limited computing ability and the limitation of communication bandwidth. In this paper, we focus on the design of lightweight verifiable secret sharing (VSS) schemes in order to achieve the secret reconstruction among a set of IoT devices, where the reconstructed secret may be the group key of them.

A. Motivation for Lightweight VSS

To date, there are two main families of approaches that have been investigated to provide VSS to participants. The

first approach provided verification data based on public key cryptography such as ASPP [3] in cyclic lattices and DLP [4]. The second approach to add verification capabilities to a scheme, was to use one-way functions to obtain fingerprints/signatures of the involved data [5]. However, the existing schemes suffer from some major problems. Firstly, existing schemes face the challenge in very large-scale deployment of IoT devices. Since verification data grew linearly with either the number of participants [5] or the threshold value [3], their performance dropped sharply as the number of IoT devices grows. Note that network bandwidth is a scarce resource. Minimizing the number of public verification data will improve the performance of VSS. In this paper, we address this challenge and propose a VSS Scheme with only one verification data used to verify a secret and all of its shares.

In addition, for these low-cost, battery-powered IoT devices, the lightweight implementation of VSS schemes has emerged as a critical issue. Because public key cryptography uses some big integers to generate the verification data, it is much slower than symmetric key cryptography, requires more processing power, and generally increases energy consumptions of participants [6]. When the batteries are low, it may cause the IoT devices to function abnormally. Existing solutions require the public-key computation (e.g., Modular exponentiation) that is an expensive operation for IoT devices in real systems. In the VSS setting, it is a challenge to design a lightweight VSS scheme that minimizes the energy consumption of a participant. To our knowledge, this paper represents the first effort in this direction.

B. Our Contribution

In this paper, we propose a lightweight VSS scheme in IoT environments. The security of the proposed scheme is based on NAHFs which are implemented through the generic symmetry-based hash function and simple bit-wise operation. The proposed scheme dictates to generate only a NAHF value as the verification data which proves the validity of the shares for all participants. Thus, the communication cost of each participant is reduced. In addition, each participant validates a received share by running an NAHF operation. Hence, the proposed scheme is computationally efficient for each participant. Furthermore, the computation and communication costs of each participant remain unchanged when the number of participants increases. That is, the proposed scheme provides the good scalability. Compared to the Feldman scheme [4] and Rajabi-Eslami scheme [3], the energy consumption of a

* Corresponding Author.

participant in the proposed scheme is respectively reduced by at least 24% and 83% for a secret. To the best of our knowledge, the approach of this paper is the first such technique that the number of verification data is only one value in the VSS scheme.

The rest of the article is structured as follows. Related work is presented in Section II, Section III presents a brief review of NAHF, Shamir's (t, n) secret sharing and VSS. Section IV is dedicated to the proposed VSS scheme including the security model, construction and security aspects. The performance analysis and simulation experiments for the proposed scheme are respectively discussed in Section V and Section VI. Section VII concludes the paper.

II. RELATED WORK

The secret sharing (SS) scheme is used as a tool in IoT applications including continuous authentication [1] and key management in sensor networks [7]. Such a scheme allows one to share a secret s among a set P of participants. The participants are assigned different values called shares and only certain authorized subsets of them were able to recover the secret using these shares. A (t, n) threshold SS scheme was introduced by Shamir [8] and Blakley [9] independently in 1979. In such a scheme, the authorized subsets consisted of all subsets of P including at least t participants. The scheme was unconditionally secure which meant that less than t participants found no information about the secret even with unlimited time and computing power. Then, many versions of SS were proposed to add some new features in the literatures [10].

A verifiable secret sharing (VSS) scheme is a generalization of a SS scheme [11], whose novelty is that everyone can verify whether the received share is a valid piece of the secret or not. The concept of VSS was first introduced by Chor et al [12] in 1985. Subsequently, based on "k-consistent" shares and interactive proof in [13], a VSS scheme was proposed to check the honesty of participants at the secret reconstruction phase. However, at the share generation phase, participants were unable to verify whether the shares they received from the dealer were valid. In 1987, a practical non-interactive VSS was proposed by Feldman [4, 5] through a homomorphic one-way function v for verifying consistency of each share. Indeed, let v be a $(+, \cdot)$ -homomorphic one-way function (that is, $v(a + b) = v(a) \cdot v(b)$); then, if v was evaluated over a polynomial $f(x) = \sum_{i=0}^{t-1} a_i x^i$, the equation $v(f(x)) = \prod_{i=0}^{t-1} v(a_i x^i)$ held. The dealer chose two primes p, q as public values and a generator g of a subgroup of order q of \mathbb{Z}_p^* , where q divided $p - 1$, and q was the lowest possible integer satisfying $g^q \equiv 1 \pmod{p}$. Then, it generated a share $s_j = f(x_j) \pmod{q}$ for each participant P_j , and published the public verification coefficients $A_i = g^{a_i} \pmod{p}$. Hence, the consistency of a share s_j was verified by checking the equality $g^{s_j} = \prod_{i=0}^{t-1} A_i^{x_j^i} \pmod{p}$. Here, the homomorphic property of exponentiation function $v(a) = g^a \pmod{p}$ was used. In the case of Feldman's scheme, the security was based on the hardness of the discrete logarithm problem (DLP). In 2019, Rajabi and Eslami [3] proposed a generic threshold VSS construction, and then presented a non-interactive VSS with security based on hardness of the approximate shortest polynomial problem

(ASPP) in cyclic lattices. In the work of Tsaloli et al. [14], by combining three different primitives (i.e., homomorphic hash functions, linearly homomorphic signatures, and threshold RSA signatures) as the baseline, an approach was proposed for protecting the secret data of clients and achieving public verifiability of the computed result. Recently, Koikara et al. [15] used a bilinear map to propose a publicly verifiable secret sharing (PVSS) scheme based on 3D-cellular automata. The VSS with bilinear pairings is not suitable for IoT systems because bilinear pairings are not friendly to lightweight devices [16]. In addition, the symmetry-based VSS is more suitable for the ultra-low energy devices as compared with the public key cryptographic approaches.

A new non-trapdoor accumulator for cumulative hashing was introduced by Nyberg [17]. This kind of accumulator is called a Nyberg's one-way Accumulator for one-way Hash Function (NAHF). In practice, the NAHF is effectively implemented by using the generic symmetry-based hash function and simple bit-wise operations. Oftentimes, this results in less memory requirements than digital signature-based solutions for verification problems. In 2017, Huang et al. [18] proposed a lightweight authentication scheme with dynamic group members in IoT environments. Here, based on a public secure NAHF, the proxy computed two accumulated hash values, W and R , which were used to verify whether the node was available and unrevoked. Recently, Fan et al. [19] presented a secure region-based handover scheme with user anonymity and fast revocation, where the region secret keys of the revoked users were accumulated by NAHFs. In the proposed scheme, the dealer generates the verification data with a NAHF such that the shares of participants can be publicly and efficiently verified. This enables us to add verification capability for participants using only one verification data.

III. PRELIMINARIES

In this section, we introduce some basic concepts of hash function, NAHF, secret sharing and VSS needed later

A. Notations

We shall use the following notations throughout the paper. A set with integers $1, 2, \dots, n$, is written either $\{1, 2, \dots, n\}$ or simply $[n]$. We denote by $|x|$ the length of the binary string corresponding to x , and $\lceil x \rceil$ the least integer that is greater than or equal to the given number x . Let $P = \{P_1, P_2, \dots, P_n\}$ be a set of n participants and D be the dealer. The threshold is denoted by t . Let $\mathbb{Z}_p, \mathbb{Z}_q$ be two finite fields and $\mathbb{Z}_q^* = \mathbb{Z}_q \setminus \{0\}$, where p is a prime modulus, q is a prime divisor of $p - 1$, and $q \geq n + 1$. We let $H : \{0, 1\}^r \times \{0, 1\}^* \rightarrow \{0, 1\}^r$ denote a Nyberg accumulated hash function, $h : \{0, 1\}^* \rightarrow \{0, 1, \dots, q - 1\}$ and $\hat{h} : \{0, 1\}^* \rightarrow \{0, 1\}^{rd}$ be two one-way hash functions, where h is used to construct the required H , and $r = |q|$.

B. Nyberg's One-way Accumulator for One-way Hash Function

In this paper, we review the concept of Nyberg's one-way Accumulator for one-way Hash Function (NAHF).

Definition 1 (One-way hash function [17]). *A family of one-way hash functions is an infinite set of functions $h_l : K_l \times S_l \rightarrow V_l$ having the following properties:*

- (1) There exists a polynomial P' such that for each integer l , $h_l(k, s)$ is computable in time $P'(l, |k|, |s|)$ for all $k \in K_l$ and all $s \in S_l$.
- (2) There is no polynomial P' such that there exists a probabilistic polynomial time algorithm which, for all sufficiently large l , when given l , a pair $(k, s) \in K_l \times S_l$, and a $s' \in S_l$, find an $k' \in K_l$ such that $h_l(k, s) = h_l(k', s')$ with probability greater than $1/P'(l)$, where (k, s) is chosen uniformly among all elements of $K_l \times S_l$ and s' is chosen uniformly from S_l .

Definition 2 (Quasi-commutativity [17]). A function $h : K \times S \rightarrow X$ is said to be quasi-commutative if for all $k \in K$ and for all $s_1, s_2 \in S$, $h(h(k, s_1), s_2) = h(h(k, s_2), s_1)$.

Definition 3 (Nyberg's one-way accumulator [17]). A family of one-way accumulators is a family of one-way hash functions with quasi-commutativity. The one-way accumulator by Nyberg [17] is constructed based on the generic symmetry-based hash function (e.g., SHA) and simple bit-wise operations. Compared to Benaloh's scheme [20], Nyberg's scheme is more efficient without employing asymmetric cryptographic operations.

Assume that $N = 2^d$ is an upper bound to the number of items to be accumulated and r is an integer. Let s_1, s_2, \dots, s_n be the accumulated items with different string sizes, and a set of the accumulated items $S = \{s_1, s_2, \dots, s_n\}$, where $n \leq N$. Assume that $H(\cdot, \cdot)$ denotes an NAHF from $\{0, 1\}^r \times \{0, 1\}^*$ to $\{0, 1\}^r$, and \odot is the bitwise operation AND. The NAHF is based on the one-way hash function $h : \{0, 1\}^* \rightarrow \{0, 1\}^{rd}$. All that is required to specify the NAHF is hashing process and AND operation. The heart of an NAHF is the hashing process. The hashing process applies a hash function h to the input to produce a r -bit output. The hashing process is composed of the following operations.

- Hashing operation: Hash the accumulated item s_i of the input and output a rd bits binary string $v_i = h(s_i)$.
- Transfer α : the NAHF does a transfer operation on the binary string v_i which is divided into r blocks, $(v_{i,1}, \dots, v_{i,r})$, of length d . The transfer of a block from a d -bit input to a bit output is performed as follows: If $v_{i,j}$ is a string of zero bits, it is replaced by 0; otherwise, $v_{i,j}$ is replaced by 1. That is, $\alpha(v_i) = (b_{i,1}, \dots, b_{i,r})$, where $b_{i,j} \in \{0, 1\}$, $j=1, \dots, r$.

In this way, we can transfer the accumulated item s_i to a bit string, $b_i = \alpha(h(s_i)) \in \{0, 1\}^r$, which can be considered as the values of r independent binary random variables if h is an ideal hash function.

The NAHF on an accumulated item $s_i \in S$ with an accumulated key $k \in \{0, 1\}^r$ can be implemented using the AND operation described as $H(k, s_i) = k \odot \alpha(v_i) = k \odot \alpha(h(s_i))$. And it also can be represented as $Z = H(k, s_i) = k \odot \alpha(v_i) = k \odot \alpha(h(s_i))$ for an accumulated item $s_i \in S$ ($i \in [n]$). The proposed VSS relies on the following properties of the NAHF $H(\cdot, \cdot)$:

- Quasi-commutativity: $H(H(k, s_1), s_2) = H(H(k, s_2), s_1)$.
- Absorbency: $H(H(k, s_i), s_i) = k \odot \alpha(h(s_i)) = H(k, s_i)$.

- An item s_i within the accumulated value Z can be verified by $H(Z, s_i) = Z \odot \alpha(h(s_i)) = Z$.

C. Shamir's Threshold Secret Sharing

There are n participants, $P = \{P_1, P_2, \dots, P_n\}$ and a dealer D . In Shamir's secret sharing scheme [8], it consisted of two phases: the share distribution phase and the secret reconstruction phase. During share distribution, the secret was $s = f(0)$, where $f(x)$ was a polynomial of degree $t - 1$ with random coefficients (except for the constant term), computed over a finite field. The participant $P_j \in P$ holding shares knew $s_j = f(x_j)$, where x_j was P_j 's unique nonzero identifier, $j \in [n]$. In secret reconstruction, any t out of n participants, P_{j_1}, \dots, P_{j_t} , were able to recover the secret s by using the Lagrange interpolation formula (1) or solving the following linear equations (2), where

$$s = f(0) = \sum_{i=1}^t s_{j_i} \left(\prod_{r=1, r \neq i}^t \frac{-x_{j_r}}{x_{j_i} - x_{j_r}} \right), \quad (1)$$

and

$$\begin{aligned} s_{j_1} &= s + a_1 \times x_{j_1} + \dots + a_{t-1} \times x_{j_1}^{t-1}, \\ s_{j_2} &= s + a_1 \times x_{j_2} + \dots + a_{t-1} \times x_{j_2}^{t-1}, \\ &\vdots \\ s_{j_t} &= s + a_1 \times x_{j_t} + \dots + a_{t-1} \times x_{j_t}^{t-1}. \end{aligned} \quad (2)$$

Note that the above coefficient matrix is a square Vandermonde matrix, which is invertible, since the x_j s are distinct.

D. VSS

In a SS scheme, participants must trust that shares they receive are correct. In a VSS scheme, additional verification data are given that allow each participant to check whether its share is correct. Each message that must be checked contains additional verification data. The verification data are sent in the clear, and can be used by the recipient to determine whether the share in the message is correct. That is, recipients use them to check that a point, (x_j, s_j) , sent to it is on the polynomial $f(x)$ and that the polynomial, $f(x)$, used as the basis for the sent shares equals the secret at $x=0$. The VSS is able to resist the following two kinds of active attacks: (1) some shares are tampered before being sent to the participants in the secret distribution phase; (2) participants submit error shares to others in the secret reconstruction phase.

IV. A LIGHTWEIGHT (t, n) VSS SCHEME

In the section, a lightweight (t, n) VSS scheme is proposed. We discuss techniques involving the security model, construction and the security aspects of the proposed scheme.

A. The Security Model of Proposed Scheme

In this section, we give the definition of a noninteractive (t, n) VSS scheme. There are n participants, $P = \{P_1, P_2, \dots, P_n\}$, and a dealer D . In the definition, there are four algorithms: share generation(SG), share verification(SHV), secret reconstruction(SR) and secret verification

(SEV). The proposed scheme consists of the share distribution phase and the secret reconstruction phase. We define a noninteractive (t, n) VSS scheme as follows:

A noninteractive (t, n) VSS scheme is a pair (share generation, secret reconstruction) of phases as follows.

- **Share distribution:** In this phase, on input a secret s and P_j 's identity x_j , D first runs SG algorithm to output a share for each participant and some verification data, where the shares are sent to the corresponding participants through a secure channel. Then, on input verification data and his share, each participant runs SHV algorithm to output accept or reject the share.
- **Secret reconstruction:** The input of this phase are the shares corresponding to a subset of participants. At first, the validity of each share is verified by other cooperating participants running SHV algorithm. Then, if the number of participants with valid shares is at least t , the secret can be computed by applying SR algorithm on the provided shares, and the recovered secret is verified by running SEV algorithm.

A non-interactive (t, n) VSS Scheme is called secure if it satisfies the following properties:

- **Threshold.** Every secret can only be recovered by any t or more participants who have received the shares, and any subset of participants with less than t participants cannot obtain any information about the secret.
- **Verifiability/reconstructability:** Every participant can verify his share in the share generation phase. During the secret reconstruction phase, the participants can validate the received shares and check if a reconstructed secret is correct.
- **Security.** The VSS scheme must be able to resist up to $t - 1$ colluded inside adversaries. In addition, any outside adversary cannot impersonate to be a member by forging a valid value after knowing at most $t - 1$ values from other members. The VSS scheme is secure, if the adversary cannot obtain the shares in polynomial time.

In addition, the following properties for a VSS are very much tailored to IoT devices as participants:

- **Efficiency.** The proposed scheme should have low calculation requirements and low communication costs at the participants to reduce their energy consumptions. This makes VSS for implementation on battery-powered IoT devices that have limited computing power.
- **Scalability.** Even if the number of participants in large-scale deployments is big, the communication cost of the scheme should be kept small to reduce the cost of the supporting network infrastructure.

B. The Proposed (t, n) VSS Scheme

Figure 1 shows the proposed (t, n) VSS scheme, where the combiner may be each participant in P . In the proposed

Fig. 1. The Proposed (t, n) VSS Scheme.

scheme, the algorithms SG, SHV, SR and SEV are the mathematical processes in the Step 1, 2, 3 and 4, respectively. The security of the scheme is based on an NAHF, which is quasi-commutative and has the absorbency property.

The correctness of the proposed (t, n) VSS scheme is guaranteed by the following theorem 1 and 2.

Theorem 1. *In the share generation, the correctness of each share s_j can be validated by the receiver through $H(V, s_j) = V$, $j \in [n]$.*

Proof 1. *If the dealer D follows the scheme accurately, we have that $V = H(\dots H(H(k, s), s_1), \dots, s_n)$. Based on the absorbency property of H , it is known that the share s_n satisfies $H(V, s_n) = V$. In fact, $H(V, s_n) = H(H(\dots H(H(k, s), s_1), \dots, s_n), s_n) = H(\dots H(H(k, s), s_1), \dots, s_n) = V$, where the second equality holds for the absorbency property of H .*

Generally, in accordance with the quasi-commutativity of H , we have

$$\begin{aligned}
 V &= H(\dots H(H(\dots H(H(k, s), s_1), \dots, s_j), s_{j+1}), \dots, s_n) \\
 &= H(\dots H(H(\dots H(H(k, s), s_1), \dots, s_{j+1}), s_j), \dots, s_n) \\
 &\quad \vdots \\
 &= H(H(\dots H(\dots H(H(k, s), s_1), \dots, s_{j+1}), \dots, s_n), s_j).
 \end{aligned} \tag{3}$$

where $j = 1, 2, \dots, n - 1$. Combining the absorbency property of H and equation (3), we obtain that $H(V, s_j) = H(H(H(\dots H(\dots H(H(k, s), s_1), \dots, s_{j+1}), \dots, s_n), s_j), s_j) = H(H(\dots H(\dots H(H(k, s), s_1), \dots, s_{j+1}), \dots, s_n), s_j) = V$, where the second equality holds for the absorbency property of H , and the third equality holds due to equation (3). This completes the proof.

Theorem 2. *In the secret reconstruction, the received shares*

s_{j_θ} and the recovered secret s can be publicly and efficiently verified via $H(V, s_{j_\theta}) = V$ and $H(V, s) = V$, respectively, $\theta \in [t]$.

Proof 2. In the secret reconstruction, the share s_{j_θ} can be publicly and efficiently verified via $H(V, s_{j_\theta}) = V$, for $\theta \in [t]$. This proof is the same as that of Theorem 1. In addition, similar to the derivation of equation (3), the secret s satisfies the following equation:

$$\begin{aligned} V &= H(\cdots H(H(k, s), s_1), \cdots, s_n) \\ &= H(\cdots H(H(k, s_1), s), \cdots, s_n) \\ &\vdots \\ &= H(H(\cdots H(H(k, s_1), s_2), \cdots, s_n), s). \end{aligned} \quad (4)$$

By using the absorbency property of H and equation (4), for the secret s we see that $H(V, s) = V$. This is because $H(V, s) = H(H(H(\cdots H(H(k, s_1), s_2), \cdots, s_n), s), s) = H(H(\cdots H(H(k, s_1), s_2), \cdots, s_n), s) = V$, where the second equality holds due to the absorbency property of H , and the third equality holds by equation (4). This completes the proof.

Remark 1. The correctness of algorithms $H(V, s_j) = V$ and $H(V, s) = V$ depends on the assumption that the output length, rd , of h satisfies $(n + 1) \leq 2^d$, where an NAHF $H : \{0, 1\}^r \times \{0, 1\}^* \rightarrow \{0, 1\}^r$ is constructed through $h : \{0, 1\}^* \rightarrow \{0, 1\}^{rd}$. When $(n + 1) > 2^d$, it is feasible to replace V with $(V_0, V_1, \cdots, V_{u-1})$, where $u = \lceil \frac{n+1}{2^d} \rceil$. For $\varsigma = 0, 1, \cdots, u-1$, $V^{(\varsigma)}$ is generated as follows: (1) different hash functions, $h^{(\varsigma)} : \{0, 1\}^* \rightarrow \{0, 1\}^{rd}$, are chosen. (2) the NAHF $H^{(\varsigma)} : \{0, 1\}^r \times \{0, 1\}^* \rightarrow \{0, 1\}^r$ is generated by the hash function $h^{(\varsigma)}$. (3) Let $s_{n+1} = s$, the ς -th value is computed as $V^{(\varsigma)} = H^{(\varsigma)}(\cdots H^{(\varsigma)}(k, s_{\varsigma+1}), \cdots, s_{\varsigma+2^d})$. To verify the correctness of $s_{\varsigma+j}$, we can check if $H^{(\varsigma)}(V^{(\varsigma)}, s_{\varsigma+j}) = V^{(\varsigma)}$, where $\varsigma = 0, 1, \cdots, u-1$, and $j \in [2^d]$.

The following theorems ensure the security of the proposed (t, n) VSS scheme.

Theorem 3. Assume that q is a large prime number. The share s_j obtained by the polynomial $f(x)$, has a uniform distribution on \mathbb{Z}_q , $j \in [n]$.

Proof 3. Let A and X be two independent random variables defined on \mathbb{Z}_q . A basic result from the theory of random variables is that if A has a uniform distribution on \mathbb{Z}_q and X has an arbitrary distribution on \mathbb{Z}_q , then $B_1 = A + X \pmod{q}$ and $B_2 = A \cdot X \pmod{q}$ have a uniform distribution on \mathbb{Z}_q , where X is chosen from \mathbb{Z}_q^* in the latter case. If b_1 is chosen uniformly from all possible values of B_1 , the probability of $B_1 = b_1$ is given as:

$$\begin{aligned} Pr[B_1 = b_1] &= Pr[A + X = b_1] \\ &= \sum_{x_j} Pr[A = b_1 - x_j] Pr[X = x_j] \\ &= 1/q \cdot \sum_{x_j} Pr[X = x_j] = 1/q. \end{aligned}$$

Similarly, when b_2 is chosen uniformly from all possible values

of B_2 , we have

$$\begin{aligned} Pr[B_2 = b_2] &= Pr[A \cdot X = b_2] \\ &= \sum_{x_j} Pr[A = b_2 \cdot (x_j)^{-1}] Pr[X = x_j] \\ &= 1/q \cdot \sum_{x_j} Pr[X = x_j] = 1/q. \end{aligned}$$

It can be easily shown that the above argument can be extended to the random polynomial function $f(x)$. Since $a_0, a_1, \cdots, a_{t-1}$ are uniformly distributed on \mathbb{Z}_q and x_j is P_j 's unique nonzero identifier, hence $a_0, a_1 x_j, \cdots, a_{t-1} x_j^{t-1}$ are uniformly distributed on \mathbb{Z}_q . Then, $f(x_j) = a_0 + a_1 x_j + \cdots + a_{t-1} x_j^{t-1}$ is uniformly distributed on \mathbb{Z}_q . Therefore, $s_j = f(x_j)$ is uniformly distributed on \mathbb{Z}_q , that is, s_j has a uniform distribution on \mathbb{Z}_q .

Theorem 4. Under the assumption that H is a secure NAHF, the secret s and some shares s_j cannot be obtained by an attacker from V , $j \in [n]$.

Proof 4. Recall from Definition 3 that an NAHF H is a one-way hash function with quasi-commutativity. Suppose the accumulated item s_j is computed in the j -th iteration of V , thus, $V = H(\cdots H(H(\cdots H(H(k, s), s_1), \cdots, s_j), s_{j+1}), \cdots, s_n)$. Note that $V = H(H(\cdots H(\cdots H(H(k, s), s_1), \cdots, s_{j+1}), \cdots, s_n), s_j) = H(Q, s_j)$, where the first equality holds due to equation (3), and $Q = H(\cdots H(\cdots H(H(k, s), s_1), \cdots, s_{j+1}), \cdots, s_n)$. Furthermore, we have that $H(V, s_j) = V$. We now need to prove that it is hard for the attacker presented with V to find (Q', s_j) such that $V = H(Q', s_j)$. At this point, One-way property of H in Definition 1 ensures that this is computationally infeasible, that is, there is no polynomial P' such that there exists a probabilistic polynomial time algorithm which finds an $s_j \in \mathbb{Z}_q$ such that $V = H(Q', s_j)$ with probability greater than $1/P'(l)$, where Q' is chosen uniformly from $\{0, 1\}^r$. Hence, it is computationally infeasible to find an s_j such that $H(V, s_j) = V$, $j \in [n]$. Similarly, it is computationally infeasible to derive the share s from V .

Theorem 5. In the proposed VSS scheme, any subset of participants of size less than t cannot obtain any information about the secret s .

Proof 5. Here, we consider the worst case, where $t-1$ participants take part in recovering the secret s . Any $t-1$ participants with different identities $x_{j_1}, \cdots, x_{j_{t-1}}$ cannot compute the secret s since they cannot solve the linear system of $(t-1)$ equations and t unknowns: $s_{j_l} = s + a_1 \times x_{j_l} + \cdots + a_{t-1} \times x_{j_l}^{t-1}$, $l \in [t-1]$, which has a degree of freedom, where $a_0 = s$. We can consider the coefficient, a_{t-1} , of the last term in $f(x)$ as a free variable from \mathbb{Z}_q . In this case, the secret s has a unique representation as a linear combination of a_{t-1} and the shares $\{s_{j_1}, \cdots, s_{j_{t-1}}\}$, where a_{t-1} is uniformly distributed over \mathbb{Z}_q . From the proof of Theorem 3, it follows that s has a uniform distribution over \mathbb{Z}_q . Hence, no information about the secret s can be extracted from these $t-1$ shares.

Combining Theorem 3, 4 and 5, we have the following theorem:

Theorem 6. The proposed (t, n) VSS scheme is secure under the assumption that H is a secure NAHF.

TABLE I. THE COMMUNICATION COSTS OF D AND P_j IN THE VSS SCHEMES

	share $ f(x_j) $	verification data	D	P_j

V. PERFORMANCE OF PROPOSED VSS SCHEME

In this section we present and discuss the efficiency and scalability for the proposed scheme in Section IV-B. We mainly consider the costs of an extension of the SS scheme to achieve verifiability. By decreasing the number of verification data, we improves on the previous VSS schemes [3, 4]. We estimate the efficiency by counting the number of basic cryptographic operations required in the extension, and also calculate its communication cost. To evaluate the scalability of the proposed scheme, it suffices to show that the costs of each participant remain unchanged in the increase in the size of the IOT network (i.e. the number of participants).

Bandwidth is a scarce resource. In a VSS, the communication cost is dominated by the sizes of both verification data and a share. From Table I, we see that in the proposed scheme, the communication costs of the D and P_j are significantly lower than Feldman scheme and Rajabi-Eslami scheme since $|q|$ is much less than $|p|$ and $mn_0|p_0|$ (see Section VI). In the proposed scheme, the verification data V is only a value in \mathbb{Z}_q , so is any share. Specifically, at the share generation phase, the dealer D broadcasts V to participants in P and transmits $s_j=f(x_j)$ to each participant P_j , $j \in [n]$, where $|V| + \sum_{j=1}^n |s_j| = r + n|q|$ bits. Upon receiving V and s_j from D at the share generation phase, each P_j obtains at least $(t-1)$ different shares s_{j_θ} from the others in P while sending s_j to them at the secret reconstruction phase. Here, $|V| + |s_j| + \sum_{\theta=1}^{t-1} |s_{j_\theta}| + |s_j| = r + (t+1)|q|$ bits. In the Feldman scheme[4], the verification data included t elements A_0, \dots, A_{t-1} (see Section II) in \mathbb{Z}_p , and the size of each share was the same as the proposed scheme. Therefore, the communication costs at D and P_j were $n|q| + t|p|$ and $t|p| + (t+1)|q|$ bits, respectively. In the Rajabi-Eslami scheme [3], the verification data was composed of $(n_0 - 1)$ -degree polynomials $F(a[0]), \dots, F(a[t-1])$ in \mathbb{Z}_{p_0} and each share contained m polynomials in R_{p_0} . Here, the polynomial ring $R_{p_0} = \mathbb{Z}_{p_0}[\alpha]/(\alpha^{n_0} - 1)$, and D_{p_0} was an appropriate subset of "small" elements of $R_{p_0}^{-1}$, where the dimension $m > 1$, the integer module $p_0 \geq 2$ and an error distribution δ . Note that each share $f(x_j)$ and the secret s were respectively

composed of m polynomials in R_{p_0} and D_{p_0} , and $F(a[i])$ was a polynomial in R_{p_0} . Thus, the communication costs at D and P_j were $(t + nm)n_0|p_0|$ and $(m(t + 1) + t)n_0|p_0|$ bits, respectively.

It is generally assumed that in an IoT system, the dealer or server has powerful computing resources and the computing power of IoT devices is limited [22]. Another advantage of proposed scheme is that the computation costs of participants are low since computational requirements are the basic criteria for known IoT devices. For each participant P_j in the proposed scheme, its computation cost is $(t + 1)T_H + tT_M$, where $H(V, s_j)$, $H(V, s_{j_\theta})$ and $H(V, s)$ are respectively computed for verifying s_j , s_{j_θ} ($\theta \in [t - 1]$) and the recovered s , and t multiplication operation in the Lagrange interpolation formula (1) are performed to recover s . Note that in Rajabi-Eslami scheme [3], $T_f = m(t - 1)T_m$, and $T_F = mT_{pm}$. This was because m polynomials with degree $(t - 1)$ needed to be computed for each $f(x_j)$ in R_{p_0} and $F(X) = \sum_{i=1}^m X_i b_i$. From the experimental results in Section VI, we know that $T_M < T_{pe} < T_H < T_e < T_E$. Table II shows that the computation cost of P_j is the lowest in the proposed scheme. In contrast, the computation cost of D in the proposed scheme, where the time to compute V increases with n , increases due to the use of NAHF H . To compute $s_j = f(x_j)$ for each participant P_j and verification data V , D needs to execute $t - 1$ multiplication operations for $f(x_j)$ and $n + 1$ NAHF operations for V , $j \in [n]$. It means that the computation cost of D is $n(t - 1)T_M + (n + 1)T_H$. Furthermore, the proposed scheme provides the good scalability since the computation and communication costs of P_j remain unchanged when the number of participants increases.

VI. SIMULATION EXPERIMENTS

We further evaluate the performance of proposed scheme using simulation experiments. The experiments are conducted on an Intel(R) Core(TM) i7-6700 CPU@3.40 GHz machine with 8.00 GB memory and Windows7 using JDK1.8. We choose to focus on SHA-512 for hashing h in NAHF H with a 128 bit output, where $N = 2^4$ is an upper bound to the number of accumulated items. When $N > 2^4$, we do this by selecting $u = \lceil N/(2^4) \rceil$ different SHA-512 as Remark 1. For Feldman scheme, the parameters p , q were chosen as suggested (see page 21 in [23]), i.e., $|p|=1024$ bits, and $|q|=160$ bits. As for Rajabi-Eslami scheme, according to the LWE parameters for hardware tests (see Table 4 in [24]), the corresponding parameters $(n_0, |p_0|) = (128, 12)$. In addition, let $m = 2$. To give a detailed quantitative analysis, we assume

¹ \mathbb{Z}_{p_0} was the set of integers from 0 to $p_0 - 1$, $\mathbb{Z}_{p_0}[\alpha]$ denoted the set of polynomials with coefficients in \mathbb{Z}_{p_0} . R_{p_0} contained all polynomials of degree less than n_0 with coefficients in \mathbb{Z}_{p_0} , as well as two ring operations, which were polynomial addition and multiplication modulo $\alpha^{n_0} - 1$. Each polynomial in R_{p_0} had n_0 coefficients in \mathbb{Z}_{p_0} , so there was a bijection between R_{p_0} and $\mathbb{Z}_{p_0}^{n_0}$. The compact knapsack problem over R_{p_0} was defined in [21] as follows: given $m = \mathcal{O}(\log_2 n_0)$ elements $b_1, \dots, b_m \in R_{p_0}$ and a target value $c \in R_{p_0}$, found coefficients $X_1, \dots, X_m \in D_{p_0}$ such that $\sum_{i=1}^m X_i b_i = c$.

that participants are MICA2 motes, which work at 8 MHz with a 8-bit processor ATmega128L, and which adopt IEEE 802.15.4 standard. As described in Cao et al. [25], the power level of a MICA2 mote is $U = 3.0$ V, the current draw in active mode is $I = 8.0$ mA, the receiving current draw is $I_r = 10$ mA, the transmitting current draw is $I_t=27$ mA, and the data rate is $r_d = 12.4$ kbps. The cost of receiving (or transmitting) one byte is $E_r = UI_r(8/r_d) = 19.35\mu J$ (or $E_t = UI_t(8/r_d) = 52.26\mu J$). The parameters are fixed in all experiments.

Experiment 1 examines the average time required to run an operation in Table II. With the above parameter settings, we consider the average value of over 160 trials for an operation. The results are as follows: $T_M=0.0022$ milliseconds (ms), $T_H=0.0858$ (ms), $T_e=1.3445$ (ms), $T_{pm}=0.0169$ (ms), $T_E = 1.6071$ (ms). Especially, the average time performing the addition operation is 0.0007ms, which is negligible compared with the others.

Experiment 2 examines the energy consumption of a participant. To compute the electrical energy consumed by a participant during t_p seconds, we apply Joule's law as $E = UI t_p$. From Table II and Table I, we have that $t_p = (t + 1)T_H + tT_M = (t + 1) \times 0.0858 + t \times 0.0022$ (ms), and $(t + 1)|q| + r$ is equal to $4 + 40$ bytes, where transmitting bytes are t and receiving bytes are $t + 20$. For P_j , the energy cost of communication is $20 \times E_t + (t + 20) \times E_r = 19.36t + 1432.2(\mu J)$, and the energy cost of computation is $3 \times 8 \times t_p = 2.112t + 2.0592(\mu J)$. Thus, the energy consumption of P_j is $21.472t + 1434.2592(\mu J) \approx 0.0215t + 1.4343(J)$. We find that the energy cost of computation is cheap compared to data communication. Again, we compare the energy consumption of P_j in the proposed scheme with that of Feldman scheme and Rajabi-Eslami scheme. From Figure 2 (a), it is evident that the energy consumption of P_j increases with the threshold value, but it is relatively stable in the proposed scheme. In particular, the proposed scheme makes P_j have the smallest energy consumption. Note that given a threshold value t , the energy reduction is equal to the difference of the corresponding ordinate values of two schemes in Figure 2(a). For each participant P_j , the results of energy reduction are shown in Figure 2(b). Compared with the Feldman scheme, the energy reduction of the proposed scheme is larger in the Rajabi-Eslami scheme, and the difference increases with t . Furthermore, Figure 2 (c) shows that, compared to the Feldman scheme and Rajabi-Eslami scheme, the energy consumption of P_j in the proposed scheme is respectively reduced by at least 24% and 83% for a secret.

VII. CONCLUSION

In this paper, we give a lightweight (t, n) VSS scheme based on an NAHF [17]. Different from previous VSS schemes, the proposed scheme generates only a NAHF value as the verification data which proves the validity of the shares for all participants. This means that the scheme has less communication cost than previous approaches to achieve the share verification. Another important property is that the computation and communication costs of each participant remain unchanged when the number of its participants increases. It is convenient for building a secure scalable IoT network. At the same time, because the correctness of each share can be efficiently checked, the new participant can verify whether his

Fig. 2. The Energy Consumption, Energy Reduction and the Percentage of Reduced Energy for P_j in the Proposed Scheme.

share is right or not. Using the proposed scheme, we can make a IoT system more secure and efficient. The presented scheme can be applied to multi-party computation, electronic voting, secure databases and many circumstances.
