The True Positive Rate and False Positive Rate values for a binary categorization model at various threshold levels are shown in Fig. 7. These numbers are frequently employed to build a ROC curve. The fraction of real positive cases that the model properly classifies as positive is measured by TPR, sometimes referred to as sensitivity or recall.

TABLE I. COMPARISON OF PERFORMANCE METRICS OF PROPOSED METHOD WITH OTHER EXISTING APPROACHES

Models	Accuracy (%)	Precision (%)	Recall (%)	F1-Score (%)
DNN [25]	88.2	87.89	90	90
MSVM [26]	93.70	94.90	96.50	94.90
LSTM [27]	97.40	97.80	98.70	97.80
Proposed HPSO-ACO-CNN	99.3	99.2	98.7	98.7

On the other hand, FPR measures the percentage of real negative cases that the model misclassifies as positive. The graph displays how these rates alter when the threshold for categorization changes from 0 to 0.6. The TPR typically rises as the threshold rises, showing that the model gets better at properly recognizing positive situations but frequently at the expense of a larger FPR. The ROC curve, created from these results, graphically illustrates the trade-off between TPR and FPR at various threshold levels, assisting in evaluating the model's categorization effectiveness and determining the best threshold in accordance with the demands of the particular application.

The suggested HPSO-ACO-CNN is a hybrid of the Deep Neural Network (DNN), Multiclass Support Vector Machine (MSVM), Long Short-Term Memory (LSTM), and Deep Neural Network for a specific task. The Table I and Fig. 8 provides a number of significant efficiency measures for each model, one for each row: "Precision" measures the model's capacity to accurately classify positive cases, "Recall" measures the model's capacity for correctly recognizing all actual positive cases, and "F1-Score" is a balanced metric combining precision and recall. "Accuracy" denotes the overall proportion of correct predictions generated by the model.

The outcomes show that the suggested HPSO-ACO-CNN model exceeds the competition with the greatest values for accuracy (99.3%), precision (99.2%), and F1-Score (98.7%), demonstrating its better performance in the task at hand. Additionally, LSTM performs well, whereas DNN and MSVM score slightly more severe on these criteria. Together, these measures offer insightful comparisons of these models' success in the particular categorization task, with higher values representing better model effectiveness.

TABLE II. COMPARISON OF DATASETS OF PROPOSED METHOD WITH OTHER EXISTING APPROACHES

Datasets	Accuracy (%)	Precision (%)	Recall (%)	F1-Score (%)
Landsat 8 Imagery 2014 [28]	89	87	87	88
Landsat 5 Thematic Mapper Imagery [29]	94.17	95	96	94
Proposed EuroSAT Dataset	99.3	99.2	98.7	98.7

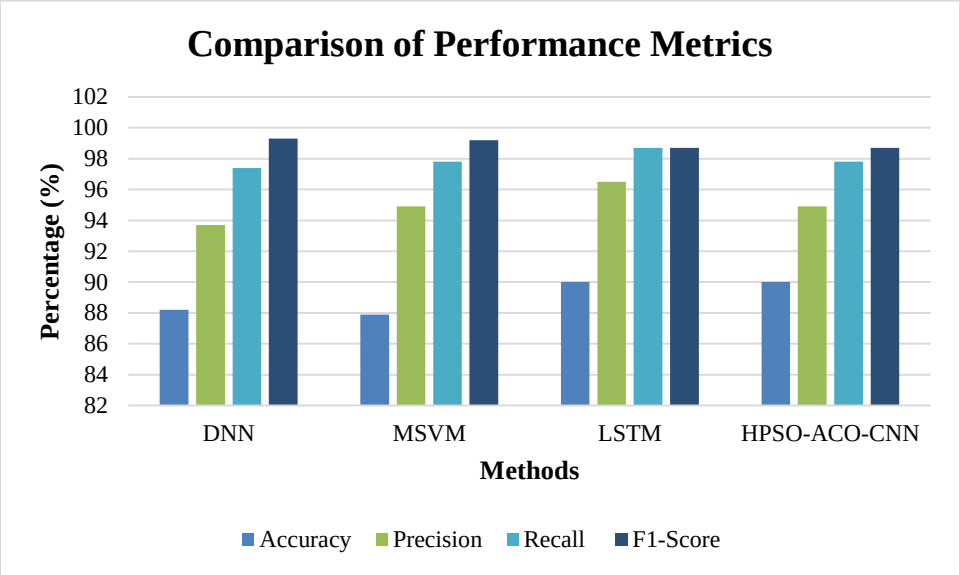

Fig. 8. Comparison of performance metrics of proposed method with other existing approaches.

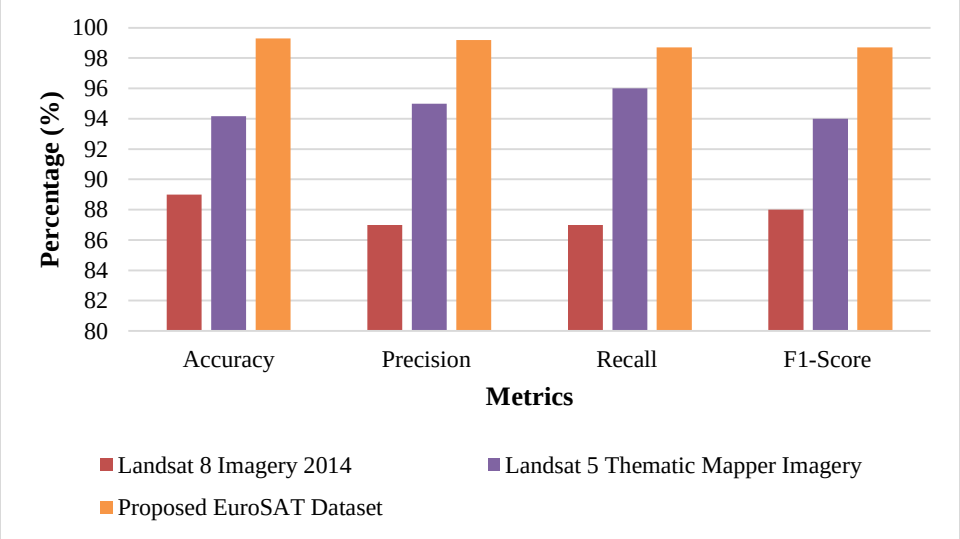

Fig. 9. Comparison of datasets of proposed method with other existing approaches.

A comparison of datasets utilizing the suggested approach in comparison to other current methodologies is shown in Table II and Fig. 9. Four important criteria are used to assess their effectiveness: F1-Score, Accuracy, Precision, and Recall. The initial dataset, the 2014 Landsat 8 Imagery, has an accuracy of 89%, 87% recall, 87% precision, and an 88% F1-Score. Landsat 5 Thematic Mapper Imagery, the second dataset, was particularly better than the initial one, with an F1-Score of 94%, accuracy of 94.17%, precision of 95%, and recall of 96%. The suggested EuroSAT Dataset performed outstandingly, achieving 98.7% recall, 99.2% precision, 99.3% accuracy, and a 98.7% F1-Score. These findings show that the suggested EuroSAT Dataset outperforms the other datasets in all four standards, indicating that it is the most effective alternative for the given objective, which is probably connected to the categorization or analysis of satellite images. Variability in data features, including resolution, spectral bands, and landscape variety, might be the cause of the variances in comparison results between datasets. The suggested methods could perform better on datasets whose properties are comparable to those that were encountered during the development of the EuroSAT dataset. These datasets might include high-resolution and diversified satellite images.

B. Discussion

The findings show that the proposed HPSO-ACO-CNN model has a number of benefits over other machine learning techniques already in utilization for the categorization of land use and land cover using satellite images. With an accuracy of 99.3%, precision of 99.2%, recall of 98.7%, and an F1-Score of 98.7%, the HPSO-ACO-CNN model outperformed in all assessment measures. These findings demonstrate that the hybrid technique, which combines a CNN with PSO and ACO, significantly improves the classification capabilities of the model. The model excels at accurately detecting positive

instances while reducing false positives and false negatives, as seen by its excellent accuracy and recall scores. A precise categorization of land cover and land use is essential in applications like environmental monitoring and catastrophe management. While DNN and MSVM are reasonable models in comparison, they fall short of HPSO-ACO-CNN's performance. Although the LSTM model also exhibits comparable performance, HPSO-ACO-CNN stands out because to its greater accuracy and precision. These results illustrate the effectiveness of combining deep learning methods with optimization algorithms, emphasizing the potential for more precise and reliable mapping of land use and land cover in the context of sustainable land management and protecting the environment.

VI. Conclusion and Future Works

The study concludes by presenting a novel technique that substantially enhances the precision of classifying land use and land cover using satellite images. The merging of ACO, CNN, and HPSO algorithms results in significant performance increases in the proposed HPSO-ACO-CNN model. Combining CNN hyperparameter optimization with spectral band selection yields remarkable accuracy, precision, recall, and F1-Score performance for this hybrid architecture. Results from experiments conducted on the EuroSAT dataset demonstrate how well the HPSO-ACO-CNN model performs when compared to other methods and standalone CNN models. In addition to addressing important problems with feature selection, parameter optimization, and model training, the work creates new opportunities for satellite image analysis. This novel method has great potential for a number of uses, such as sustainable land use, urban planning, environmental monitoring, and disaster management. It highlights how deep learning techniques and optimization strategies may be combined to improve remote sensing applications. Regarding potential avenues for future research, there are a number of intriguing options to consider. An intriguing line of investigation is the expansion of the HPSO-ACO-CNN architecture to handle larger and more complicated datasets of satellite images, potentially incorporating other spectral bands and land cover categories. Additionally, assessing the model's resilience and scalability in various environmental conditions and geographical areas may yield unexpected findings. Finally, there is potential to further the more general goals of environmental conservation and sustainable land management by investigating applications of transfer learning and customizing the model for additional Earth observation tasks, such change detection and crop monitoring.

***Abstract*—TSP is a well-known combinatorial optimization problem with several practical applications. It is an NP-hard problem, which means that the optimal solution for huge numbers of examples is computationally impractical. As a result, researchers have focused their efforts on devising efficient algorithms for obtaining approximate solutions to the TSP. This paper proposes Iterative Approximate Methods for Solving TSP (IAM-TSP), as a new method that provides an approximate solution to TSP in polynomial time. This proposed method begins by adding four extreme cities to the route, a loop, and then adds each city to the route using a greedy technique that evaluates the cost of adding each city to different positions along the route. This method determines the best position to add the city and the also the best city to be added. The resultant route is further improved by employing local constant permutations. When compared to existing state-of-the-art methods, our experimental results show that the proposed method is more capable of producing high-quality solutions. The proposed approach, with an average approximation of 1.09, can be recommended for practical usage in its current form or as a pre-processing step for another optimizer.**

Keywords*—Greedy algorithms; TSP; NP-Hard problems; polynomial time algorithms; combinatorial problems, optimization methods

I. INTRODUCTION

At the beginning of the seventeenth century, Thomas Penynington and William Hamilton modeled the first mathematical problem corresponding to the Traveling Salesman Problem (TSP). This problem represents a game in which the winner connects twenty points by moving from one point to another, following some precise paths. This game/problem is called Hamilton Circuit Theory [1]. Afterward, in graph theory, TSP becomes a problem of identifying the optimal (shortest) Hamiltonian cycle visiting a set of cities (points) using a matrix of distances between the cities. TSP is one of the classic problems of combinatorial optimization, and it is widely investigated and considered a standard for assessing the performance of computational methodologies and algorithms.

The principal objective of TSP is that the salesman visits all the cities in the minimal tour and then returns to the starting point with the assumption that the distances between the cities are known and the necessity of visiting each city is only once. Despite high-size instances of TSP being resolved in the literature, TSP is proven to be NP-hard even for small-size instances [2].

The theoretical and practical relevance of the TSP problem comes from the fact that numerous applicable real-world and engineering problems can be solved by adapting the TSP solutions, such as circuit design [3], scheduling [4], and DNA [5, 6], in addition to logistics and transportation and even space exploration missions [7]. Therefore, the study of TSP has significant theoretical and practical value, leading to cost savings and other benefits.

Moreover, the application fields of TSP include any problem involving the search for the shortest paths. These fields vary in domains from big data classification [8, 9, 10], deployment and routing of IoT networks [11, 12, 13, 14, 15, 16], financial prediction [17, 18], image processing [19], and [20], computer vision [21], [22], and [23]. TSP can be defined by finding a Hamiltonian cycle that visits each vertex precisely once, with the least amount of total weight feasible, given a full undirected weighted graph G = (V, E) with vertex set V and edge set E. The total weight of a cycle is equal to the weights of each of its individual edges. The book in [24] presents a comprehensive mathematical and theoretical analysis of the calculability and complexity of the TSP. One of the critical issues of methods of resolution of TSP is the enhancement of the accuracy of the algorithm to rapidly find the optimal or near-optimal solutions.

Indeed, heuristics and meta-heuristics are the most successful methods used to resolve the TSP [25, 26, 27]. In this regard, Genetic Algorithms (GA), Ant Colony Optimization (ACO), Simulated Annealing (SA), and Particle Swarm Optimization (PSO) are among the most commonly used algorithms to resolve TSP. GA was successfully used for problems involving global search due to its rapid convergence and fast search process. However, it has some issues and has poor performance when achieving the local search. ACO is another robust optimizer with a high-resolution capacity. However, its convergence performance highly depends on the initial parameters, mainly the appropriate initial quality of the pheromone. PSO is characterized by its ease of use since it has a few numbers of initial parameters to set. However, other optimizers give better results for many TSP test problems. SA is another optimizer known for its capacity to avoid local optima and is often hybridized with other algorithms for this capacity.

However, like with ACO, the initial parameter values have a significant impact on the search process. Despite substantial research on TSP, its combinatorial nature suggests that there is still opportunity for development in this field, motivating the work of this paper. TSP is inextricably tied to handling other combinatorial problems with comparable characteristics, such as the Traveling Salesman Problem with Time Windows (TSPTW), Vehicle Routing Problem (VRP), and Capacitated Vehicle Routing Problem (CVRP). TSP approaches and algorithms are frequently used as a foundation for addressing these related optimization challenges. As a result, progress in TSP solving may provide useful insights and tactics relevant to a broader class of combinatorial problems in logistics, transportation, and network optimization. Because these challenges are interdisciplinary, knowledge and approaches can be transferred across fields, creating a more thorough grasp of combinatorial optimization.

The major contribution of this paper lies in presenting an Iterative Approximate Method for Solving TSP (IAM-TSP), which provides a polynomial-time approximate solution to the TSP. The proposed method begins by including four extreme cities along the path. Following that, a loop successively adds each city to the route by calculating the cost at various points along the route. The approach considers each city to add and finds the most suitable location to put it, the one that minimizes the total cost. This method is improved further by using local constant permutations on the output of IAM-TSP, which considerably improves the final route, referred to as IAM-TSP+.

We evaluated the proposed algorithms against standard TSP datasets to determine how they performed in terms of key performance measures. The proposed IAM-TSP performed nearly identically to some of the typical TSP approximation algorithms given in the results section, but the proposed IAM-TSP+ surpassed all approximation methods compared on the majority of TSP instances.

The rest of the paper is organized as follows. Section II illustrates and discusses the advantages and drawbacks of the recent most relevant studies resolving the TSP. Section III identifies and investigates the proposed methodology for resolving the TSP. Section IV presents the experimental setup and the results, Section V concludes the study.

II. Related Work

Given TSP's extensive history, its cutting-edge landscape is extremely diverse. To solve the TSP, several techniques, paradigms, and approximations algorithms have been used. Heuristics, for example, are a type of approximation method aimed to finding near-optimal solutions to NP-hard problems in polynomials time. One popular and simple method for building a TSP tour involves starting the tour at any node, traversing minimum-cost arcs to each successive node until all nodes are visited, and then returning to the starting node to finish the tour. This method is known as the Nearest Neighbor heuristic [28].

There are also many popular methods, such as: the 2-Opt heuristic [29], Farthest Insertion algorithm [30], Nearest Insertion algorithm [30], Cheapest Insertion algorithm [30], Arbitrary Insertion algorithm [31], Repetitive Nearest Neighbor algorithm [32], Concave hull with heuristics, and Concave Hull No Heuristic [33]. In what follows, the main recent studies proposing TSP resolution methodologies are investigated: The study in [33] introduces a concave hull-based algorithm to resolve the Euclidean symmetric TSP by establishing concentric hulls and then merging them in one tour. Two novel metrics are suggested: the “Average Waiting Distance” and the “min AWD” of a tour. The results show that an optimal AWD does not guarantee the optimal tour.

In study [34], the authors enhanced the accuracy of TSP solutions for numerous sizes of the problem. The used algorithm is a modified ACO with a better convergence during the TSP search process. To prevent trapping into local optima, this algorithm decreases the high concentration of pheromone during the route selection. The diversity in the algorithm is ensured using entropy weighted learning. According to the results, this work improved ACO and solved TSP better than the standard ACO.

A new variant of TSP, called TSPJ, which includes the schedule of jobs in a set of positions, was introduced in study [35]. Since in TSP, the transport time is longer than the operation time, the considered objective in TSPJ is to minimize the make-span, equal to the needed time to achieve the longest job. The resolution of the TSPJ involves four local search methods. Using the CPLEX system, the results indicated that the solutions given by the four used heuristics are too close to the optimal (a gap less than 6%). In the same regard, the study in [36] aims to resolve the TSPJ. Applicative and practical contexts of TSPJ had been discussed, as well as the parameters specific to TSPJ such as the completion time, configuration time, and resource variation.

In study [37], the authors used the aim was to resolve a TSP variant called the multiple TSP (mTSP) problems using a hybrid algorithm. The latter relies on an EAX heuristic to optimize the intra-tour and a tabu search neighborhood search to optimize the inter-tour. The objectives of the problem were the minimization of both the longest path and the total traveled distance. To reduce the neighborhood search time, a reduction approach is proposed to avoid computing the nonpromising possible solutions. The experiments involve a comparison with five approaches tested on 41 known TSP test problems and 36 new large-size ones. However, the other variants of TSP were not assessed, and comparisons with other classes of heuristics were not achieved.

The study in [38] suggests a new seriation strategy named “tree-penalized Path Length” (tpPL). Data seriation is a famous problem in data analysis. Itis the process of sequencing and ordering data according to their similarity. TSP in this study is considered a seriation method. The goal is to linearly order the data using simultaneously the TSP, tpPL, and optimal leaf order (OLO) methods. Optimal paths are transferred from TSP to OLO. In terms of computational complexity, TSP and tpPL have the same order of complexity. Hence, TSP heuristics may be used to resolve the tpPL. Tested on more than forty datasets, the tpPL has a better performance than TSP and OLO with the same computational complexity. The study in [39] introduces a compression-based TSP heuristic for data micro-aggregation.

Micro-aggregation is a method for disrupting and aggregating personal data using the concept of k-anonymity. By simultaneously considering the respect for privacy and the usefulness of data, the introduced TSP heuristic was the most efficient in solving the problem of micro-aggregation. In contrast, heuristics relying on TSP encrust scalability issues. Unlike other heuristics, the algorithm proposed in this study can reduce the execution time of the TSP. The tests carried out on small and medium-sized data affirm the trade-off between computation time and the rate of loss of micro-aggregation information.

In study [40], a new problem, named the traveling thief problem (TTP), is proposed by combining the knapsack problem (KP) and the TSP. The PTT resolution method relies on sequences selection heuristics. A set of selection operators/thieves are involved to select the cities/objects to progressively create the tour.

The study in [41] introduces two new TSP versions. Named pollution TSP(PTSP) and energy minimization TSP (EMTSP), the new versions add environmental constraints to the TSP. The aim of PTSP is to reduce fuel consumption, and carbon emissions. The aim of EMTSP is to reduce the cost of a trip according to the distance and the carried load. The method of resolution of the two TSP variants, MILP-GA-LS, relies on a mixed integer linear programming model to identify initial possible solutions, then multi-operator GA to enhance the found solutions. Afterward, an iterative local search algorithm was used to enhance the solutions. However, numerous constraints were not considered such as the time-window of customers. Moreover, an issue arises concerning the complexity of the introduced approach, since it was proven that, for small-size instances of PTSP and EMTSP, exact methods give better results than the MILP-GA-LS.

In study [42], a new ACO variant is proposed to solve the TSP. Named DAACO; this algorithm dynamically changes the number of ants to avoid falling into local optima and to prevent long time of convergence. Besides, DAACO uses a local selection process to enhance the quality of ants and the needed time for the search process. Among the used twenty TSPLIB test problems, all the DAACO solutions were optimal except one. These results confirm the advantageous quality of solutions and time of convergence of DAACO compared to other optimizers.

In study [43], a hybrid Ant Colony (AC)-Tabu Search (TS)-Firefly Algorithm (FA) called ACTS-FATS is proposed. The hybridization avoids the probability of premature convergence, then, reduces the chance of trapped in local optima. Tested with the TSPLIB95, the hybridization does not generate additional execution time compared to AC, TS and FA.

In study [44], Dhouib-Matrix, a column-row method, is proposed to resolve polynomial time TSP. The process of this method is as follows: after defining the distance matrix, a start position is selected to choose rows. Then, columns are discarded, and the route is transformed to a tour. The advantage of the introduced Dhouib Matrix is that it needs only n iterations to find the route between n cities.

In study [45], a comparative study is proposed to discuss the recent algorithms and methodologies used to resolve the TSP using metaheuristics. The focus is set on the numerous versions of the BA, FA and PSO optimizers.

In study [46], a new version of the TSP, called TSP-D is proposed. The latter is a classic TSP that involves a truck and a drone (Unmanned Aerial Vehicles (UAV)). In TSP-D, it is assumed that UAV has low battery capacities and can transport cargo per flight. The issue is to determine which UAV and which truck should serve which client. The tests demonstrate that the time of service can be reduced by using the UAVs with distinct speeds according to the cargo weight. However, the used samples (number of clients) are between 30 and 60, which makes the method valid only for small-size TDP-D instances.

The authors in [47] propose an algorithm to minimize travel costs and maximize the overall profit. Simulated annealing (SA) and genetic algorithm (GA) with dedicated mutation operators were used. A concept of tour plots is used to generate the final solutions. In terms of computation time, the SA is better than the GA.

In study [48], Qi-ACO, an ACO based on quantum computing, is developed to resolve the four-dimensional TSP (4DTSP). Fuzzy type-2 variables are used due to the uncertain aspect of the investigated problem of travel emissions and costs. The 4DTSP is characterized by the existence of numerous paths and conveyances between the cities. A process is implemented in Qi-ACO for generating qubits considering the constraints of carbon emission, cost, and time. The initialization and update of pheromone is based on qubit. A faster computation is achieved in Qi-ACO due to the quantum calculations. Performed statistical tests to confirm the performance of the introduced approach. However, numerous constraints are not considered such as vehicle speed and route selection. The readers are referred to [49] for more comprehensive methodologies on modeling and designing greedy heuristic methods to resolve the TSP.

III. The Proposed Iterative Approximate Methods for Solving TSP (IAM-TSP)

The IAM-TSP is proposed in this paper as an approximation to the TSP, which has a greedy algorithmic nature. It begins by selecting four cities from the input set to represent the east, north, west, and south most positions. These cities are added to the route list in the following order: east, north, west and south, followed by a return to the beginning point (east). The algorithm then enters a loop, adding each remaining city to the path one by one. The method calculates the cost of adding a city to various points along the route throughout each iteration. It carefully investigates all feasible positions for each city, picking the best position and city at the lowest cost. Finally, this approach computes the route's total cost and outputs the final result.

The cost is calculated using the Euclidean distance between the consecutive cities on the route. Algorithm 1 shows the pseudocode processes of the proposed IAM-TSP. Fig. 1 illustrates the progress of the IAM-TSP solution of the Rat195 LIBTSP real-world problem [50]. Because the TSP is a

minimization problem, the term "best" refers to the smallest value throughout this paper, i.e., minimum route.

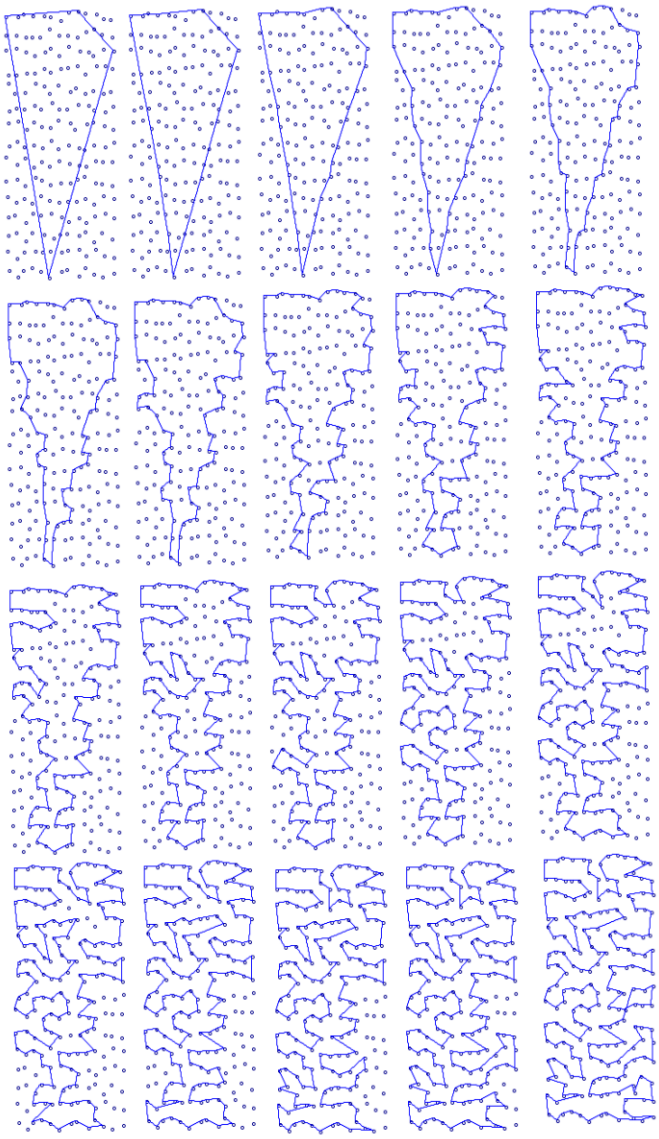

Fig. 1. The progress of the IAM-TSP solution of the Rat195 LIBTSP real-world problem, the progress is made from left to right and from top to bottom, and the results are displayed after ten iterations from the previous state.

According to Algorithm 1, the proposed IAM-TSP has a time complexity of $O(n^2)$, where n is the number of cities in the Cities x y list. This is because, in the while loop, the algorithm finds the best position to put each city from the Open list into rout and checks every feasible solution, which takes O(n) time. This operation is repeated until Open is empty, which means that in the worst scenario, the while loop runs n times, giving a total time complexity of $O(n^2)$.

The space complexity of the solution is $O(2n + n^2)$, where n is the number of cities in the Cities xy list. This is because we use two lists rout and open of size n, which take O(2n) space, and the quadratic space comes from the space reserved by the Possible Solutions matrix, whose size is n rows, each hosting n cities. The rest of the data structures used in the solution take O(1) or O(n) space, so the overall space complexity can be asymptotically approximated to $O(n^2)$. However, if we establish a square matrix storing the distances between each city and the others, space complexity stays asymptotically quadratic too; this is not done in this study, but it is a typical approach to removing the burden of distance computation. It should be emphasized that IAM-TSP provides an approximation solution for the TSP, and it does not ensure finding the optimal solution, because finding the best position for each city alone does not guarantee finding the optimal solution, which necessitates the involvement of all cities at the same time.

In order to improve the IAM-TSP performance, and because involving all cities makes the problem NP-hard, we opt for involving a constant number of local cities (k), and calculate all the permutation sequences starting from the first city in the output Route until the k city, finding the best solution and updating the Rout during this process, after which the algorithm goes into a loop moving by one city to find the next k permutations until $n - k$, this enhanced version is called IAM-TSP+. Algorithm 2 shows the pseudocode processes of the proposed IAM-TSP+, and Fig. 2 depicts the IAM-TSP+ resultant Route of the ATT48 TSPLIB real-world problem [50] in comparison to its optimal route.

Algorithm 1: The proposed IAM-TSP algorithm

Require: Cities xy (List of cities with x and y coordinates) of size n (number of cities)
Ensure: Cost (Total cost of the route using Euclidean distance), and Route (the best possible sequence of cities)
1: Create an empty list Route to store the order of visited cities.
2: Get the East, North, West, and South cities and add them to the Route list. This is done using the minimum/maximum of x and y coordinates.
3: Initialize a Boolean list Visited of size n (number of cities) and set all elements to false.
4: Set the Visited status of the cities in Route to true (East, North, West, and South).
5: Create an empty list Open to store the cities that have not been visited.
6: Add all cities in Cities xy to Open if their Visited status is false.
7: while Open is not empty do
8: Create an empty list of list Possible Solutions to store the possible solutions (routs).
9: for each city i in Open do
10: Find the best location to insert it into Route and add the new route to possible Solutions.
11: end for
12: Find the best solution Best in Possible Solutions and keep track of the city ID.
13: Update Route by Best.
14: Remove the city ID from Open that satisfies Best.
15: end while
16: Calculate the cost of the Route using the Euclidean distance and store it in
Cost.
17: return Cost, Route

Algorithm 2: The proposed IAM-TSP+ algorithm

Require: Cities xy of size n and k=5 (local permutations)
Ensure: Cost, Route
1: Route=IAM-TSP(Cities xy)
2: for i = 1 to n − k do
3: Create an empty list of list Possible Solutions
4: Possible Solutions= all k local permutations of Route(from i to i + k)
5: Update Cost(Possible Solutions)
6: index = *argmin*(Cost)
7: Route = Possible Solutions[index]
8: end for
9: return Cost(Route), Route

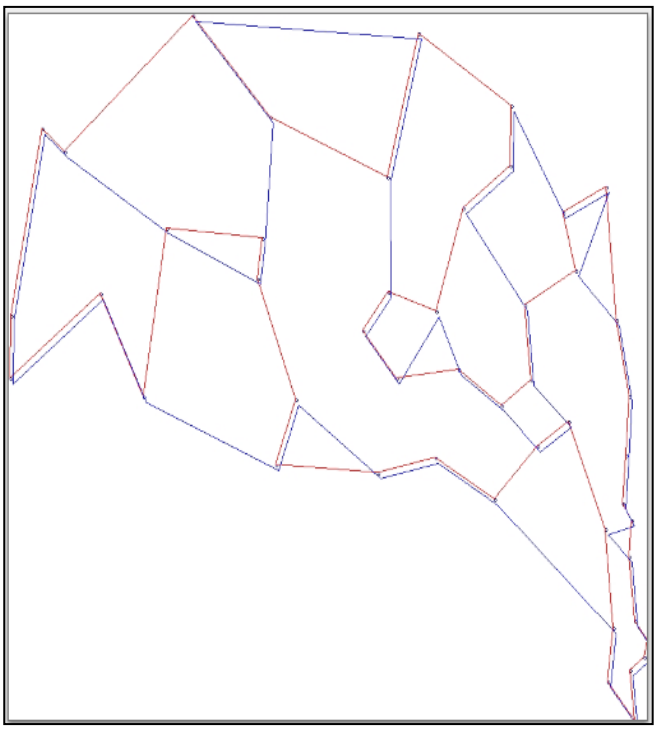

Fig. 2. The IAM-TSP+ resultant route of the ATT48 TSPLIB real-world problem (in blue) n comparison to its optimal route (in red), k = 5, IAM-TSP+ cost = 34877, and the optimal cost = 33523. The optimal route is a little shifted right and down to avoid edge overdrawing.

According to Algorithm 2, the proposed IAM-TSP+ has a time complexity of $O(n^2 + n.k!)$, where n is the number of cities in the Cities xy list. This is because the improved version uses the proposed IAM-TSP as an initial solution, this time is added to the time consumed by sliding the k permutations along the Route, which consumes O(n.k!) in the worst scenario, giving a total time complexity of $O(n^2 + n.k!)$. Since k is a constant number, the time complexity of O(n.k!) is often greater than that of $O(n^2)$. O(n.k!) may still be more efficient than $O(n^2)$ for small values of k, but as (k) grows higher, the growth rate of O(n.k!) quickly exceeds that of $O(n^2)$. Therefore, the time complexity of IAM-TSP+ can be asymptotically approximated to O(n.k!). The space complexity of the IAM-TSP+ is similar to that of the proposed IAM-TSP, with the exception of the space required by the possible Solutions matrix, which contains k! rows of routes, each of which hosts n cities, resulting in a total space complexity of $O(n^2 + n.k!)$, which can be asymptotically approximated to O(n.k!). This is a problem for machines that have limited memory resources, particularly when k is large, and therefore, k needs to be decided based on the available memory resources.

IV. Experimental Setup and Results

To verify the quality and effectiveness of the proposed methods for solving TSP, IAM-TSP and IAM-TSP+ were applied to nine TSP instances, each with a known optimal solution. Those TSPs are from the TSPLIB [50], which has vertices between 40 and 500, namely: a280, att48, berlin52, KroA100, ch150, ch130, pr76, lin105, and pcb442. We chose these specific instances to facilitate comparison to other methods that have been repeatedly used in many studies.

We compare the performance of the proposed methods to other related methods that proposed in the recent years; these include:

- NN: Nearest Neighbor algorithm
- FI: Farthest Insertion algorithm
- CH: Concave hull with Heuristic.
- CNH: Concave hull No Heuristic
- NI: Nearest Insertion algorithm.
- CI: Cheapest Insertion algorithm
- AI: Arbitrary Insertion algorithm
- RNN: Repetitive Nearest Neighbor algorithm
- 2-Opt: 2-Opt algorithm

It deserves to be noted that the aforementioned methods were not developed for this work; rather, we directly reference their results on each standard TSP as stated by [33], where all parameters used for each method can be obtained. It is also worth noting that the majority of these methods' results were obtained by repeating each method a number of times and reporting the average performance. However, we do not need to do the same for the proposed methods because each produces the same result on a specific TSP regardless of how many times the method is run.

We performed simulation experiments using C# of Microsoft visual studio 2022. The hardware and software specifications of the system are as follows:

11th Gen Intel(R) Core (TM) i7-1165G7 @ 2.80GHz, 8.00 GB RAM, and Windows 11 Pro, 64-bit operating system.

The results of the proposed methods to the other compared methods are shown in Table I, in which the optimal tour length (cost) is recorded as reported in the TSPLIB standard library. As it can be seen from Table I, The proposed IAM-TSP+ outperforms the IAM-TSP on all TSPs, which is to be expected given that the latter is an input to the former and the former employs nine local permutations along the resultant route, giving it more chances to identify better solutions.

Furthermore, the proposed IAM-TSP+ outperforms not only IAM-TSP, but also, all methods compared on 5 TSPs, namely att48, berlin52, ch130, KroA100, pr76, followed by the FI method, which also performs well.

Aside from the FI, the proposed IAM-TSP outperforms many other methods without the need for additional improvement and achieves solutions closer to optimal in two instances: att48 and pr76. It is interesting to note that both of the proposed methods achieve performance that is very close to the optimal solution in some instances. In order to illustrate the different performances of both of the best performers, IAM-TSP+ and FI, Fig. 3 compares the resultant routes' costs of both methods on several TSPs while Fig. 4, 5, and 6 provide comparisons of the proposed methods to the other nine related methods on small-scale TSP instances. As it can be seen from these figures, the proposed methods achieve better or comparable performance when compared to the other approximation methods that attempt to find the best possible TSP solution.

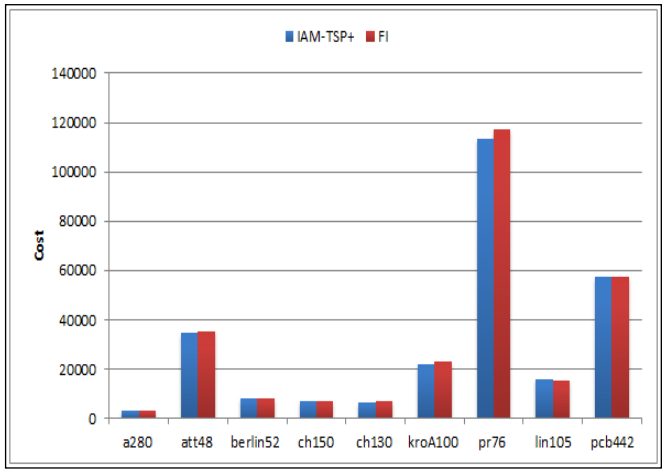

Fig. 3. The routes' cost results of the proposed IAM-TSP+ compared to that of the FI method.

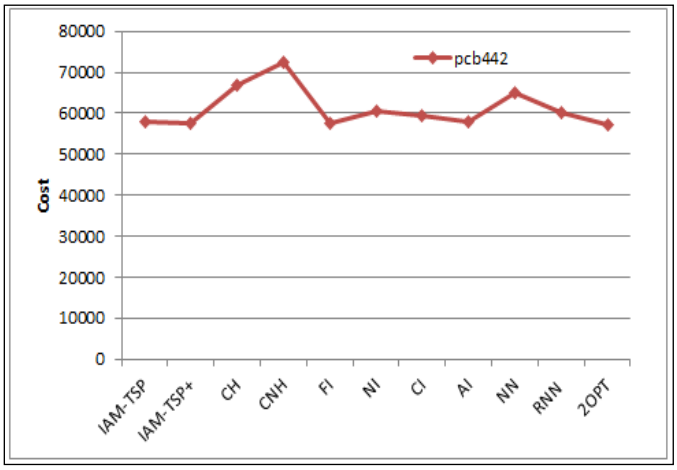

Fig. 4. The routes' cost results of the proposed methods compared to that of the other methods on Att48 TSP.

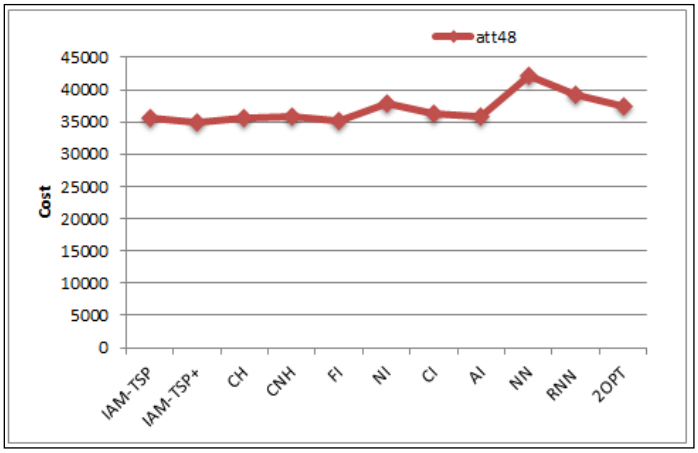

Fig. 5. The routes' cost results of the proposed methods compared to that of the other methods on pcb442 TSP.

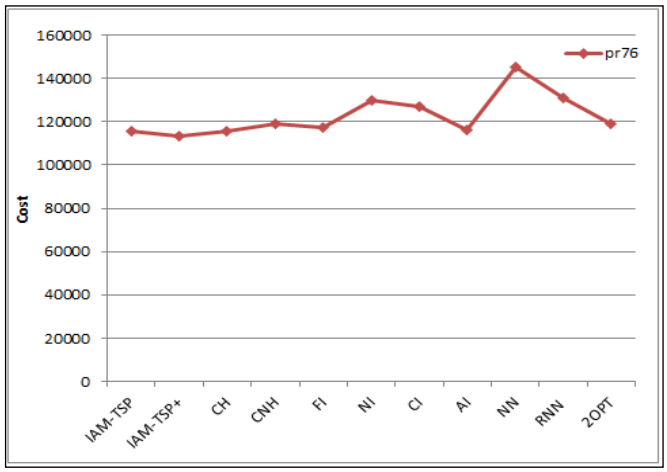

Fig. 6. The routes' cost results of the proposed methods compared to that of the other methods on pr76 TSP.

The approximation ratio, which is the ratio of the method's output to the optimal tour cost, quantifies how much the approximate solution differs from the optimal solution. The approximation ratios of all methods compared are presented in Table II. As it can be seen in the table, the proposed IAM-TSP+ delivers the best overall approximation, with an average of 1.09 overall TSPs, compared to the next competitor (FI), which has an average approximation of 1.10.

The proposed AIM-TSP also performs well, with an average approximation of 1.11, surpassing seven comparable methods. In addition to the approximation ratio, the error rate represents the percentage difference between the solution's fitness value and the known optimal solution, and it is determined as follows [51]:

$$\text{Error Rate} = \frac{solution - optimal\ solution}{optimal\ solution} * 100\% \quad (1)$$

The comparison results for the error rates are presented in Table III. As it can be seen in Table III, the proposed IAM-TSP+ delivers the minimum overall error rate, with an average of 8.51% overall TSPs, compared to the next competitor (FI), which has an average error rate of 9.50%. The proposed AIM-TSP also performs well, with an average error rate of 11.44%, surpassing seven comparable methods. Considering the costs, approximation ratios, and error rates of the resulting Routes, the proposed methods, specifically the IAM-TSP+, outperform all related methods aimed at solving the TSP in general.

V. CONCLUSION

In this paper, we presented two geometric-based approximation greedy algorithms for solving the classical TSP, one of which we call IAM-TSP which is proposed based on locating four extreme nodes/cities and then iterating to determine the best potential positions of each node/city. The other method is known as IAM-TSP+, and it is simply an improved version of the first one, with employing local constant permutations to improve the first method's result.

The experimental results of the proposed methods on nine TSP instances show that, when compared to nine recent related methods, the proposed methods (particularly the IAM-TSP+) provide promising solutions for the classical TSP. This is seen in the resulting routes' cost effectiveness, approximation ratios, and error rates. The enhanced performance (of the IAM-TSP+) is due to the selection of the best local solution, which was accomplished by exploring all k-permutations and considering the best local solution after obtaining the initial solution from the pure IAM-TSP, where k = 5 in all experiments.

The proposed method's limitations include the time and space complexity, which is rather high for the proposed IAM-TSP+, making the evaluation of the proposed methods on large TSP instances particularly difficult on restricted resource machines. As a result, parallel or distributed computation may facilitate the evaluation of proposed methods. In addition to employing the output route as an initial seed for the genetic algorithm [52, 53]. Our future research will focus on such issues.

***Abstract*—Every year, numerous lives are tragically lost because of traffic accidents. While many factors may lead to these accidents, one of the most serious issues is the emergency services' delayed response. Often, valuable time is lost due to a lack of information or difficulty determining the location and severity of an accident. To solve this issue, extensive research has been conducted on the creation of effective traffic accident detection and information communication systems. These systems use new technology, such as deep learning algorithms, to spot accidents quickly and correctly and communicate important information to emergency workers. This study provides an overview of current research in this field and identifies similarities among various systems. Based on the review findings, it was found that researchers utilised various techniques, including MLP (Multilayer Perceptron), CNN (Convolutional Neural Network), and models such as DenseNet, Inception V3, LSTM (Long short-term memory), YOLO (You Only Look Once), and RNN (Recurrent Neural Network), among others. Among these models, the MLP model demonstrated high accuracy. However, the Inception V3 model outperformed the others in terms of prediction time, making it particularly well-suited for real-time deployment at the edge and providing end-to-end functionality. The insights gained from this review will help enhance systems for detecting traffic accidents, which will lead to safer roads and fewer casualties. Future research must address several challenges, despite the promising results showcased by the proposed systems. These challenges include low visibility during nighttime conditions, occlusions that hinder accurate detection, variations in traffic patterns, and the absence of comprehensive annotated datasets.**

Keywords*—Deep learning; road traffic; road accident detection; MLP; CNN; LSTM; DenseNet; RNN; inception V3

I. INTRODUCTION

Road crashes are one of the most prominent reasons for death, disability, and hospitalization of people worldwide. 1.35 million people worldwide lose their lives due to road accidents every year [1]. Almost 3,700 people worldwide lose their lives in collisions with automobiles, buses, motorbikes, bicycles, lorries, or pedestrians every day [1]. Cyclists, motorcyclists, and pedestrians account for more than half of the fatalities. According to estimates, crashes rank as the eighth most common cause of mortality worldwide across all age categories and the most common cause of death for children and young adults (ages 5 to 29) [1]. The traffic authority has seen that many vehicles are travelling at high speeds and without fear in crowded areas. The results of traffic accidents are fairly evident. To address these issues, though, a reliable traffic monitoring and management system is needed [2].

Unfortunately, the age group most affected by road accidents is people aged between 18 and 45 years, which accounts for approximately 70% of accidental deaths [3]. Most of these fatalities occur due to a lack of medical care given at the appropriate time. The expenditures associated with medical care, property damage, legal actions, and reduced worker productivity are significant. In addition to the human cost, road accidents place significant economic pressure on countries, taxing healthcare systems and diverting revenue away from other vital sectors, which hinders economic expansion. Due to its vital impact on public safety, economic stability, and general societal well-being, road accident detection is of the utmost importance. To prevent these serious consequences, effective road accident detection is urgently required.

Current accident reporting systems that rely on reports from witnesses or have slow response times frequently cause delays in facilitating traffic control and providing emergency help. The lengthening of travel times for other road users as well as secondary accidents, congestion, and a worsening of injury severity can all result from this delay.

Deep learning [4] is a subset of machine learning that employs multilayer neural network models that are designed to function similarly to the human brain. Unlike other machine learning approaches, deep learning can automatically learn from data such as photos, videos, or text without the aid of any subject expertise. Deep learning employs a multi-layered neural network to extract features from the data and gets better and better at recognizing and classifying data on its own rather than depending on labels included in the unstructured data. In areas like machine vision, computer vision, speech recognition, audio recognition, natural language processing, social network filtering, pharmaceutical engineering, bioinformatics, medical image analysis, and gaming programs, deep learning architectures like deep neural networks, deep belief networks, recurrent neural networks, and convolutional neural networks have been used with related and, in some cases, improved outcomes.

A subfield of artificial intelligence (AI) called computer vision [5] allows computers and other systems to retrieve useful data from photos, videos, and other visual inputs, to analyze objects in photos and videos just like people do, and to take decisions or offer suggestions based on that data. Computer vision tasks include methods for acquiring, processing, and analyzing digital images to generate numerical or symbolic data. Using digital images and deep learning models, computer vision allows computers to accurately identify and classify objects and respond to them. A convolutional neural network understands single images, whereas recurrent neural networks work with video inputs, allowing computers to learn how a series of images is related to one another. Computer vision software can process images in real-time to detect road edges, read traffic signals, and identify other cars, objects, and pedestrians from the camera output.

Deep learning is revolutionizing road accident detection systems by using neural networks to improve responsiveness, accuracy, and adaptability. Deep learning allows these systems to use convolutional neural networks (CNNs), recurrent neural networks (RNNs), and other sophisticated designs to analyze complex visual and sensor data collected from various sources. Deep learning algorithms may develop robust and adaptable models that can cope with the intricacies of the real world by learning from a variety of datasets that cover a range of weather conditions, lighting conditions, and road types. Additionally, its capacity for real-time processing makes it easier to discover accidents quickly, enabling emergency services and traffic control authorities to act right away.

Several research gaps and unresolved issues emerged as the literature on deep learning-based road accident detection systems continued to develop. Even though deep learning techniques have been used in this field in important ways, a thorough synthesis of the literature in the field reveals some gaps that call for more research. This review article offers a current assessment of the state of the field, considering substantial advancements, new patterns, and cutting-edge technology in road accident detection systems. A current summary of the most recent developments in the field is covered. This research paper advances knowledge in this field by methodically evaluating and synthesizing the body of literature on deep learning-based road accident detection systems. This analysis can help researchers and practitioners and can act as a starting point for new research and technological breakthroughs. Policymakers and emergency service providers can prioritize investments in technology, infrastructure, and staff by comprehending the benefits and drawbacks of various deep learning-based solutions.

The rest of the paper is organized as follows: Section II describes the methodology employed to conduct the literature review and discusses the databases, search terms, and inclusion/exclusion criteria used to select relevant papers. Section III then includes a detailed analysis of each selected piece of literature, discussing the main findings, and contributions of each study. Also, a concise summary of the key findings and outcomes of the reviewed papers is included in this section. Section IV provides conclusion, summarizes the main findings and contributions of the literature review, and Section V provides recommendations for future research directions.

II. Materials and Methods

A. Literature Sources and Search Strategies

The information for this review was obtained by looking at publications that have been published between January 2019 and June 2023 using the well-known search engines Google Scholar, Scopus, and Web of Science. A combination of keywords like artificial intelligence, deep learning, machine learning, artificial neural networks, convolutional neural networks, and accident detection was used for data searching.

B. Identification and Selection of Relevant Studies

The articles from the preliminary search that had abstracts with full texts were retrieved. Along with computer searching, non-electronic sources were also used, such as manual searches for relevant journals and publications. The articles were chosen in accordance with the title and after reviewing the abstracts pertaining to our study subject. 202 publications that fit the review's objectives were primarily found through the initial search. Due to data duplication, nine articles were ignored, and 57 were removed due to topic irrelevance. Thus, 136 articles were included for the second stage of data selection. These articles were then subjected to the subsequent inclusion and exclusion criteria.

C. Eligibility Criteria of the Studies

According to the inclusion criteria, the articles must be specifically focused on deep learning-based road accident detection systems; they must also explicitly address the deep learning technology utilized in the study model; they must explicitly discuss the data sets that were used for the model's evaluation, validation, or training; and they must explicitly mention a quantitatively measurable predictive outcome. Articles written in languages other than English and those with topics other than deep learning technology were excluded. 118 articles were excluded after applying the criteria.

D. Data Extraction and Management

The number of articles was further lowered to 18 after applying these eligibility requirements.

Fig. 1 displays the flowchart of the screening and selection of literature.

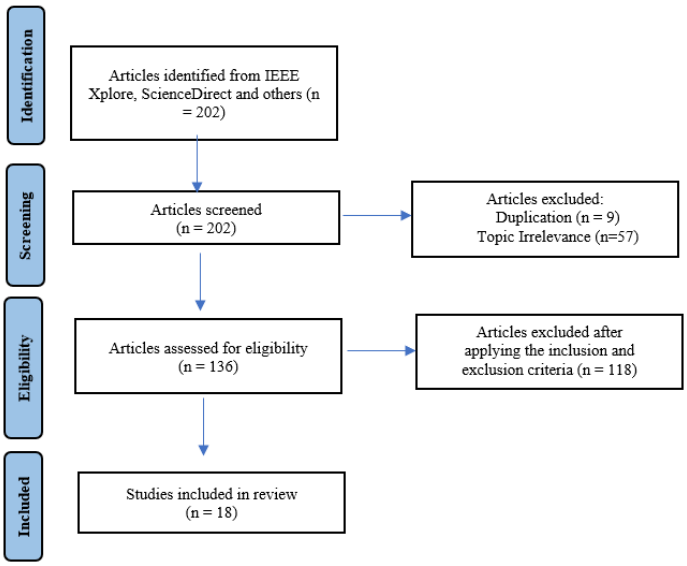

Fig. 1. Flowchart for screening and selection of literature.

III. Discussion

This study in [6] investigates relevant data variables, such as accident severity, the number of casualties, and the number of cars, to uncover trends in road automobile accident data and to suggest a predictive model. Consequently, a pre-processing model is created to transform raw data using interquartile outlier removal, generalization of data attributes, and the elimination of missing and nonsensical features. The performance of road accident prediction is studied using and evaluating four classification methods: naïve Bayes, random forest, decision trees, and multinomial logistic regression. Except for naïve Bayes, the results address acceptable levels of accuracy for car accident prediction. The results are examined using a data-driven methodology to identify the critical variables causing traffic accidents and to suggest ways to prevent them.

In this research [7], a deep learning accident prediction model is proposed by combining extended features such as sentiment analysis, emotions, weather, geocoded locations, and time information with data derived from tweet messages. According to the data, accident detection accuracy increased by 8%, bringing the test's accuracy up to 94%. The suggested methodology fared better than the state-of-the-art methods now in use, increasing accuracy by 2% and 3%, respectively, to reach 97.5% and 90%. The high-performance computing constraints brought forth by detector-based accident detection, which required massive data calculation, were likewise addressed by our method. The outcomes have increased confidence that utilizing cutting-edge features improves traffic accident identification and prediction.

The work done by [8] provides an overview of the technologies used in road accident detection and information transfer system. They also emphasized the importance of automatic road accident detection and information communication systems in all vehicles, whose role is to send a notification message to the nearest hospital and police station upon detecting an accident. As the performance of such systems can be greatly improved with the inclusion of technologies like social network data analysis, sensor data, machine learning, and deep learning, the authors have used artificial neural networks to build a new model. The entire system is structured as three modules, where the first module comprises the collection of image data. The second module is about pre-processing the data and the last module comprises accident detection and notification, which extracts visual and temporal features using the PYTORCH architecture and neural networks called a multi-layer perceptron (MLP). The proposed system proved to be very useful in detecting incidents with an F1 score of 0.98 and accuracy of 98 percent.

The high number of accident-related fatalities in India is a topic of this study [5], which highlights the importance of quick guidance. The paper suggests a method for identifying accidents using real-time CCTV data from roadways. It uses a Hierarchical Recurrent Neural Network (H-RNN) model that has been trained to distinguish between accident- and non-accident-related video frames. H-RNN is a potential option for quick accident detection because of its accuracy in image classification—over 95%—and applicability for video analysis—it can capture temporal dependencies. With the help of this study, accident victims will receive much better response times and outcomes.

The research described in [9] highlighted the need of minimizing the time required by an accident-detection system in sending notifications to the emergency services. To meet this objective, the authors proposed a software-oriented accident recognition system using convolutional neural networks (CNN) that could send real-time alerts to the nearest hospitals and police stations. The new system used only the available resources with the modifications brought through the deployment of AI techniques on edge devices attached to roadside CCTV cameras for classifying images. As the input to the convolutional neural network (CNN), live footage from CCTV cameras were used, from which the probability of the occurrence of an accident was generated. Accident Recognition and Alerting System (ARAS) is divided into three main components, based on their functionality. The components are the Edge Accident Recognition Module (EARM), Alert Database (AD) and Alert Web Interface (AWI). The EARM is responsible for recognizing accidents and sending alert messages. The alerts are received by the AWI, which is a website provided to the emergency services. The AD acted as a common point between the EARM and the AWI. Three kinds of CNN architectures are used which are Inception v3, DenseNet, and ResNet-50 respectively thus resulting in three new models. The performance of these models was compared, and it was found that Inception v3 detected the accident throughout as opposed to DenseNet and ResNet-50. Also, the Inception v3 model displayed the best prediction time, proving it to be an effective choice for real-time, end-to-end, edge deployment. These models

additionally help in avoiding the transmission of duplicate alerts.

A new support system for self-driving cars is proposed in [10] that could detect vehicular accidents through a dashboard camera and spontaneously report it to local authorities. The Mask R-CNN framework is used for object detection along with an object tracking algorithm to make the new system more efficient. The object detection component serves to identify the type of vehicle as either a car, bus, or truck. The output of this step includes the class IDs, generated masks, bounding boxes, and the detection scores of vehicles for a video frame. Whereas the part comprising a centroid tracking algorithm is used for vehicle tracking.

Additionally, trajectory intersection, velocity computation, and lane detection are also included to improve the performance of the vehicular accident detection framework. The proposed model is compared with existing models using two important performance criteria, i.e., Accident Detection Rate (ADR) and False Alarm Rate (FAR). As the number of parameters is more, the reliability of the new system in accurately recognizing accidents also got magnified with 79.05% Accident Detection Rate and 34.44% False Alarm Rate. Despite these advancements, the system is handicapped by the unavailability of large, annotated datasets that can be used to test and improve the system further.

The research study in [11] proposed Object Detection and Tracking System (ODTS) for automatically detecting and monitoring unexpected events on CCTVs in tunnels. The unexpected events are categorized as either Wrong-Way Driving (WWD), Stop, Person out of the vehicle in a tunnel, or fire. The system accepts selected frames of video at specified time intervals as input, which are then converted into Bounding Box (BBox) and is simultaneously classified into its corresponding type by the detection module which uses a faster RCNN learning algorithm for the same. The detected objects are then assigned a unique ID number by the object tracking module which uses the SORT framework. However, automatic object detection systems in tunnels suffer from the common problem of low illumination videos.

A deep learning model of Faster R-CNN was used for training dataset to address this issue. However, the model does have a limitation in that the ODTS employs an object tracking function with car objects only. The ODTS module applied the Car Accident Detection Algorithm (CADA) for classifying several events. The inclusion of these technologies resulted in the system being able to identify the incidents within 10 seconds after testing with the image that contained each incident but due to the lack of sufficient Fire objects in the training set, the likelihood of false detection in the case of Fire is high.

An automated system for detection of accidents at traffic intersections is proposed in [12]. The proposed framework is made of three main modules, which are object detection, object tracking and the accident detection module respectively. The object detection part is primarily based on the YOLOv4 approach, which makes it very efficient and accurate. The item monitoring module uses the Kalman filter and the Hungarian algorithm for affiliation whose performance is further enhanced with the use of a new cost function. It can accommodate several challenging situations, such as occlusion, overlapping objects, and shape changes that occur while tracking the objects.

Whereas the accident detection module was constructed with the aid of trajectory conflict analysis. The trajectories of the objects are analysed in phrases of velocity, angle, and distance so that extraordinary forms of trajectory conflicts consisting of vehicle-to-vehicle, vehicle-to-pedestrian, and vehicle-to-bicycle can be detected. These unique features make the model suitable for real-time traffic surveillance. The performance of the proposed framework is evaluated using the video sequences under numerous illumination conditions that were obtained from YouTube. The robustness of the system is proved through the lower fake alarm rates and an excessive detection rate.

A traffic accident prediction system that predicts traffic accidents on highways is proposed in study [13]. To accurately predict accidents, the model uses Java's high-level neural network API framework. Here are the steps the model goes through: A convolutional layer is first given traffic accident records as input and is then filtered to remove duplicate fields. After removing the unwanted records, the adjusted dataset is fed to the new layer. Weights are then assigned to the retrieved features based on random number generation, and finally network backpropagation is performed until the error reaches a threshold. The performance of the proposed convolutional neural network (CNN) is evaluated and compared with the traditional neural network-based backpropagation prediction methods. The results show that the new algorithm has much lower loss and higher prediction accuracy compared to the conventional devices. The incident prediction model proposed in this paper has only a small impact on the prediction rate, but it can be improved by choosing other features to input to the CNN or applying a more efficient model instead of the CNN.

A framework for automatic detection of road accidents in surveillance videos is proposed in [14]. A convolutional auto-encoder was incorporated in the model for extraction of deep representation, in the form of appearance and motion features as well as their correlations, from the spatiotemporal video volumes (STVVs) of raw pixel intensity and then detection for any abnormalities in surveillance videos. The accident detection ability of the model is further increased by combining the complementary appearance and motion information. Additionally, a collision is also sensed using the information about the joints of the trajectories of the vehicles over space-time dimensions. Once the joint trajectories are made, a one-class SVM with an RBF kernel is used to generate the outlier score from his intermediate representation to identify unusual/unseen/abnormal/outlier events. The performance measure of this model is evaluated using real accident videos collected from the

CCTV surveillance network of Hyderabad City in India. The result witnessed a reduction in the false alarm rate and an increase in the reliability of the detection system by using the proposed approach. But the system still faced the challenges of low visibility at night, occlusions, and large variations in the normal traffic pattern, which need to be addressed in the future.

To ensure that victims receive timely aid, the study given in [15] created a system to identify traffic incidents in real time and send an immediate alarm message to the nearest control unit. As the existing structures that use features such as IR sensors, IMU sensors, ARDUINO UNO etc., lack accuracy in detecting accidents, the authors attempted to build in more accuracy and effectiveness in their system through the usage of deep learning techniques such as convolutional neural networks. As no dataset regarding accidents occurring in India was available dataset was created to train the CNN model. The trained system is then included with the cameras, positioned at accident-susceptible areas, to seize the video of the vehicles on the road. Then for video classification, deque was used for performing the rolling prediction averaging. Once an accident is detected, officials are informed about the same by sending them an alert message using the GSM module that's included in conjunction with the camera. The proposed version proved to be more dependable and economical compared to the current structures. It could detect accidents with a high level of accuracy with almost eighty-five percent of successful image prediction. The author similarly proposed incorporating speed-detection cameras as future work, which could make the system more efficient.

Using both video and audio data generated from dashboard cameras, the research in [16] proposed a car crash detection system. Multimodal data is composed of three different types of data, namely, video data, audio features of audio data, and spectrogram images of audio data which were collected from a video sharing platform like YouTube. The data were then standardized and normalized to occupy a standard frame. Deep learning techniques like gated recurrent unit (GRU) and convolutional neural network (CNN) were then used to classify the data as either positive or negative clips. The CNN module consisted of five conv2D layers with ReLu activation function, four batch normalization layers with 0.9 momentum, three max pooling layers, and a global max pooling layer. A weighted average ensemble is used as an ensemble technique for combining the three different classifiers. Finally, the classification performance of the proposed car crash detection system was compared with the existing system, and it was found that the proposed system performed better than its base counterpart, which relied on single modal data (i.e., video or audio data only) to detect possible car-crashes. The proposed model could bring in a drastic improvement in the accuracy of the system. The authors further proposed an enhancement to their model using the inclusion of three-dimensional filters, which may further improve the efficiency more.

An automated system capable of detecting traffic accidents from video is proposed in [17]. A deep learning (DL)-based approach is used, which shows a high performance in accomplishing computer vision tasks that involves complex features relationship. The work assumes that accident events can be represented using data that have visual features occurring in a temporal way. The model hence comprises a feature extraction phase that uses the convolutional method, followed by temporary pattern identification accomplished using recurrent neural networks. For accident detection, a dense ANN approach is used.

Therefore, the model can be structured into three portions where each portion focuses on spatial feature extraction, temporal feature extraction and binary classification, respectively. The model was trained using the imageNet dataset. As the precision of the accident detection system was found to be under satisfactory, the model was modified using a transfer learning process and the weights for the model were adjusted using a new dataset. The modification included a ConvLSTM layer-based neural network being added up to the existing architecture for enhanced feature extraction and usage of a dense artificial neural network block using regularization methods for better accident detection.

Under the ConvLSTM layer-based neural network model, the feature vector computed by the adjusted InceptionV4 architecture was taken as the input. For this, two sets of data are used, where the first one comprised image for the visual extractor and the other had videos for training the temporal extractor. Both data sets contain positive and negative accidents. The modification also included the application of four techniques in video segmentation, in which the first one consisted of video segmentation without frame discrimination., the second one was used to skip the frame intruder to reduce the redundancy, the third technique helped in calculating a pixel-to-pixel comparison of two consecutive images and finally the fourth technique is substantially similar to the third except that the threshold was set to 0.98 against the 0.9 mark in the third. Through the modification the accuracy improved to 0.98. But the proposed model still had a few limitations, which is, the model required large datasets with clear data to get trained well.

A feature fusion-based deep learning model for video-based accident detection is suggested in study [18], that could achieve better detection speed and accuracy with restricted computing resources. The system comprises an interest module for capturing the appearance features of the crash images. The module was blended with ResNet to enhance the speed of the traditional convolution neural network. A 1 x 1 convolutional layer is employed to reduce the size of the output feature map, which is then entered into the Conv-LSTM network to accurately extract the motion features of crashes. This Conv-LSTM network has a bonus over its traditional counterpart in terms of being lighter and preserving spatial information. Finally, a global pooling layer is used to locate a crash. This proposed system won over the current video-based crash detection

systems as they suffered from low detection accuracy and excessive computational costs. However, the proposed version has a few limitations like falsely detecting traffic scenes as crashes, showcasing few misdetections in complicated, rare, and ambiguous environment, etc. The model may also be, in addition, stepped forward to become aware of one-of-a-type types/severity tiers of crashes.

An accident detection system that may track accidents at the generation of occurrence is given in [19]. The proposed model is a fusion of CNN and LSTM layers for the classification of nonstop video captured by the camera. In the CNN-LSTM network, CNNs are used for image feature extraction and exceed LSTMs for sequence prediction. When compared with other existing models composed of high-priced sensors and pointless hardware, the proposed model showed improved performance in terms of cost, reliability, and accuracy. In the future, the model's performance may be enhanced using some supervised and unsupervised techniques. Particularly, supervised learning can be used to discover the accidents from the frames which can be flagged anomalously via way of means of unsupervised models. More state-of-the-art techniques for monitoring accident-prone areas may be used.

A system to detect accidents from video footage provided to it using a camera is proposed in [20]. The objective of this model, which is built using advanced Deep Learning Algorithms, i.e., convolutional neural networks (CNN) and the LSTM network is to detect accidents within seconds of its occurrence. In the CNN-LSTM network, CNN is used for modeling spatial data like images and feature extraction which is passed on to the LSTM for sequence prediction. The pictures captured through the Pi-cameras are broken down into frames and fed to the automated system and while an accident is detected, an alert message is dispatched using the GSM module. Along with the message, the frame at which an accident is detected and the percentage of chances of accident are also conveyed. Upon assessing the model's performance, it yields an average accuracy of 92.83%.

An automatic car accident detection method based on Cooperative Vehicle Infrastructure Systems (CVIS) and machine vision such that roadside intelligent devices recognize and locate crashes efficiently is given in [21]. For this purpose, a new image dataset (CAD-CVIS) is created based on video sharing websites consisting of various kinds of accident types, weather conditions, and accident locations. The data includes video features of the car's motion parameters, and the concept of accident detection is since the motion parameters will change dramatically when an accident occurs. The CAD-CVIS dataset used in the study was divided into three parts. A training set (80%) used to train the parameter weights of the network, a validation set (5%) used to fir and test hyperparameters such as learning rate and dropout rate and a test set (15%) used to evaluate the performance of various algorithms for detecting car accidents. Here, each part of the dataset contains all types of accident.

A deep neural network algorithm, YOLO-CA, was used to detect accidents and their location. The performance of the model was enhanced by including Multi-Scale Feature Fusion (MSFF) and a dynamically weighted loss function to help detect small objects better. Finally, the performance of the proposed model was evaluated and compared with other object detection models, which showed significant improvements in terms of response time by rescue agencies and rescue efficiency.

A prototype that uses a machine learning approach to reduce road accidents caused by reasons such as drowsiness, fatigue, and inattention is developed in [22]. The CNN algorithms help avoid accidents, notify drivers when they detect drowsiness, and are very efficient at classifying datasets. This approach combines machine learning techniques with other concepts such as avoidance of drinking, direction control, speed control, and distance maintenance. The new system is superior to many existing systems as it uses more sophisticated and robust sensors than the others. Additionally, the proposed system uses IoT components cheaper than available mechanisms such as Wireless Sensor Networks (WSN), Cloud computing, and Industry 4.0, etc., so it offers a high-tech solution to avoid accidents at low cost. In conclusion, it can be stated that the proposed system offers a great opportunity to avoid accidents at an affordable price.

Table I presents an overview of the reviewed papers. A comprehensive overview of the reviewed papers, highlighting the dataset used, technique employed, observations made, and performance, is given in the table. The dataset used column provides insight into the specific data sources utilised in the studies. This information is essential for understanding the scope and applicability of the research findings. The methodology column outlines the methodologies, algorithms, or experimental approaches employed by the authors. This section sheds light on the scientific tools and methods utilised in each study, allowing readers to assess the validity of the research. The observation column summarises the key findings or outcomes of each paper. The performance column summarises the accuracy of the models.

TABLE I. SUMMARY

Author & Year	Dataset used	Methodology	Observations	Performance
(Pourroostaei Ardakani et al., 2022)	Online traffic accident dataset based on UK	Decision trees, Random Forest, Multinomial logistic regression, and Naïve Bayes algorithm	This paper presents a predictive model for road car accidents, focusing on significant data features like accident severity, casualties, and vehicles. Four classification methods are used, with acceptable accuracy levels. Among the four, random forest algorithm can predict car accidents with more accuracy.	85% accuracy
(Azhar et al., 2022)	Twitter messages	Deep learning techniques	The paper presents a deep learning accident prediction model that uses tweet messages and additional features like sentiment	94% accuracy

			analysis, emotions, weather, and geo-coded locations.	
(L et al., 2022)	The web scraping method was used to construct the image dataset from scratch.	Feed forward Neural networks (MLP)	Visual and temporal feature extractors are used to distinguish between traffic collisions. The training process for fine-tuning the weights used the picture dataset. Because there aren't many instances given, the solution only applies to car accidents—motorcycles, bicycles, and pedestrians aren't included.	92% accuracy
(Parthiban et al., 2021)	CADP dataset, which includes recordings with accidents, and the DETRAC dataset, originally designed for vehicle object location.	Hierarchical Recurrent Neural Network	Compared to traditional RNNs, the H-RNN is more appropriate for video extraction. H-RNN based picture classifiers have provided precisions of over 95% for comparatively smaller datasets and require less preparation.	92.38% accuracy
(Chitale et al., 2020)	The TrafficNet dataset from DeepQuest AI	CNN, InceptionV3, Densenet and Resnet-50	A software-oriented approach employing CNN to detect road accidents. This produces the likelihood that an accident may occur or not. In contrast to DenseNet and ResNet-50, Inception v3 identified the accident continuously. The best prediction time was also achieved by the Intermediate Representation of Inception v3, indicating that this model is a good option for real-time, end-to-end edge deployment.	93.75% accuracy
(Chand et al., 2020)	The Microsoft Common Objects in Context dataset and dash-cam footage of accidents from YouTube	Mask R-CNN	The proposed model compared Accident Detection Rate (ADR) and False Alarm Rate (FAR). The suggested approach has an accurate accident detection rate of 79.05% for cars and a false alarm rate of 34.44% for cars.	79.05% accuracy
(Lee & Shin, 2019)	CCTV footage	Faster RCNN	Proposed Object detection and tracking system (ODTS) by fusing an object tracking method with a deep learning-based object detection procedure. The model achieved average precision values of 0.8479, 0.7161, and 0.9085 for cars, people, and fires, enabling the system to detect all accidents in less than 10 seconds.	84.79% precision for detecting cars
(Ghahremannezhad et al., 2022)	Customized dataset	YOLOv4 method with a pre-trained CNN model CSPDarknet53.	The Euclidean distances between all object pairs are calculated to identify the objects. The angle of collision trajectory conflicts involves near-accident and accident occurrences. With a false alarm rate of 6.89% and a detection rate of 93.10%, the proposed structure performed well.	93.10% detection rate
(Thaduri et al., 2021)	Traffic accident dataset	CNN, backpropagation	Polling method removes unnecessary data. The proposed CNN is compared with the backpropagation prediction method. Compared to the conventional BP algorithm, the suggested algorithm has a substantially smaller loss and a higher prediction accuracy.	98% accuracy
(Singh & Mohan, 2019)	CCTV Surveillance footage	Autoencoder, one class SVM	The proposed framework uses denoising autoencoders trained on traffic videos to automatically learn feature representation from spatiotemporal volumes of raw pixel intensity, replacing traditional hand-crafted features.	77.5% detection rate
(Rajesh et al., 2020)	Customized dataset	CNN	Dropout is used to prevent overfitting. The model was created using sequential API GSM module for alert. The proposed system uses a GSM module to detect road accidents, sending alert messages to nearby control rooms. It is reliable, economical, and highly accurate.	85% accuracy
(Choi et al., 2021)	Images from dashboard cameras	GRU, CNN	Utilizing video data, a CNN-and-GRU-based classifier, a GRU-based classifier utilizing audio characteristics from audio data, and a CNN-based classifier using spectrogram images from audio data make up the suggested model.	98.60% accuracy for Case Study 1 and 89.86% for Case Study 2
(Robles-Serrano et al., 2021)	Customized dataset	ConvLSTM	The suggested approach assumes that visual characteristics that appear over time describe traffic accident incidents. Thus, the model architecture consists of an extraction phase for visual features and a transient pattern identification phase.	98% accuracy
(Lu et al., 2020)	Traffic image datasets	ConvLSTM, ResNet, Vgg	The framework proposes a residual neural network and attention modules for extracting crash-related appearance features from urban traffic videos, which are then combined with Conv-LSTM for simultaneous capture.	87.78% accuracy
(T.S. et al., 2021)	CCTV image dataset	CNN, LSTM	The proposed model combines CNN and LSTM layers for continuous video classification, incorporating ResNet-50 and LSTM layers for spatial and temporal characteristics, with adjustments made for training images.	99.9% accuracy
(Ghosh et al., 2019)	CCTV video dataset	CNN, RNN	The proposed model combines CNN and LSTM layers for continuous video classification, inspired by Inception v3, with temporal and spatial features added to the existing Convolution	92.38% accuracy

			Network, divided into convolution and recurrent parts.	
(Tian et al., 2019)	The novel image dataset CAD-CVIS.	YOLO-CA	The paper presents an automatic car accident detection method using Cooperative Vehicle Infrastructure Systems (CVIS) and machine vision, utilizing a novel image dataset and a deep neural network model YOLO-CA, which enhances performance in detecting small objects.	90.02% average precision
(Razeeth et al., 2021)	Customized image datasets	CNN	The study uses machine learning to detect drowsiness, improve drunk and speed control, and prevent collisions using IoT. It uses convolutional neural network with Keras and MQ13, MAX30105, and L298N sensors.	Drowsiness is detected successfully, and collisions are prevented

IV. Conclusion

The analysis of related work highlights several studies and their methodologies. For instance, researchers have developed models using artificial neural networks, convolutional neural networks (CNN), and object detection algorithms to improve road accident detection. These models utilize image data, pre-processing techniques, and accident detection and notification modules to achieve high accuracy and efficiency. Techniques like social network data analysis, sensor data, and trajectory conflict analysis have also been employed to enhance detection capabilities. Researchers employed a variety of techniques like MLP, CNN, and CNN models, including DenseNet, Inception V3, LSTM, YOLO, RNN, and others. Although the MLP model showed high accuracy, the Inception v3 model provided the best prediction time, proving its suitability for real-time, end-to-end edge deployment.

The proposed systems demonstrate promising results, including high accuracy rates, low false alarm rates, and efficient real-time detection. However, challenges such as low visibility at night, occlusions, variations in traffic patterns, and the lack of annotated datasets still need to be addressed in future research. In most of the papers, the delays in giving timely medical attention to the injured are quoted as the major reason for the increase in traffic fatalities. The models used both video and audio data from the dashboard camera for detection. The major problem with these types of datasets is their size. To develop effective deep learning models, we must train our models on a large dataset.

In conclusion, this review reveals significant advancements in road accident detection using machine learning and deep learning approaches. The studies highlight the importance of accurate and efficient detection systems that can improve emergency response and reduce the impact of accidents.

V. Future Work

To overcome the problems related to data scarcity, we are planning to use different strategies, like different pre-trained convolutional neural networks or Spinal net, for feature extraction. Also, further research is needed to overcome the identified challenges in the existing literature and enhance the reliability and performance of such systems.

IoT-based Autonomous Search and Rescue Drone for Precision Firefighting and Disaster Management

Shubeeksh Kumaran, V Aditya Raj, Dr. Sangeetha J, V R Monish Raman
Department of CSE, M. S. Ramaiah Institute of Technology, Bengaluru, India

***Abstract*—Disaster management is a line of work that deals with the lives of people, such work requires utmost precision, accuracy, and tough decision-making under critical situations. Our research aims to utilize Internet of Things (IoT)-based autonomous drones to provide detailed situational awareness and assessment of these dangerous areas to rescue personnel, firefighters, and police officers. The research involves the integration of four systems with our drone, each capable of tackling situations the drone can be in. As the recognition of civilians and protecting them is a key aspect of disaster management, our first system (i.e., Enhanced Human Identification System) to detect trapped victims and provide rescue personnel the identity of the human located. Moreover, it also leverages an Enhanced Deep Super-Resolution Network (EDSR) x4-based Upscaling technology to improve the image of human located. The second system is the Fire Extinguishing System which is equipped with an inbuilt fire extinguisher and a webcam to detect and put off fire at disaster sites to ensure the safety of both trapped civilians and rescue personnels. The third system (i.e., Active Obstacle Avoidance system) ensures the safety of the drone as well as any civilians the drone encounters by detecting any obstacle surrounding its pre-defined path and preventing the drone from any collision with an obstacle. The final system (i.e., Air Quality and Temperature Monitoring system) provides situational awareness to the rescue personnel. To accurately analyze the area and its safety levels, inform the rescue force on whether to take precautions such as wearing a fire proximity suit in case of high temperature or trying a different approach to manage the disaster. With these integrated systems, Autonomous surveillance drones with such capabilities will improve the equation of autonomous Search and Rescue (SAR) operations to a great extent as every aspect of our approach considers both the rescuer and victims in a region of disaster.**

Keywords*—Search and rescue; firefighting; internet of things; disaster management

I. INTRODUCTION

India has a history of being particularly susceptible to natural disasters due to its geo-climatic conditions. Landslides, cyclones, earthquakes, floods, and droughts have been frequent occurrences. Every single year from 1990 to 2000 [1], there were approximately 4344 calamities and over 30 million people were greatly affected by disasters followed by a significant increase in frequency and extremity of natural disasters between 2000 and 2020. The government has initiated steps to improve its rescue support and approach to responding to disasters, but there is lots of room for improvement to protect the vulnerable and significantly reduce the impact of natural disasters in this densely populated country. Over the past few decades, Unmanned Aerial Vehicles (UAV) have increased in popularity rapidly. Drones are UAVs that are controlled using remotes or can fly autonomously [2]. They can be made to perform Search and Rescue (SAR) operations, provide early disaster warnings to humans, analyze the damage, deliver important supplies to isolated or inaccessible locations, and aid in communication with blacked-out areas. This paper deals with providing a sophisticated drone for autonomous search and rescue operations during disasters with the motive to rescue the lives of both the victims and the rescue personnel with the added capabilities of firefighting. This is achieved by the integration of multiple precision IoT sensors and cameras for completely utilizing the drone's position in a zone of disaster that is unsafe for any human. Apart from transmitting real-time sensor data to the ground rescue team, it is also integrated with a sophisticated Enhanced Human Identification System to keep track of all humans encountered during the drone's SAR operation. The paper also explains how inbuilt fire extinguishers installed in drones can be utilized to extinguish dangerous fires located at disaster sites, thereby providing a safe entry/exit path for rescue personnel, and hence improving the rescue effectiveness and efficiency.

In the past several researchers have worked on the various potential applications of drones in disaster management, such as Search and Rescue (SAR), damage assessment and communication. As discussed in study [3] the benefits to explore a range of applications of drones in disaster management and how they can change the entire aspect to solve key challenges involved. Similarly, in [4] presents the design and creation of a low-cost, autonomous drone that is capable of communication, surveillance, and transportation of medical supplies utilizing an integrated GPS and real-time video streaming. In [5], the author conducts a brief survey of video surveillance using drones and highlights the challenges that come along with the technology, such as battery life, data transmission, image processing, and privacy concerns. The high-rise buildings have less accessibility, but when sensors are set up and in case any fire is detected, it is meant to send a message to the control room and give the GPS location to the cloud-enabled drone can be piloted to the affected spots and give situational awareness to firefighters, was the idea given by the author of [6]. Similarly, drones can be used for assisting in rescues during times of disasters [7]. The authors of [8] present the idea of integrating fire-fighting drones that will act as first respondents and will ensure enhanced response time and send necessary details to the control center. [9] presents a similar approach for the early detection of forest fires using two sets of drones, i.e., Fixed wing Unmanned

Aerial Vehicles (UAV) and Rotary-wing UAV with the assistance of artificial intelligence. In study [10] the author gives a brief insight into the concept of using drone as a technology-driven solution that highlights the potential to revolutionize this domain by providing improvised access to healthcare services during times of disaster. In research [11], the authors provide a conceptual framework of drone swarms for fire suppression activities. The framework consists of various stages, such as fire detection, decision-making, and intervention. The results of study [12] indicate the approach of utilizing UAVs as aerial base stations to help in providing reliable communication coverage and connectivity in disaster scenarios. Low-cost-drone-borne synthetic-aperture radar imaging system that can generate high-quality images in various scenarios, including complex terrain and urban environments. The proposed system has the potential range of applications, disaster management, agriculture, and urban planning are a few examples [13]. The study in [14] presents a similar hybrid drone-based radar system for vital sign imaging in disaster management scenarios. Lastly, the development of an Enhanced Deep Super-Resolution Network (EDSR) [15] that can upscale images to make their resolution better can be used to identify humans with utmost precision after locating them.

Overall, the previous and related works show that drones have significant potential for firefighting and disaster-management applications. However, many challenges must be addressed to fully realize the potential of drones in disaster management. Most of the papers have been seen to implement a single task with the help of multiple drones which is not cost-effective and brings in the complication of maintaining them and having to always keep track of their coordination. Similarly, another challenge that was noticed in a few papers was that the overall features for disaster management were not implemented. Keeping these ideas and the demerits of the previous works in mind, this paper implements the integration of a single drone with the concepts of deep learning and the Internet of Things, the drone is infused with multiple systems such as the Air quality and temperature monitoring system, Active Obstacle Avoidance system and most importantly the Fire Extinguishing system. This brings novelty into the research in the implementation approach that has not been explored yet until now.

The rest of this paper is organized as follows. Section II explains the methodology of the proposed work where we introduce a system that has four systems integrated with our drone which consist of an Enhanced Human Identification system, Fire Extinguishing system, Active Obstacle Avoidance system and Air Quality and Temperature Monitoring system. In Section III, we will delve into Hardware setup, Section IV provides the results. The paper ends with Section V and Section VI respectively where we have written concluding remarks on the potential capabilities of the research and future scope.

II. METHODOLOGY

This research work depends on the strong autonomous capabilities of the drone. Being autonomous is the foundation and is achieved by the integration of a companion computer Raspberry Pi 3B which is connected to the flight controller, the Pixhawk 2.4.8 as shown in Fig. 1. The connection is made via the telemetry port on the Pixhawk. All the data is communicated using appropriate MAVLINK protocols. With this setup, we have achieved Raspberry Pi-controlled drone movements.

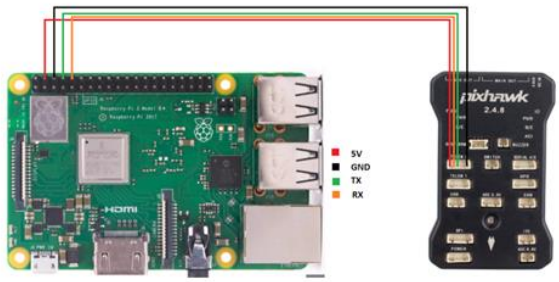

Fig. 1. Connections from raspberry Pi to Pixhawk 2.4.8.

Now the drone is capable of autonomous takeoff, landing, and maneuvering based on both a predefined path, as well as the surrounding conditions perceived by the sensors and cameras used. These main functionalities have been explained in detail in the following system:

1) *Enhanced* human identification system
2) *Fire* extinguishing system
3) *Active* obstacle avoidance system
4) *Air* quality and temperature monitoring system

A. Enhanced Human Identification System

The drone is equipped with an inbuilt webcam to provide rescue personnel with live footage to keep them regularly updated on the surrounding environment of the affected disaster site. However, the main purpose of this system is to provide a human detection system to identify trapped victims in disaster sites. This enables us to keep track of all the humans encountered in the drone's path during its flight. Unfortunately, the drone is expected to be recording subpar images in harsh situations where surroundings are filled with smoke, dust, fire, and relative movement of the drone and human. Hence, we are leveraging a EDSR based image resolution enhancement architecture to be able to identify the human with increased ease after the face detection system stores the faces in the database. Therefore, we are able to achieve a resulting output image with a four times Scaling Factor.

1) Advanced face detection: We have implemented the human identification by deploying a face detection feature that uses OpenCV and Deep-Learning technique called Single Shot Detector (SSD), where once a face is identified, the image of that face is clicked and saved in a database which is accessible only to rescue personnels. Once the image is stored, an alert message is sent to the rescue personnel with a prompt, informing them that a victim has been identified. This feature uses the "Twilio" API to send messages which uses a secure authentication token and a specific SSID which makes this a highly secure communication line as seen in Fig. 2. Using this

information, rescue personnel can keep track of the victim's location and carry out their rescue operation more efficiently.

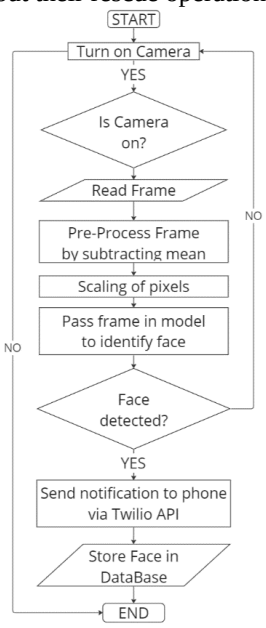

Fig. 2. Workflow of advanced face detection.

In the Algorithm 1, we have explained the Single Shot Detector which is used to identify the human face from an input frame.

Algorithm 1: Single Shot Detector

a) Load the pre-trained model and define the input size.

b) For each image in the input:

- Preprocess the image.
- Feed the image through the network.
- Obtain the predicted class scores and bounding box coordinates.
- Apply non-maximum suppression to remove overlapping boxes.
- Draw the remaining boxes on the image and output the result.

2) EDSR x4 image enhancement: The Enhanced Deep Super Resolution (EDSR) x4 architecture is based on a sophisticated CNN specifically designed to upscale low-resolution images to specifically bring out the hidden details. It is inspired by the ResNet architecture that is characterized by a deeply stacked layers which leverages residual connections. The architecture initially employed a scaling factor of 2, subsequently 3 and then finally 4 in order to reaching a x4 scaling factor. This accelerates both the training and the overall performance of the model. The images form the database are retrieved to process through EDSR and the Layers and Components for EDSR x4 as seen in Fig. 3 is explained as follows:

a) Input Layer:

- Accepts the low-resolution image as input.

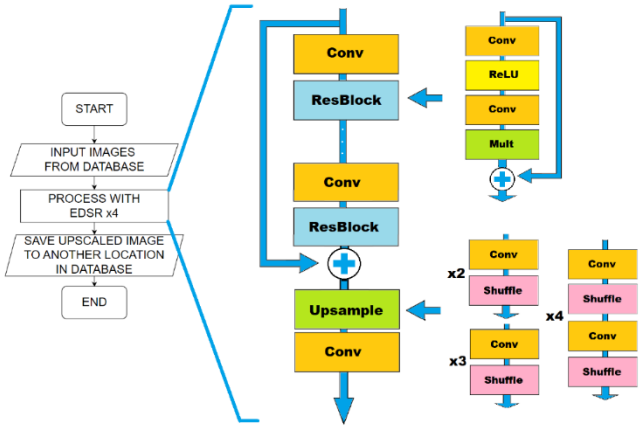

Fig. 3. Workflow of EDSR x4 image enhancement.

b) Feature Extraction Layers:

- Utilizes convolutional layers without batch normalization and ReLU activation to extract relevant features from the input image.
- ResNet-style architecture is employed for feature extraction.

c) Residual Blocks:

- These are the core building blocks of EDSR x4, following the ResNet style.
- Each residual block consists of:
  - Convolutional layers without batch normalization and ReLU activation.
  - Skip connections that bypass one or more convolutional layers and are added to the output.
  - Constant scaling layers placed after the last convolutional layers in each residual block with a factor of 0.1.
- The absence of batch normalization allows for greater range flexibility in the features' networks.

d) Skip Connections:

- These connections enable the network to learn residual details, facilitating the learning of high-frequency details.

e) Upsampling Layers:

- Utilizes techniques like nearest-neighbor interpolation or transposed convolution to upscale the feature maps.
- These layers increase the spatial resolution while preserving the learned features.

f) Output Layer:

- Produces the high-resolution image as the final output.
- By processing the human face images from the database using this technique, we can overcome the drawback of blurred images taken by the drone and

hence identify the human with ease due to its higher resolution resulting image.

B. Fire Extinguishing System

This system mainly deals with the detection and extinguishing of fire at disaster sites to ensure safety of both trapped civilians and rescue personnel. These outcomes are achieved by utilizing Raspberry Pi for on-board computations required to detect fire through an inbuilt Raspberry Pi camera along with servo motor to activate the fire extinguisher at the bottom of the drone. First, the armed drone monitors a particular area in its pre-defined path to check for any fires. Once the fire is detected, the drone lowers its altitude to get an effective range to carry out extinguishing process by using the inbuilt fire extinguisher after which it returns to optimum altitude to resume its surveillance process. The entire workflow of the fire extinguishing system is shown in Fig. 4.

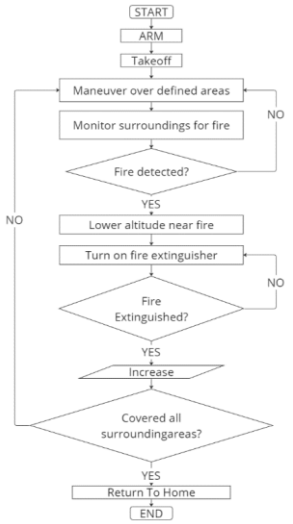

Fig. 4. Workflow of fire extinguishing system.

This classifier contains patterns of fire in images that have been previously trained, and it is used to identify potential fire regions in the video frames. Initialize Camera:

The cv2.VideoCapture() function is used to initialize the camera and establish a connection to capture live video feed. The camera is set to capture frames continuously in a loop.Process Video Frames: The code captures video frames from the camera in a loop using vid.read() function. For each frame, it performs the following operations:

1) Convert to grayscale: The frame is converted to grayscale using cv2.cvtColor() function. This step reduces the computational complexity and simplifies the fire detection process as the color information is not needed for fire detection.

2) Detect fire regions: The grayscale frame is passed to the loaded cascade classifier using fire_cascade.detectMultiScale() function. This function detects potential fire regions in the frame based on the patterns learned by the classifier.

3) Draw rectangles: For each detected fire region, a rectangle is drawn around it uses cv2.rectangle() function. This visually highlights the detected fire regions in the frame.

4) Display processed frame: The frame with highlighted fire regions is displayed using cv2.imshow() function. This allows visual inspection of the processed frame with detected fire regions.

5) Exit the loop: The code continues capturing video frames, applying fire detection, playing the alarm sound, and displaying processed frames until the 'q' key is pressed. Once the 'q' key is pressed, the loop is exited, and the code terminates.

Overall, the code continuously captures video frames, detects fire regions in the frames, plays an alarm sound, and displays processed frames with highlighted fire regions, providing a guide to the fire extinguishing system using a cascade classifier and a camera.

C. Active Obstacle Avoidance System

The active obstacle avoidance system is the main backbone of the autonomous flying aspect of the drone; it is to ensure the safety of the drone as well as any civilians the drone encounters. The system works primarily with the help of the four HC-SR04 sensors on each side of the drone as seen in Fig. 5, which are connected to the Arduino-Uno which is in turn connected to the Pixhawk flight controller. The drone's front and back movement is controlled by the Pitch. If the Pitch increases the drone moves backwards and if it decreases the drone moves forward. Similarly, the roll of a drone refers to the rotation of the drone around its longitudinal axis. When a drone rolls, it tilts to the left or right while keeping its heading unchanged. Roll controls the drone's left and right movements. If the roll increases the drone moves towards the right and if it decreases the drone moves towards the left.

Fig. 5. Representation of the front, back, right, and left sensors on the drone.

The Pixhawk flight controller controls the movement of the drone and receives commands from the remote control through its radio receiver. The Arduino-Uno is linked to the Pixhawk's RX and TX ports to integrate the active obstacle avoidance system with the flight controller. This is done to enable communication between the two devices. The Arduino-Uno sends obstacle detection information to the Pixhawk flight controller via the TX pin, which the Pixhawk interprets to adjust the drone's flight path to avoid the detected obstacles. The reason why digital pins 10 and 11 are used for this connection is that they are designated as hardware serial

communication pins on the Arduino-UNO board. By using hardware serial communication, the communication between the Arduino-Uno and the Pixhawk flight controller is fast, reliable, and minimizes the risk of communication errors

The first step in the methodology is to acquire the data from the ultrasonic sensors. The ultrasonic sensors are used to detect obstacles in the immediate vicinity of the drone and calculate the distance of the obstacle from the drone. The data acquired from the sensors is processed using algorithms that calculate the distance of the obstacles from the drone. Once the distance from the ultrasonic sensors has been acquired the sensors change the Pitch or roll value of the drone depending on which sensor has detected an obstacle.

The equation for the change in Pitch when an obstacle is detected by the FRONT SENSOR within its range is given by Eq. (1):

$$PITCH\_BACK = 1500 + 30 + ((100 - FRONT\_SENSOR) * 6) \quad (1)$$

where PITCH_BACK = the Pitch value to make sure the drone moves back,

1500 = Mid Term,

30 = initial increment when object detected at 99cm,

100 = Range of the sensors(cm),

FRONT_SENSOR = Front sensor distance (cm).

The relation between the Pitch and the distance is given by the following graph in Fig. 6.

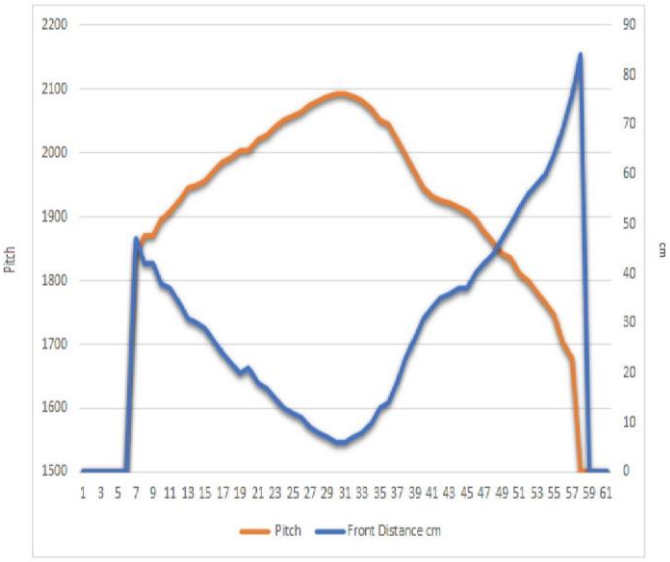

Fig. 6. Graph depicting the relation between pitch and the front distance.

Fig. 7 shows the working of the active obstacle avoidance system wherein we can see, once the ultrasonic sensors start operating, they start detecting any obstacle within the radius of 100 centimeters around it. Then through the digital pin number, they get to know which sensor has detected an obstacle and depending on that the roll or the Pitch must be changed, and then it either increases or decreases Pitch if the object is detected in the front or back respectively. The roll is changed by either decreasing or increasing it when the obstacle is detected on the right or left side respectively.

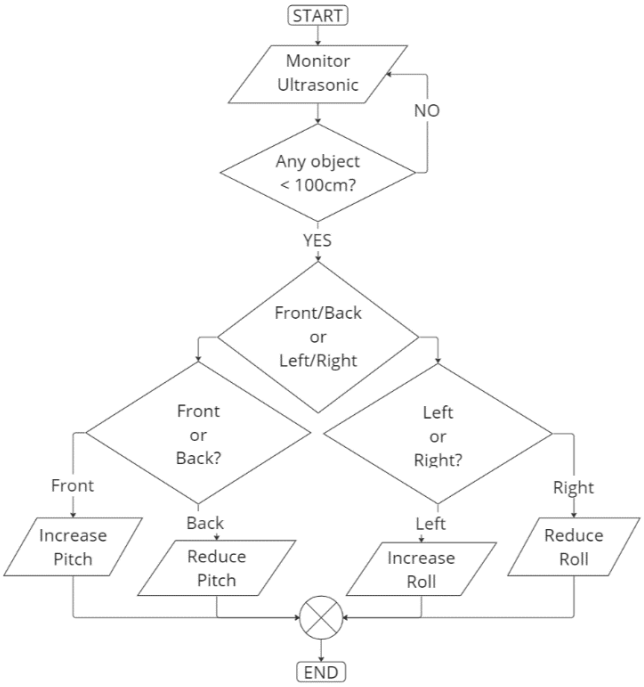

Fig. 7. Workflow of active obstacle-avoidance system.

D. Air Quality and Temperature Monitoring System

This system takes advantage of the drone's position in a region of disaster prior to the arrival of the rescue team. Alerting the rescue teams is done based on current environment conditions which are determined by several factors like temperature, humidity and air quality. To monitor these factors regularly our drone is equipped with a Temperature and smoke sensor which is seamlessly integrated into smartphones through an application called Blynk.App which obtains the data through the NodeMCU ESP8266 module and stores the data in Blynk.Cloud. Blynk.App is a mobile application to prototype, deploy and manage connected electronic devices at any scale. Real-time data are obtained by these connected devices and are stored in the Blynk.Cloud. Using an API, the devices easily connect to the platform and take advantage of all its advance features. The live values of the surrounding environment are being read by this system and can be viewed through the application for monitoring purposes.

1) Air quality monitoring: The sensor used to perceive data is the MQ2 sensor, which is sensitive to H_2, LPG, CH_4, CO, alcohol, smoke, propane, and air. Fig. 8 explains the step-by-step working of this monitoring system. The toxicity of the air and the presence of smoke is what we are interested in this Air Quality System. Once the sensor starts, the toxicity of the air is calculated by the concentrations of methane, ethane, butane, propane, and hydrogen present in the surrounding environment. The final toxicity value has to be perceived in terms of parts per million (ppm) for the convenience of easily

making decisions. The ppm calculation is based on the resistance ratio (RS/R0). RS is calculated using Eq. (2). Using the RS value calculated in Eq. (1) we find the R0 value using Eq. (3).

$$RS = [(VC - RL)/Vout] - RL \quad (2)$$

$$R0 = RS/\text{Fresh air ratio value from the datasheet} \quad (3)$$

Where RS = Change in resistance on detecting gas,

R0 = Stable sensor resistance in the fresh air,

V_C = Voltage Current,

V_{out} = Output voltage,

RL = Load Resistance.

Now that we have access to the live ppm values, we are able to conveniently perform analysis. In this research work, we have assumed three values of the threshold for monitoring purposes (i.e. 500 ppm, 700 ppm, and 800 ppm) for feasible testing. These values can be changed and set accurately for real-life scenarios. So, based on these three threshold values we generate appropriate response messages which will be uploaded to the Blynk.Cloud from where the message is sent to the user's phone via the Blynk.App. This way the rescue team can utilize appropriate safety gears and precautions based on the severity of the situation determined by this system.

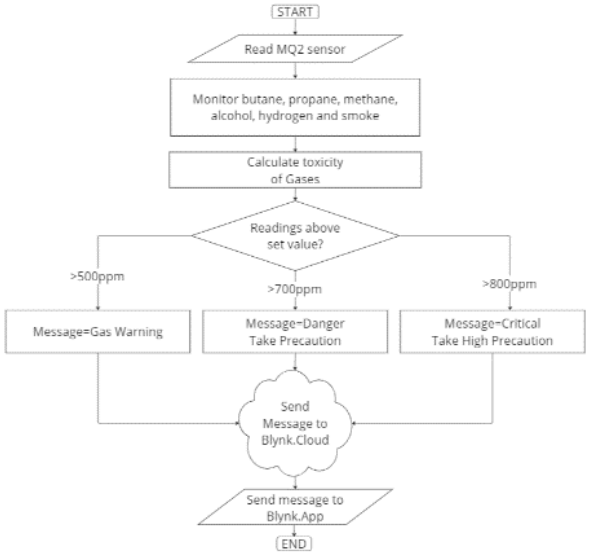

Fig. 8. Workflow of air quality monitoring system.

2) Temperature monitoring system: We are using the DHT11 sensor to monitor the temperature in the surrounding area. This sensor is connected to both the Raspberry Pi and the NodeMCU 8266 module. The workflow of this system is shown in detail in Fig. 9. Once the DHT11 Sensor starts, we obtain the temperature value in Celsius. Based on what temperatures the human body can bear or withstand, we have taken into consideration 35°C and 40°C as threshold values.

Based on the temperature threshold, the response message will help the rescue team to take appropriate safety measures. These appropriate response messages will be uploaded to the Blynk.Cloud from where the message is sent to the user's phone via the Blynk.App. These messages generated are sent to the rescue team and ground station to provide awareness about the situation in the disaster zone. Alerts are sent to the smartphone in several ways such as Blynk application as a popup alert, phone notification with the alert message and Sent as a mail to the recipient of choice with relevant information obtained from Blynk.Cloud.

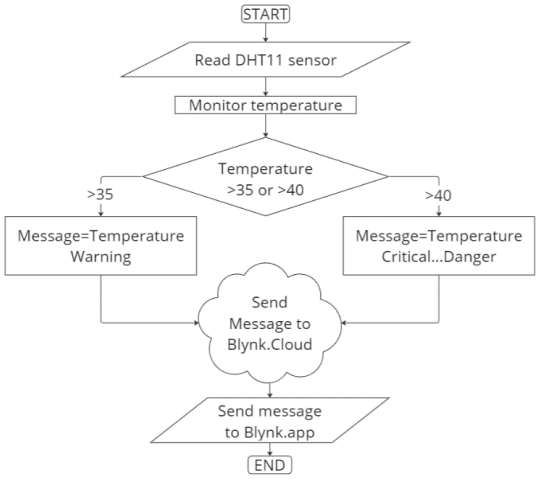

Fig. 9. Workflow of temperature monitoring system.

In real life scenarios, there are possibilities where there exists a high temperature environment where the content of smoke in the area might be less or even negligible, likewise, even the possibility of high smoke presence without the presence of fire as shown in Fig. 10.

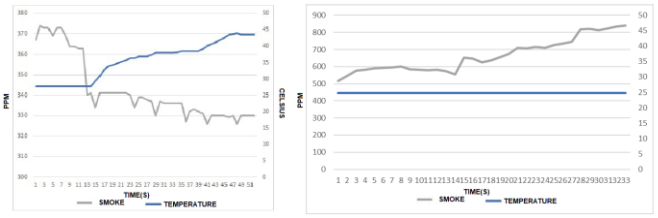

Fig. 10. Sensor readings for cases of high smoke / temperature.

Alerts are based on predefined safety values to ensure a safe and assessed environment as seen in Table I.

TABLE I. SPECIALIZED ALERT MESSAGES BASED ON ENVIRONMENTAL CONDITIONS

Parameter	Condition	Alert Message
Temperature	Temperature is greater than 30°C.	"Temp Over 30°C."
Temperature	If the temperature is greater than 45°C.	"Take Precaution!! Temp Over 45°C."
Gas Toxicity/Smoke	If greater than 500 ppm.	"Gas Conc Over 500 Ppm."
Gas Toxicity/Smoke	If greater than 700 ppm.	"Take Precaution!! Conc Over 700 Ppm."
Gas Toxicity/Smoke	If greater than 800 ppm.	"Condition Critical Gas Conc Over 800 Ppm."

III. HARDWARE SETUP

The various components required to establish the four systems have to be placed on the drone accordingly. The Fig. 11 shows how the Enhanced Human Identification system where the camera that is attached to the Raspberry Pi is placed in front of the drone such that we get the exact look at the Drone's view. The Active Obstacle Avoidance system consisting is placed on all four sides of the drone as seen in Fig. 11.

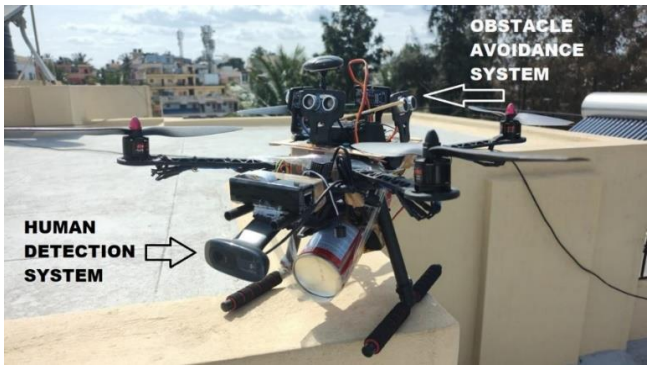

Fig. 11. Setup of the enhanced human identification system and the active obstacle avoidance system.

Fig. 12 shows the setup of the Fire Extinguishing system where the Fire extinguisher is placed under the drone and connected to a servo motor that presses on the spray when fire is detected.

Fig. 12. Setup of the fire extinguishing system.

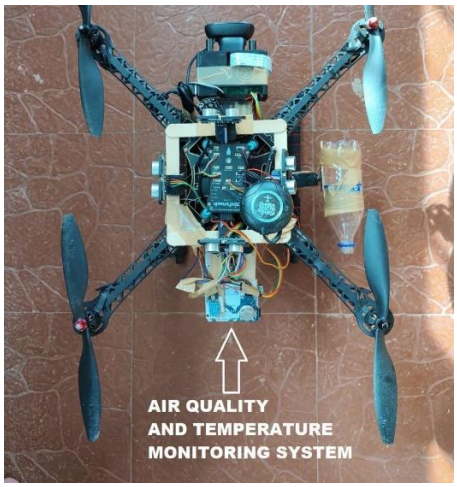

Fig. 13. Setup of the air quality and temperature monitoring system.

Lastly, Fig. 13 shows the setup of the MQ-2 sensor and DHT-11 sensors which are a part of the Air Quality and Temperature Monitoring system is attached over the drone's length such that the sensor readings are not affected by the heat generated by the components.

IV. RESULTS

The IoT-based autonomous drone has the true potential to revolutionize aid and relief in the field of disaster management. The drone's advanced capabilities to collect real-time data, analyze complex situations and facilitate well-informed decision-making can make a huge impact in the effectiveness of emergency response efforts, leading to an efficient method with increased safety measures to minimize the impact of disasters. To explain the working of our proposed solution, we have divided the following explanations into each of the dedicated systems of our proposed model which includes Enhanced Human Identification System, Fire Extinguishing System, Active Obstacle Avoidance System and Air-Quality and Temperature Monitoring System.

A. Enhanced Human Detection Identification System

1) Advanced face detection: The face detection system is used to keep track of the civilians encountered by the drone during its surveillance operation. This system works in real-time and continuously monitors the surroundings for humans. This happens as shown in Fig. 14. The Face Detection System uses Single Shot Detector Algorithm to detect trapped victims as seen in Fig. 14(a) and is stored into a dataset to keep track of the trapped victim as seen in Fig. 14(b). Once the victim is detected an alert message is sent to the rescue personnel to notify them of the trapped victim as seen in Fig. 14(c).

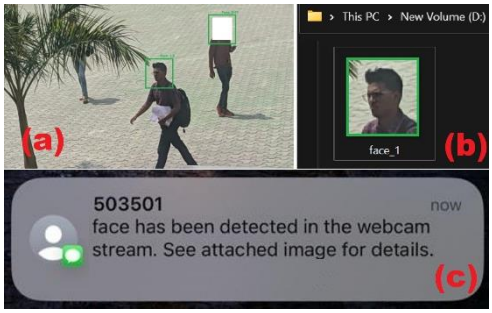

Fig. 14. (a): Detection of facial features in real time (b) Detected faces stored at dedicated location (c) Push notification alerts when face is detected.

2) EDSR x4 image enhancement: Once the image is stored in the database, by the Advanced Face Detection, it is enhanced to achieve a better resolution to identify the human easily. In Fig. 15(a), we can see the original image, and Fig. 15(b) shows the enhanced image using the EDSR Super-Resolution. It is evident that the enhanced image is more detailed and the facial features are brought up. Additionally, it has enhanced the 100 pixel x100 pixel image into a 400 pixel x 400 pixel image. This enhancement is done after its stored in the database because this process is resource intensive and therefore not viable to be a part before its stored in the database in the Advanced Face Detection System.

B. Fire Extinguishing System

This system utilizes a pre-trained cascade classifier-based fire detection system which can accurately detect the fire shown. Since we could not replicate large scale fires, we used images from online resources for testing purposes before deploying it on the drone. This image given as input can be seen in Fig. 16(a) and the camera's perspective of it is given in Fig. 16(b).

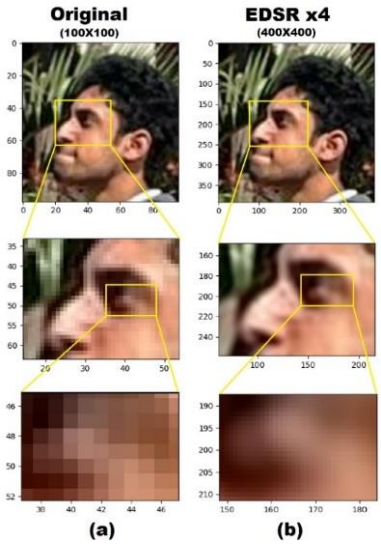

Fig. 15. (a): Original image from the database (b) EDSR x4 scaled image.

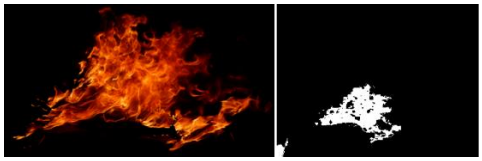

Fig. 16. (a) Sample fire used for testing fire detection (b) Camera's perspective of the fire.

The drone in on the ground as shown in Fig. 17(a), and it begins to take off and surveil in the defined areas. Once the drone encounters the fire region, it begins to extinguish the fire as shown in Fig. 17(b). We have been able to come up with an approach that effectively detects fire in the presence of high temperatures and smoke and tries to extinguish it. In our testing and evaluation phase, it was found that the system detected the fire with huge accuracy and precision.

Fig. 17. (a) Drone on ground with paper on fire in front (b) Drone extinguishing the fire.

C. Active Obstacle Avoidance System

Obstacle avoidance is an add-on feature to the autonomous maneuverings of the drone to ensure the drone does not collide with anything. The Arduino-Uno is used for this specific purpose, with it we have placed HC-SR04 ultrasonic sensors in all four directions of the drone to consider obstacles from any of the four sides. This system has multiple use cases, let us consider a civilian running away from disaster in a state of panic, and may not notice a drone in the field due to several reasons such as loud surroundings, too much smoke to look around, etc. Collision with the drone will cause injuries to the civilian which is against the objective of the drone's mission. Hence by using ultrasonic sensors, we overcome this problem. Another such use case can be the possibility of a building wall breaking down towards the drone where it must move away to protect itself. Hence, this system is programmed to consider all the obstacles at any given time and prioritizes the obstacle closer to the drone over the obstacle further away from it. Hence, we shall now consider these cases and understand the working of the active obstacle avoidance system. Hence, from the below cases considered it is observed that various combinations of sensor input are being given, the reaction of the drone is consistent and prioritizes the closer obstacle ensuring the safety of the objects surrounding it.

Case 1 - Obstacle in the Front and Back of the Drone.: There is an obstacle in the front and back of the drone. In this case, as we can see in Fig. 18(a), as the front distance increases the Pitch decreases and as the back distance increases the Pitch increases.

Case 2 - Obstacle in the Front and Right of the Drone: As we can clearly see from the graph below in Fig. 18(b), when there is an object in the front the pitch changes and the roll remain unchanged, while when there is an object detected in the left the pitch remains unchanged while the roll changes. Finally, when there is an obstacle detected both in the front and back the object changes both its pitch and roll which makes it move diagonally and the graph in Fig. 18(b) depicts the relationship between them.

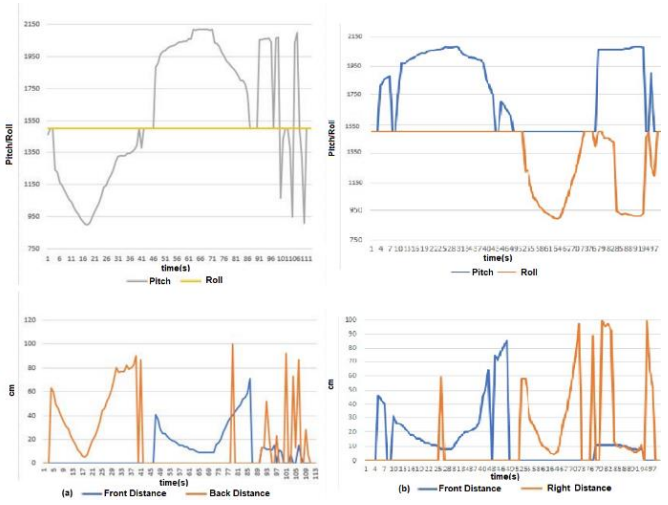

Fig. 18. Graph depicting the relation between Pitch, roll, and front and right distance for Case 1 (18 (a)), Case 2 (18 (b)).

Let us consider a situation as shown in Fig. 19(a) wherein the drone detects an obstacle with its FRONT SENSOR within the set range, now the drone has to move backwards and that can be achieved by increasing the Pitch of the drone as per the Eq. (3) as seen in Fig. 19(b).

D. Air Quality and Temperature Monitoring System

This system consists of sensors integrated with the drone to monitor the temperature, humidity and toxicity levels of the surrounding area to alert rescue personnel of the need to prepare themselves with high safety measures with the required precaution that can save their lives.

Fig. 19. (a): Obstacle introduced in front of the drone (b) Drone moving away from the introduced obstacle.

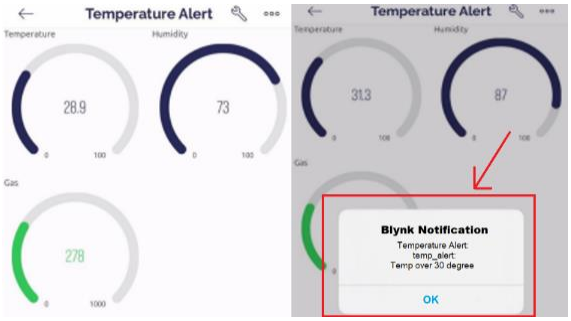

Fig. 20. (a): Live monitoring of sensor values on smartphone (b) Illustration of blynk.app alerting the user in case of high temperature.

The values read by the sensors are processed and shown in an easy minimalist way on the Blynk application for easy understanding by the user as seen in Fig. 20(a) which has gauges for temperature, humidity and gas. The depicted gas value is the combined toxicity of the composition of Butane, Methane, LPG, Smoke, Alcohol, Propane, and Hydrogen which is measured in ppm. If there is a spike in any of these levels, then the smartphone is alerted regarding the critical status based on the scenario in the following methods: Firstly, as seen in Fig. 20(b), the Blynk.App notifies the user with a popup alerting the user about the increased temperature conditions at the current location of the drone and similarly displays popups for unusually high gas toxicity. Secondly, As phone notification with the alert message. Fig. 21(a) shows the alerts for temperatures above 30 ℃. Similarly, notifications will be provided for higher temperatures as well. As seen in Fig. 21(b), the notification system ensures the user is alerted even when not using the Blynk application by providing a push notification feature which demonstrates the different notifications sent to the phone based on our tested gas toxic levels of 500ppm, 700ppm and 800ppm as per Table I and finally, Sent as a mail to the recipient of choice with relevant information.

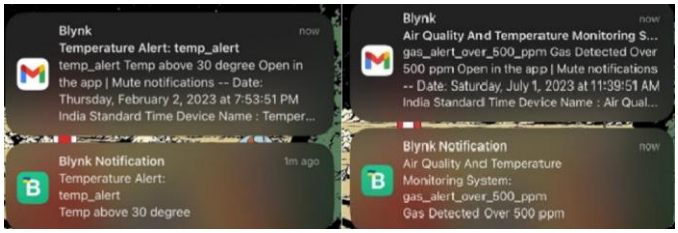

Fig. 21. (a): Blynk.app notification and mail sent to users for high-temperature.(b): Blynk.app notification and mail sent to users for high-toxic levels.

These alerts to the user are purely based on the readings from the sensors used. Hence, we are successfully able to accurately analyze the environmental situation using the onboard sensors and provide the rescue team with appropriate alert messages which will allow them to decide their approach to rescue. They can also opt to wear fire proximity suits in case of high temperatures, or chemical mask suits for protection against breathing toxic gases during the rescue. Due to a lack of testing with real toxic gases, we have set the temperature and gas threshold to ideal values to show output alerts. However, these values can be tuned as per real-life conditional levels easily.

V. Conclusion

In conclusion, the use of IoT-enabled drones for disaster management has enormous potential for enhancing the efficiency of emergency services during natural disasters and other emergencies. Rescue teams can quickly survey disaster-affected areas, find survivors, evaluate damage, and give first responders, on the ground real-time, situational awareness by utilizing these four systems namely Enhanced Human Identification System, Fire Extinguishing System, Active Obstacle Avoidance System and Air-Quality and Temperature Monitoring System. These systems provide added capabilities to these unmanned aerial vehicles solving major problems faced by rescue personnel. Emergency rescue personnel can use this knowledge to make wise decisions in saving the victims. With added Deep Learning model, the drone is more efficient in detecting human and fire, so that we can identify the trapped victims in disaster sites and extinguish dangerous fires, thereby creating an effective rescue process which ensures safety of victims and the rescue personnel involved.

VI. Future Work

Our current implementation of the method was designed with careful consideration of our economic constraints. The proposed solution adopts a cost-effective approach, employing a Raspberry Pi 3B as a companion computer and a basic Pixhawk 2.4.8 flight controller. However, the reliability of our obstacle avoidance system, utilizing the SR04 sensor, falls short of industrial standards due to its low resolution in distance input. Furthermore, the software approach employed for face detection, utilizing the Single Shot Detector, though faster, lacks accuracy. To enhance the overall efficiency of our methodologies, acquiring industry-standard components for drones is imperative. The following outlines the future scope of the project:

1) Incorporating a Nvidia Jetson Nano as a companion computer will enable us to integrate more sophisticated and resource-intensive algorithms, thereby enhancing computational capabilities.

2) The integration of thermal cameras is proposed as a more effective alternative to traditional cameras. Thermal cameras demonstrate improved capability in detecting humans through smoke, dust, and debris, making them invaluable in challenging environments.

3) Exploring more effective and lightweight alternatives to traditional fire extinguishing techniques is a potential avenue for improvement. This could involve adopting innovative approaches to firefighting that align with the latest industry standards.

By implementing these advancements, we anticipate a significant improvement in the overall efficiency and performance of our proposed methodologies for drone applications in various scenarios.

***Abstract*—Palm Vein Recognition (PVR) is a new biometric authentication technology that provides both security and convenience. This paper describes a contactless PVR system (CPVR) that uses an integrated learning approach (ILA) to recognise the palm veins from the given input images while ensuring user comfort and ease of use. Contactless palm vein scanning technology is used in the proposed system, eliminating the need for physical contact with the scanning device. The proposed method combines advanced feature extraction techniques with a light gradient boosting machine (LightGBM) and transfer learning. A pre-trained model, EfficientNetB1, is used to train the model to extract significant factors from the input PVR images. The proposed method improves user comfort and reduces the risk of cross-contamination in environments where hygiene is critical, such as hospitals, banking, and other secured places. The cutting-edge contactless palm vein scanner captures the unique vein patterns beneath the user's palm without requiring direct physical contact. The proposed ILA illuminates and captures vein patterns using near-infrared (NIR) light, ensuring high accuracy and robustness. The system employs advanced pre-processing techniques and enhanced image segmentation techniques to continuously improve recognition accuracy. It adjusts to changes in the user's vein patterns over time, considering factors like ageing and injuries. The ILA improves the system's ability to adjust palm positioning and lighting changes. The ILA is also a Contactless Palm Vein Recognition System with numerous applications, such as access control, secure authentication for financial transactions, healthcare record access, and more. The system is built to be scalable, allowing organisations to use it in various settings, ranging from small-scale installations to large enterprise-level deployments. Finally, the proposed approach ILA used to recognise accurate users increased the detection rate.**

Keywords*—Palm Vein Recognition (PVR); Light Gradient Boosting Machine (LightGBM); Transfer Learning; Integrated Learning Approach (ILA)

I. INTRODUCTION

A Contactless Palm Vein Recognition System (CPVR) is a form of biometric identification that identifies people based on the unique vein patterns in their palms. It is an intensely reliable and accurate authentication method that can be used for various applications such as access control, identity verification, and secure interactions. The system typically uses near-infrared (NIR) light to illuminate the palm's veins. Hemoglobin in the blood absorbs this light, creating a distinct pattern of dark lines (veins) against a brighter background. The reflected light is captured by a camera or sensor, which makes an image of the palm's vein pattern. Advanced algorithms are used to extract and encode the unique vein pattern as a biometric template from this image. Because it requires a living hand with blood flow to function, Palm Vein Recognition (PVR) is known for its accuracy and resistance to spoofing. There are several limitations over the 2D-PVR such as less authentication, mismatched results Etc. In CPVR the advanced technique that helps in providing the high security is full-view 3D finger vein verification technique [1]. This technique leverages the unique patterns of blood vessels within an individual's finger to verify their identity [2]. In biometrics and computer vision, learning significant and selective indicators for palm print feature extraction and identification is essential [3]. Palm print recognition is a biometric authentication technique that uses an individual's palm's unique patterns of lines, ridges, and wrinkles [4].

Collecting and organizing data from various sources, ensuring accuracy and diversity, and implementing a secure storage and access system are all part of creating an innovative multidimensional vein database with fingerprints from the palm dorsal and wrist [5]. CNNs are commonly used in computer vision tasks because they can learn hierarchical features from images automatically. Concatenation refers to the process of combining or stacking features learned at different layers of the network for further processing [6]. A semantic feature selector is a component that aids in the identification and selection of the most pertinent features from a concatenated set of features. This step is critical for reducing the dimensionality of the data and retaining only the most discriminative features for vein recognition [7]. The concatenated feature vector is subjected to a semantic feature selector or another machine learning algorithm. This selector aids in the identification of the most informative features while excluding less relevant ones [8]. It could employ techniques like feature importance scores or attention mechanisms. Based on the vein pattern, the system uses classification or similarity scores to authenticate or verify the individual's identity.

The auto-encoder is trained to reduce the reconstruction error between the input vein images and the decoder output. This procedure fine-tunes the encoder to extract relevant vein patterns while filtering out noise and irrelevant data [9]. To

learn a compact and meaningful representation of the vein images, a DenseNet-based auto-encoder is used. Because of their dense connections and feature reuse, DenseNet architectures have produced excellent results in image-processing tasks. The auto-encoder's encoder compresses the input images into a lower-dimensional latent space while preserving essential features. When an individual's identity is verified, their vein image is passed through the trained encoder, producing a feature vector. Then, between this feature vector and the feature vectors stored in the database, a similarity measure, such as cosine similarity or Euclidean distance, is computed [10]. The individual is verified as a legitimate user if the similarity score exceeds a predefined threshold.

II. Literature Survey

Cho et al. [11] introduced a novel approach that identifies the palm vein and the palm-print obtained from the given input image in NIR spectral bands. The proposed novel approach focused on extracting the features of palm-vein and palm-print that enhances the model using the LBP approach. The scores gained by identifying the proposed and noticed techniques have shown. Finally, the scores show that the proposed approach received better results based on the checking performance. Xi et al. [12] introduced the parallel NN approach integrated with the texture features applied to facial expressions—the proposed approach developed by using the CNN, RBN, and capsule network. The components were extracted using GLCM and combined with features belonging to actual images. The accuracy reaches 98.16%, which is more improved up to 3.71% compared with existing models. Finally, the proposed approach provides a better solution for image classification.Putro et al. [13] introduced the CNN-based face detector with a tiny architecture. The proposed approach contains two types of features, unique and multimodal facial features that help predict the multiple variations. The training mainly improves the outcomes by managing the loss and twitch on training configuration. The proposed approach solves the wider face detection issues by integrating the training features with the proposed method. Finally, the proposed system executes the 53 frames per second by processing high-resolution videos. Vu et al. [14] proposed the fast palm ROI extraction technique to tackle the complex issues. The proposed approach follows the contactless platform by using the free hand posture that finds the problems and increases the accuracy for ROI. Finally, the proposed method obtained high accuracy based on the extraction of palm ROI. Wu et al. [15] proposed a sophisticated denoisingResNet model, which combines the wavelet denoising (WD) and squeeze-and-excitation ResNet18 (SER) approaches. Skin noise and optical discoloration were removed from palm vein images using the WD method. The WD approach uses residual learning technology to improve the tiny-frequency feature into the DL feature. Finally, the suggested approach had been verified via a series of investigations. Sun et al. [16] introduced the plan view detection algorithm based on NPE and KELM. The proposed approach is integrated with preprocessing, feature extraction, and dimensionality reduction based on classification and recognition. Finally, the results show better performance compared with existing systems. Li et al. [17] introduced a novel prevention system called VeinGuard. The novel approach combines DL algorithms, designed using the local-GAN, which prevent adversarial palm-vein image attacks. This approach contains the input images from different attacks that show the malicious attacks and reduce the computation time. Finally, the proposed system offers better accuracy based on adversarial attacks. Qin et al. [18] introduced the SSPP called the PVI approach, which contains multi-stage and multi-direction AGAN. An advanced data augmentation is used to find the patches in one image. The proposed approach includes the total conv GAN layers that distribute the input in different directions and detect the PVI. The proposed shows the accuracy, which is high compared with existing approaches. Yang et al. [19] introduced the low-rank initialization that extracts significant data from finger vein images. Various image-based fluctuations weaken the correlation among the original pictures and destroy the low-rank initialization. Finally, training aids in redesigning the low-rank coefficient to improve finger vein recognition performance. Qin et al. [20] introduced the iterative DBN that helps extract the vein features from the label data, and it is dynamically generated by using limited time to modify the DBN. The proposed system is integrated with several steps, like segmentation of input images by identifying the pixels of the image. The redesigned training model is used to predict the chances of the existing approach. The proposed method achieved accurate hand-vein recognition, showing better accuracy.Yang et al. [21] proposed a novel FV-GAN approach that solves various issues, such as extracting the accurate FV patterns with low-contrast IR finger images with less awareness. DL models such as CNN and others show a massive response on detection FV, but due to the more significant number of layers and size of the finger image, it takes more processing time. CNN has the drawback of showing less feature initialization because of low-quality FV image that contains eccentric and vessel breaks. To overcome all these issues, a novel approach, FV-GAN, offers high performance in reducing processing time. Das et al. [22] proposed the CNN-based FV identification system that analyzes the functionalities of the developed network from four publicly available networks. The proposed approach aims to provide constant and high accuracy when implemented with various qualities. The evaluation results show that the proposed CNN model obtained a high accuracy above 95.1%, which is high compared with existing models. Pan et al. [23] proposed the advanced DCNN approach that helps detect the Multi-Scale Deep Representation Aggregation (MSDRA) model using a pre-trained model DCNN to see finger veins. The proposed approach combines various techniques, such as detecting the multi-stage features with classification using SVM. The proposed method uses two datasets for the evaluation of results. Finally, the MSDRA shows better accuracy based on finger vein recognition.Song et al. [24] introduced the CNN model that contains two methods: difference image and measuring the distance among the feature vector obtained from the CNN. The difference between images is vulnerable to noise, and differences in pixel values create them. The proposed approach solves the issues developed by DenseNet, which shows massive performance in

terms of accuracy. To address issues with massive noise, Shen et al. [25] introduced a lightweight CNN model for finger vein image recognition and matching, obtaining the ROI and finger vein pattern feature. The proposed system solves the problems identified based on the lack of accuracy and more computation time. The proposed system received 99.4% and 99.45% accuracy, which is better than existing models. Hou et al. [26] proposed a new loss technique that learns the inter-class and intra-class data simultaneously by using the CNN for finger vein verification. Finally, the proposed approach obtained the efficiency and effectiveness of the proposed method. Kuzu et al. [27] introduced advanced finger vein pattern detection that captures accurate patterns using the CNN. The dataset is from videos with different times from 101 subjects. The proposed approach obtained an accuracy of 99.34%, better than existing approaches. Huang et al. [28] proposed the observation technique called joint attention that enables vigorous adaptation and data accumulation to extract the fine-grained details, which improves the finger vein patterns to obtain the identity features. The dimensionality reduction removes the feature maps and outcomes with highly significant features. Finally, the proposed approach, JAFVNet, shows effective performance in terms of accuracy. Yang et al. [29] developed a new biometric security system based on finger vein biometrics. The proposed BDD-ML-ELM looks at safeguarding the initial finger-vein structure even if its altered revision is affected; ultimately, the BDD-ML-ELM enhanced attack detection reliability over the current techniques.Yang et al. [30] presented the FVRAS-Net, a significant CNN approach using an MTL model to achieve high security and real-time performance. Finally, the proposed method achieves accuracy in terms of Finger-Vein Recognition rate.

III. METHODOLOGY

This section explains the methodology of this paper. The proposed approach is an integrated approach that recognizes the palm vein by using integrated learning approach (ILA). ILA contains various methods that help in fine tune the results for better outcomes. A pre-trained model EfficientNetB1is used as training model as a first step. Second, various preprocessing or noise filter approaches are used to remove the noise from input images. A feature extraction method feature-level fusion combined with several methods obtains the accurate features from the palm vein dataset. Finally the transfer learning is used to combine with LightGBM gives the accurate output for the development of Contactless Palm Vein Recognition System (CPVR) which is shown in Fig. 1. Fig. 1 also represents the methods that are used in this work.

A. Pre-trained Model for Contactless Palm Vein Recognition System (CPVR)

EfficientNet is a DL-based pre-trained model released in 2019. EfficientNetB1 is a neural network architecture developed in 2019 by Google researchers. These architectures are known for being efficient in terms of computational resources and model size, making them suitable for a wide range of computer vision tasks. The EfficientNet family is based on a concept known as compound scaling, which involves simultaneously scaling the network's depth, width, and resolution. It allows for a balance between model capacity and computational cost. EfficientNetB1 is one of the models in this family, with fewer computational resources than more significant variants like B2, B3, and so on. To reduce computational complexity while maintaining representation power, it employs a variety of efficient building blocks, including depthwise separable convolutions. This paper employs the EfficientNetB1 as a pre-trained model and trains the Palm Vein using datasets such as polyu 2D images.

The following key factors of EfficientNetB1 are given below:

B. Width Scaling Factor (ϕ)

The width scaling factor, often denoted as phi (ϕ), determines the width of the network and affects the number of channels in each layer. It's typically chosen from a set of predefined values. For EfficientNetB1, ϕ is set to 1.0.

C. Depth Scaling Factor (α)

The depth scaling factor, alpha (α), determines the number of layers in the network. It's also chosen from a predefined set. For EfficientNetB1, alpha is set to 1.1.

D. Resolution Scaling Factor (Resolution)

The resolution scaling factor is used to adjust the input image resolution. Given that the base resolution is 224x224 for EfficientNetB1, you can calculate the new resolution using this formula:

$$\text{New Resoulution} = 224 * \text{resolution} \quad (1)$$

where "resolution" is a value greater than 1, which increases the input resolution, or less than 1, which decreases it.

E. Number of Layers (N)

In ever block the no of layers of EfficientNetB1 can be calculated using the depth scaling factor alpha (α) as follows:

$$N = 1.33^{\propto} \quad (2)$$

where$\propto$ represents exponentiation.

F. Number of Channels in Each Layer (C)

In ever block the no of layers of EfficientNetB1 can be calculated using the width scaling factor phi (ϕ) as follows:

$$C = 32 * \text{round}(\phi * 1.0) \quad (3)$$

G. Number of Blocks in Each Stage (S)

The number of blocks in each stage is a design choice, and for EfficientNetB1, it typically consists of 4, 6, or 8 blocks in each stage. This value can vary depending on specific implementations.

H. Preprocessing Technique

Preprocessing is a critical step in removing noise from input PVR images. Noise removal is an important step in image processing that improves image quality by removing unwanted artifacts or distortions caused by various sources of noise. To reduce noise in the palm vein image, median filtering is used. Uneven illumination or sensor artifacts can both cause noise. The median filter is effective at removing salt-and-pepper noise, which causes some pixels to randomly

change to maximum or minimum values. It replaces each pixel with the median value of a specified neighborhood. Another method for removing noise is the Wavelet transform, which divides an image into multiple scales and allows for separate processing of different frequency components. Wavelet denoising techniques use threshold to remove noise while preserving image features. The Gabor Filter is also used to enhances the texture features can highlight the vein patterns.

The median filter for every input is represented as:

I. Median Filter

Let $I(a, b)$ initializes the actual image.

Let $I_{filtered}(a, b)$ represents the final output image.

1) Operation of median filter

- The median filter operation is carried out by dragging a window of a given size (MN) across the entire image.
- The median filter calculates the pixel values within the window centered at (a, b) for each pixel in the input image at coordinates (a, b).
- The corresponding pixel in the output (filtered) image at the exact coordinates (a,b) is then assigned the median value.

2) Median calculation: Sort the pixel values in the window in ascending order and choose the middle value to find the median value in a pixel's neighborhood. If the window size is even, the average of the two central values will be used. The median calculation for a 33 is as follows:

$$I_{filtered}(a, b) = \text{median}(I(a-1)(b-1), I(a, b-1), I(x+1, y-1), I(a-1, b), I(a, b), I(a), I(b) \quad (4)$$

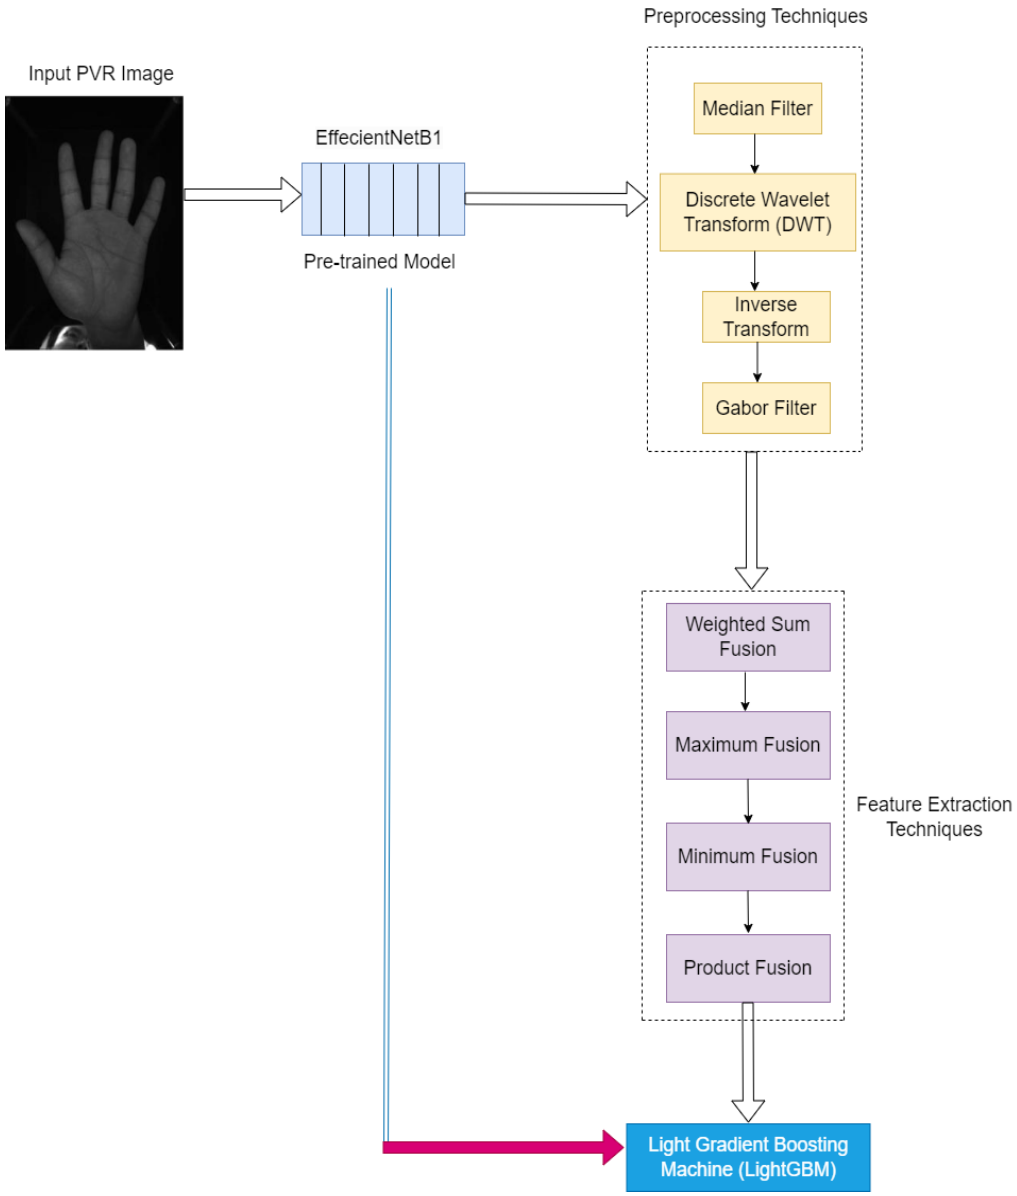

Fig. 1. Architecture diagram.

IV. DISCRETE WAVELET TRANSFORM (DWT)

The DWT is a mathematical technique for analyzing and decomposing two-dimensional images into various frequency components. A signal is divided into two parts in the DWT: approximation (low-frequency components) and detail (high-frequency components). A low-pass filter (LPF) and a high-pass filter (HPF) are used to achieve this decomposition. These filters are also known as analysis filters. The DWT equations are written as follows:

In the first step, the decomposition of input signals represented asx[n]:

Apply the LPF to achieve approximation coefficients (cX):

$$cX[j] = \sum_k x[k] * ho[k - 2j] \quad (5)$$

where, h0[k] is the impulse response of the LPF.

Apply the HPF to achieve the detail coefficients (cY):

$$cY[j] = \sum_k x[k] * h1[k - 2j] \quad (6)$$

where, h1[k] is the impulse response of the HPF.

Here, j represents the scale or level of the wavelet transform, and cX[j] and cY[j] are the estimation and specific coefficients at scale j, respectively.

A. Inverse Transform

The synthesis filters and formulas can reconstruct the actual signal from the estimation and specific coefficients. Synthesis filters are frequently the "dual" filters of analysis filters.

Apply the LPF to achieve approximation coefficients (cX) to get the approximation at the previous scale ($cX[j-1]$):

$$cX[j-1] = \sum_k cX[k] * g0[2(j-1) - k] \quad (7)$$

where,$g0[j]$is the impulse response of the syntheis LPF.

Apply the LPF to achieve approximation coefficients (cY) to get the approximation at the previous scale ($cY[j-1]$):

$$cY[j-1] = \sum_k cY[k] * g1[2(j-1) - k] \quad (8)$$

where,$1[k]$is the impulse response of the syntheis HPF.

Iteratively repeat these reconstruction steps, beginning with the finest scale (j = J) and ending with the coarsest scale (j = 1) until you obtain the reconstructed signal x[n].

B. Gabor Filter (GF)

It is one of the significant filters that used for tasks such as Palm Vein Recognition (PVR). These filters capture an image's texture and spatial frequency characteristics. Gabor filters can be used in Palm Vein Recognition to extract features unique to the palm veins. The equations and formulas for Gabor filters and their application in Palm Vein Recognition are as follows:

The 2D GF is defined as:

$$G(x, y; \lambda, \theta, \sigma, \gamma = \exp\left(-\frac{x'^2 + \gamma^2 y'^2}{2\sigma^2}\right) \cos\left(2\pi \frac{x'}{\lambda} + \theta\right) \quad (9)$$

where:

x and y are the coordinates of the pixel in the image.

$\lambda$is the wavelength of the sinusoidal component of the filter.

θRepresentsinclination of the GF.

σRepresents standard deviation.

$\gamma$is the spatial ratio, controlling the ellipticity of the filter.

$x' = x\cos(\theta) + y\sin(\theta)$and $y' = -x\sin(\theta) + y\cos(\theta)$ are the rotated coordinates.

C. Gabor Filter Bank:

A GF bank is created by varying the values of and capturing information at multiple scales and orientations. The filter responses for each parameter combination are computed for the input image.

V. FEATURE EXTRACTION TECHNIQUE FOR CPVR USING FEATURE-LEVEL FUSION

In Palm vein Recognition (PVR), feature-level fusion combines multiple palm vein features extracted from different sources or sensors to improve overall recognition accuracy. Various mathematical operations are used to achieve the fusion process. The following fusion methods used to extract the features from input images:

Weighted Sum Fusion: This method assigns weights to each feature source and combines them linearly.

$$\text{Fused Feature} = \sum(W_i * \text{Feature}_i) \quad (10)$$

Maximum Fusion: This method selects the maximum value for each feature dimension across all sources.

$$\text{FusedFeature}[j] = \max\left(\text{Feature}_{1[j]}, \text{Feature}_{2[j]}, \ldots, \text{Feature}_{N[j]}\right) \quad (11)$$

Minimum Fusion: Similar to Maximum Fusion, but it selects the minimum value for each feature dimension.

$$\text{FusedFeature}[j] = \min\left(\text{Feature}_{1[j]}, \text{Feature}_{2[j]}, \ldots, \text{Feature}_{N[j]}\right) \quad (12)$$

Product Fusion: This method multiplies the feature vectors element-wise from different sources.

$$\text{FusedFeature}[j] = \text{Feature}_{1[j]}, \text{Feature}_{2[j]}, \ldots, \text{Feature}_{N[j]} \quad (13)$$

where, N is the number of feature sources.

A. Light Gradient Boosting Machine (LightGBM) with Transfer Learning

LightGBM is a well-known gradient boosting framework that can be used for various machine learning tasks such as Palm Vein Recognition. LightGBM is a gradient-boosting framework that predicts using an ensemble of decision trees. It is intended to be fast, memory efficient, and scalable. In machine learning, transfer learning is typically defined as using knowledge gained from one task or dataset to improve performance on a related job or dataset. On the other hand, transfer learning is not commonly applied to gradient-boosting algorithms like LightGBM, which are primarily used for

tabular data and need a simple mechanism for incorporating knowledge from other domains or tasks. The following steps help to provide better outcomes for CPVR.

Step 1: Loss Function: For regression and classification tasks, LightGBM employs a variety of objective functions. During training, these functions are optimized.

$$\text{For Regression: } L(y, F) = \frac{1}{2} * \sum (y_i - F_i)^2 \quad (14)$$

Step 2: For binary classification, the logistic loss is commonly used

$$\text{For Regression: } L(y, p) = \sum \log\left(1 + e^{(-pi)}\right) + n\,(1 - y_i) * \log(1 + e^{pi})) \quad (15)$$

L is the loss function.

y is the true label.

F or p is the predicted output of the model.

Step 3: Gradient and Hessian Calculation

LightGBM computes the gradients and Hessians of the loss function concerning the predicted values. These gradients and Hessians determine the magnitude and direction of the model's parameter updates (trees). The gradients and Hessians are unique to the loss function.

Scalars function $f(x)$ where x is a vector of variables.

Gradient (∇f): The gradient of f is a vector that consists of partial derivatives of f with respect to every variable in x, it is initialized as $\frac{\partial f}{\partial x}$. Each component of the gradient is measured as follows:

$$\frac{\partial f}{\partial x_i} \quad (16)$$

where, x_i is the i-th variable in the vector x. Thus, the full gradient vector is:

$$\nabla f = \left[\frac{\partial f}{\partial x_1}, \frac{\partial f}{\partial x_2}, \ldots, \frac{\partial f}{\partial x_n}\right] \quad (17)$$

Hessian $(\nabla^2 f)$: The Hessian matrix is a matrix of squares containing the derivatives that are partial to f about each variable in x. It is denoted as $\frac{\partial^2 f}{\partial x^2}$. the elements of the Hessian matrix are computed as follows:

$$\frac{\partial^2 f}{\partial x_i \partial x_j} \quad (18)$$

where, x_i and x_j are variables in the vector x. So, the full Hessian matrix is an n×n matrix, where n is the number of variables, and its elements are computed for all combinations of i and j.

Step 4: Tree Building: LightGBM builds trees in a leaf-wise manner. The algorithm selects the leaf node that results in the maximum reduction in the loss function. The leaf-wise growth strategy is different from traditional depth-first or level-wise strategies used in other gradient boosting algorithms.

Step 5: Leaf Value Calculation: When a tree node is split, LightGBM calculates the value assigned to each leaf node. This calculation aims to optimize the loss function, taking into account the gradients and Hessians. The optimal leaf values are used to update the predictions.

Step 6: Shrinkage (Learning Rate): LightGBM typically uses a shrinkage parameter (learning rate) to control the step size of updates during the optimization process. This parameter prevents the model from making large adjustments in each iteration.

B. Dataset Description

The CASIA multi-spectral palm print image database was compiled from online sources and includes 3600 samples for training and 3600 samples for testing collected from 100 people [31]. Here six types of palm print images are shown in Fig. 2.

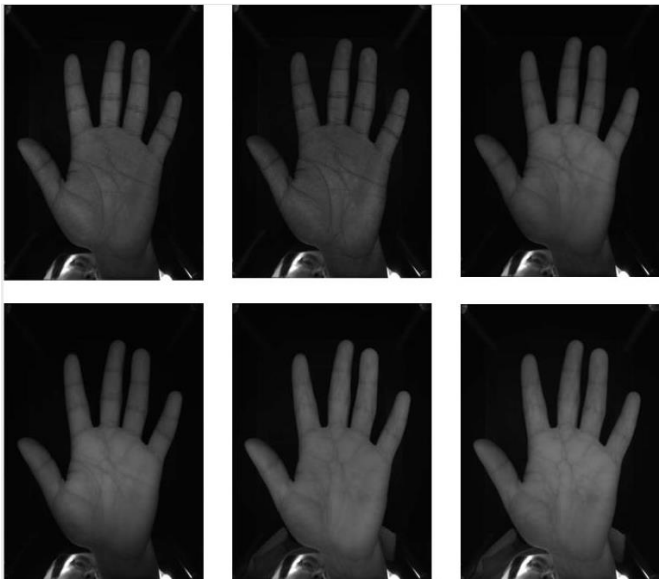

Fig. 2. Six types of palm vein images.

C. Performance Metrics

False Acceptance Rate (FAR): FAR calculates the likelihood of the system misidentifying an unauthorized user as authorized. A lower FAR denotes greater security.

$$\text{FAR} = \frac{\text{No of False Acceptances}}{\text{Total No of Identification Attempts}} \times 100\% \quad (19)$$

where:

"Number of False Acceptances" represents total no of incorrectly accepts an imposter.

"Total Number of Identification Attempts" is the total number of authentication or identification attempts, including both genuine and impostor attempts.

False Rejection Rate (FRR): The FRR calculates the likelihood of the system not accepting an authorized user. A lower FRR is preferable for user ease.

$$\text{FRR} = \frac{\text{No of False Rejections}}{\text{Total No of original Attempts}} \times 100\% \quad (20)$$

"Number of False Rejections" refers to the instances where the system incorrectly rejects a valid input or user.

"Total Number of Genuine Attempts" is the total number of times the system was presented with valid inputs or users.

Equal Error Rate (EER): The EER is a case where FAR and FRR are equivalent. Lower EER values suggest better system efficiency overall.

$$EER = \frac{(FAR+FRR)}{2} \quad (21)$$

D. Experimental Results

This section focused on evaluation results of the LightBGM with transfer learning of PVRC. Python is powerful programming language that provides the better libraries to implement the proposed algorithm. An advanced hardware requirements like 32 GB RAM and I7 processor is needed to the system to execute the large PVR image dataset. The performance of pre-trained models such as EfficientNetB1 compared with several pre-trained models achieved the better results. The training and testing loss of EffecientNetB1 is explained in Fig. 3 and Fig. 4.

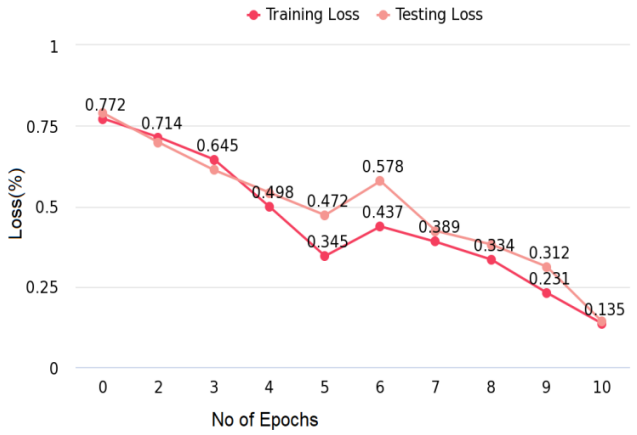

Fig. 3. The performance of EffecientNetB1 in terms of training and testing loss.

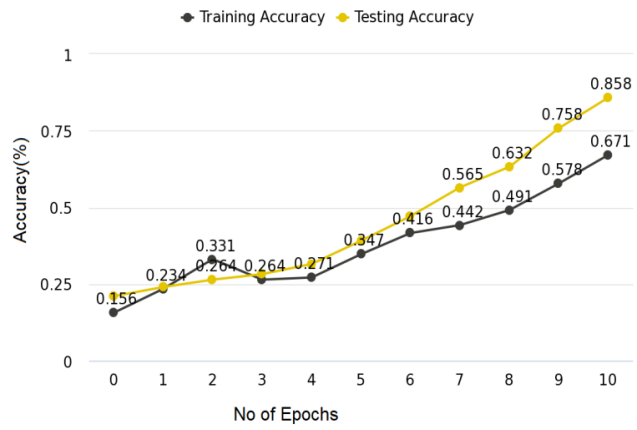

Fig. 4. The performance of EffecientNetB1 in terms of training and testing accuracy.

Fig. 3 shows the training and testing loss of EffecientB1 pre-trained model. Totally for 10 Epochs the loss is about 0.135% for 1st Epoch. There is Epoch iteration is starts from 10 Epoch to zeroEpoch. Here the training loss is low with 0.772% represents the lowest error rate. The training loss is about 0.743% which is low compare with testing loss and it prevents the over fitting. Fig. 4 shows the training and testing accuracy the training accuracy is about 0.671% and testing accuracy is about 0.858%.

Table I shows the comparative performance of various existing and proposed pre-trained models based on the FAR parameters. From the comparison it is shown that the proposed model shows the better outcomes compare with existing models. Table II shows the performance of several pre-trained models compared with the proposed model and obtained the outcomes based on the given parameter FRR. The FRR(%) shows very low compare with existing models that represents the better performance. Finally, these models help the proposed approach to show significant outcomes.

Table III shows the comparative outcomes of various pre-trained models for analyzing the performance in terms of ERR. Among all the models the proposed model shows the low error rate with high performance. Table IV shows the high performance in terms of all the parameters. Fig. 5 shows the overall performances of list of algorithms for CPVR.

VI. CONCLUSION

The Integrated Learning Approach (ILA) for CPVR was introduced in this paper as a promising advancement in biometric security technology. Palm Vein Recognition is inherently secure because it relies on an individual's palm's unique vascular patterns. Contactless systems, in particular, reduce contamination risk while improving user convenience. The ILA combines several algorithms and methods to improve the system's accuracy and reliability. It ensures the system can produce consistent results even in various environmental conditions. Contactless systems are user-friendly and non-intrusive because they do not require physical contact. It can boost user acceptance and make the system suitable for various applications. Palm Vein Recognition is generally fast, allowing for quick and efficient access control or authentication. ILA improves this speed even further by optimizing the recognition process. Finally, ILA holds great promise in enhancing security, accuracy, and user experience across various applications. Its combination of contactless technology and advanced algorithms makes it an appealing option for businesses looking for dependable and secure biometric authentication solutions. However, as with any technology, factors such as implementation, user education, and ongoing maintenance must be considered to maximize the benefits of such systems while ensuring user privacy and data protection.

***Abstract*—All human beings experience different levels of psychological stress during their daily activities, and stress is an integral part of human life. So far, few studies have attempted to identify different levels of stress by analyzing physiological signals. However, it should be noted that developing a practical system for detecting multiple stress levels is a challenging task, and no standard system has been developed for this purpose. Therefore, in the current study, we propose a new detection system based on linear and nonlinear analysis of photoplethysmogram (PPG) and electrodermal activity (EDA) signals to classify three levels of stress (low, medium and high). In the current study, we recorded the physiological signals of EDA and PPG during three trials of a Stroop color word test that induced three levels of stress in 42 healthy male volunteers. Mean, median, standard deviation, variance, skewness, kurtosis, minimum, maximum, and RMS features in the time domain were calculated from physiological signals as linear features. Also, approximate entropy, sample entropy, permutation entropy, Hurst exponent, Katz fractal dimension, Higuchi fractal dimension, Petrosian fractal dimension, detrended fluctuation analysis (DFA), and embedding dimension and time delay parameters from phase space reconstruction of the signals were calculated as nonlinear features. The combination of nonlinear and linear features extracted from both PPG and EDA signals resulted in the highest mean accuracy (88.36%), intraclass correlation (ICC) (98.82%) and F1 (89.24%) values in the classification of three levels of mental stress through multilayer perceptron neural network. Our findings showed that the combination of nonlinear and linear approaches for biological data analysis (PPG and EDA) could help to develop a stress detection system.**

Keywords*—Stress detection; biological signal; linear analysis; nonlinear analysis; classification

I. INTRODUCTION

All human beings experience different levels of psychological stress during their daily life activities, and stress is an integral part of human life. Stress refers to situations and feelings in which people perceive expectations to be beyond their capabilities [1]. In fact, stress can be defined as the mind or body's response to any need for change [2]. Human stress is controlled by the activation of the limbic system and the hypothalamus-pituitary-adrenal axis, which control the release of adrenaline and cortisol (stress hormones) in the bloodstream [3]. The circulation of these hormones in the human body through the bloodstream leads to different physiological variations. As a result, the heart rate begins to increase relative to the normal condition, increasing blood pumping to the muscles and various organs. Therefore, blood pressure and breathing rate increases [4]–[6]. In addition, adrenaline causes the release of stored fat and glucose into the bloodstream, preparing the body to respond to stress [7]. Furthermore, it has been shown that different areas of the human brain, such as the prefrontal cortex, play an important role in regulating various signs of the body during stress [8]. All this cumulative evidence shows that physiological systems and signals undergo changes during psychological stress.

On the other hand, it should be noted that excessive stress affects people's health. It has been introduced as a risk factor involved in the occurrence of major psychiatric diseases such as schizophrenia, depression and anxiety disorders [9]– [11]. Mental stress affects the ability for problem-solving, creativity, work memory and decision-making in humans. In addition, it can be a risk factor for various physical illnesses such as strokes, diabetes, and cardiovascular diseases [12], [13]. Therefore, determining the level of stress in different situations can help people to control it using stress reduction techniques and avoid the unpleasant consequences of excessive stress on health. Accordingly, in recent years, many pattern recognition methods have been developed to detect different emotions and their levels from biological signals [14]–[16]. Electroencephalogram (EEG), electrocardiogram (ECG), electromyogram (EMG), electrodermal activity (EDA), respiratory signal (RSP), blood volume pulse (BVP) and photoplethysmogram (PPG) are among the biological and physiological signals that have been computationally analyzed for this purpose. However, the main challenge in stress detection systems is the fact that each person is unique and shows emotions in different ways. This makes the topic of research hot. Although most studies on emotion recognition used ECG and EEG signals, we attempted to record and analyze PPG and EDA signals in the current study because they can be recorded via two-finger electrodes on the non-

dominant hand without compromising privacy and comfort. Moreover, some early studies demonstrated that PPG and EDA are good indicative tools to assess emotions.

II. Related Works

Paul Ekman was the first researcher who tried to recognize different emotions through physiological signal analysis [17]. Later, several researchers tried to continue his interesting path by analyzing different physiological signals. However, most studies focused on emotions like joy, fear, sadness, disgust, anger and surprise, and very few studies attempted to detect different levels of mental stress. Healey and Pickard induced three levels of stress (low, moderate, and high) during a driving task and analyzed ECG, EMG, RSP, and EDA signals recorded from healthy participants. They used linear frequency analysis and a linear discriminant analysis (LDA) classifier and reported a good accuracy of 97% for distinguishing three levels of human stress [18]. Shirvan et al. proposed a computational technique based on different linear and nonlinear analyses (including statistical analysis, fractal dimension analysis and detrended fluctuation analysis) of functional near-infrared spectroscopy (fNIRS) signals to detect low and high levels of stress. They used a feature selection method and support vector machine (SVM) classifier at both individual and group settings for stress levels classification and reported an accuracy of 88.72% in this regard [19]. Yannakakis and Hallam induced two levels of fun (low and high) in healthy participants through an interactive game and analyzed the recorded ECG, EDA and BVP signals by linear statistical analysis. They used SVM and Artificial Neural Networks (ANN) in the classification stage and reported 70% accuracy in recognizing two levels of fun [20]. Katsis et al. induced low stress, high stress, euphoria and disappointment in subjects through a driving task and analyzed the linear dynamics of the recorded ECG, EMG, EDA and RSP signals. In the classification stage, they used SVM and a neuro-fuzzy inference system and achieved 79.3% accuracy for the classification of the four states [21]. Valenza et al. induced multiple levels and valence and arousal in healthy volunteers through an international affective picture system and analyzed the nonlinear dynamics of the recorded ECG, EDA and RSP signals. In the classification stage, they used a quadratic discriminant classifier and achieved more than 90% accuracy in affective arousal and valence recognition [14].

As mentioned, few studies have attempted to identify different levels of stress by analyzing physiological signals. However, it should be noted that developing a practical system for detecting multiple stress levels is challenging, and no standard system has been developed for this purpose. Therefore, in the current study, we propose a new detection system based on linear and nonlinear analysis of PPG and EDA signals to classify three levels of stress (low, medium and high).

III. Materials and Methods

A total of 42 healthy male volunteers participated in the research with an average age of 26.31 ± 5.12 years. The research method was first explained to all participants, and informed consent was obtained from them before beginning the experiment. All subjects had a normal or normalized vision. A psychiatric interview was conducted by a psychiatrist to ensure the mental health of all participants to have no symptoms of major psychiatric disorders, cognitive problems, insomnia, anxiety, or social dysfunction. In addition, participants had no history of major physical illnesses, drug or alcohol abuse, and neurological disorders.

A. Stress Induction

In the current study, we utilized the Stroop color word test in a visual basic windows environment to induce three levels of stress in the participants. This test comprises three different experiments: preliminary experiment, congruent or non-conflict experiment, and non-congruent or conflict experiment. In the preliminary experiment, the color of the word appeared black. In the congruent experiment, the color of the work that appeared is similar relative to the color in the written word. In the non-congruent experiment, the color of the word appeared in different colors relative to the written word. Fig. 1 shows the Stroop color word test used in the current study for inducing stress. In each task and experiment, participants should indicate the color of the word. Each experiment lasted three minutes. In all experiments, each trial was displayed for three seconds, and participants were asked to respond to each trial using a mouse. Previous studies have shown that this test can reliably elicit three levels of stress in human subjects. Indeed, the preliminary experiment induces a low-stress level, the congruent experiment induces a medium stress level, and the non-congruent experiment induces a high-stress level [22], [23]. A 16-inch monitor was placed in front of participants at a 70-cm distance from them to perform the Stroop test.

B. Physiological Signal Acquisition

As mentioned, in the current study, we captured the EDA and PPG physiological signals during three experiments of the Stroop color word test. EDA indicates the variations in the electrical properties of the skin because of mentally induced sweat gland activities upon external stimuli. Skin resistance varies with the status of sweat glands in the skin. Sweating is controlled by the sympathetic nervous system, and thus, skin resistance is an indication of psychological arousal [24]. On the other hand, PPG is a simple optical non-invasive method to determine volumetric changes in blood in peripheral circulation that has been shown to be related to affective states [25].

In the current study, the Shimmer3 EDA+ module, along with an optical pulse sensor, was used for recording the EDA and PPG signals. This device is an extensible wireless sensor platform for recording sampled EDA data in real-time. The optical pulse sensor attached to this module also can record a PPG signal from a finger. This module digitized data at a 250 Hz sampling rate and streamed the data to a host PC in real-time. Two dry electrodes, along with the optical pulse probe, were attached to the fingers of subjects' non-dominant hands to record the EDA and PPG signals. The Shimmer3 module has shown to be an accurate and reliable wearable sensor platform for capturing physiological signals, which can be utilized for biomedical research applications [26].

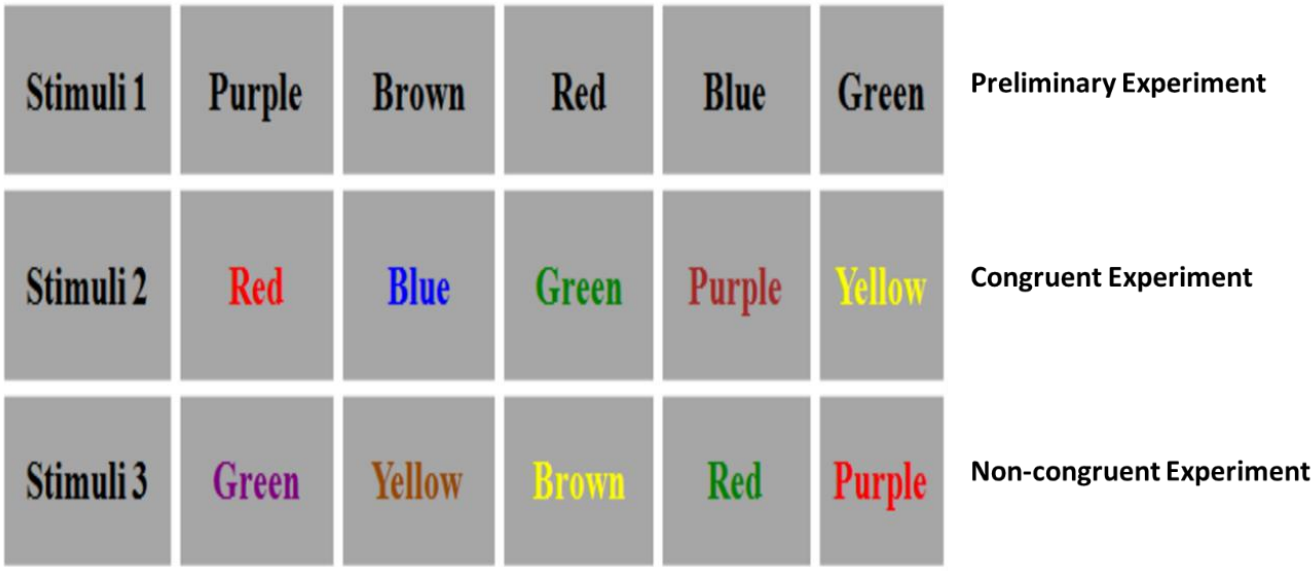

Fig. 1. The Stroop color word test was used in the current study to induce three levels of stress.

C. Linear and Nonlinear Analysis for Feature Extraction

The linear features extracted from EDA and PPG signals include mean, median, standard deviation, variance, skewness, kurtosis, minimum, maximum, and RMS in the time domain. These linear statistical features have a low computational cost which has been shown to be effective in various biomedical research applications. Mathematical definitions of these features and their details can be found in [27], [28]. On the other hand, the nonlinear features extracted from EDA and PPG signals include approximate entropy, sample entropy, permutation entropy, Hurst exponent, Katz fractal dimension, Higuchi fractal dimension, Petrosian fractal dimension, detrended fluctuation analysis (DFA), and embedding dimension and time delay parameters from phase space reconstruction of the signals (see Table I). Mathematical definitions of these features and their details can be found in [29], [30].

TABLE I. LIST OF LINEAR AND NONLINEAR FEATURES EXTRACTED FROM PPG AND EDA SIGNALS

Analysis	Extracted features from PPG and EDA signals
Linear	Mean, median, standard deviation, variance, skewness, kurtosis, minimum, maximum, RMS
Nonlinear	Approximate entropy, sample entropy, permutation entropy, Hurst exponent, Katz fractal dimension, Higuchi fractal dimension, Petrosian fractal dimension, detrended fluctuation analysis, embedding dimension, time delay

IV. RESULTS

Before feature extraction, we first applied a simple segmentation method to the recorded signals through a rectangular window with a length of 45 seconds. Considering the sampling frequency of 250 Hz, each segment contained 11250 data points. Also, each segment had a label to show the individual's stress level. All the above features were extracted from each segment, and the average values extracted for all segments with the same label were defined as the main feature in the classification step. Linear features were first extracted from PPG and EDA time series, and then, nonlinear features were estimated from the signals through the described nonlinear dynamic algorithms. Fig. 2 and Fig. 3 show examples of PPG and EDA signals recorded at three stress levels, respectively. Also, Fig. 4 depicts the histogram of time delays obtained from PPG and EDA signals.

In the classification stage, 70% of features were utilized to train a multilayer perceptron (MLP) neural network, 10% was utilized for model validation, and the remaining 20% was used to test the MLP. In the validation stage, the leave-one-subject-out approach was utilized to estimate the performance of MLP. We investigated different combinations of features and signals (i.e., EDA and PPG) to arrive at the optimal way to detect the stress level. In other words, we utilized various feature combinations for MLP modeling and assessed the classification results of each combination to obtain the best solution for this three-class classification problem. Assessment metrics utilized in the current study for evaluating different strategies were accuracy, intra-class correlation coefficient (ICC) and F1-measure.

Fig. 5 to Fig. 7 show mean classification accuracies, F1-measures and ICC values obtained for each feature combination by MLP classifier. As shown, the best accuracy of 79.5% was obtained by nonlinear features extracted from PPG signals. The best accuracy of 80.42% was obtained by combined features (i.e., linear and nonlinear features) extracted from EDA signals. In addition, the best accuracy of 88.36% was obtained by combining features extracted from PPG and EDA signals. Indeed, the combination of nonlinear and linear features extracted from both PPG and EDA signals resulted in the highest mean accuracy (88.36%), ICC (98.82%) and F1 (89.24%) values in the classification of three levels of mental stress.

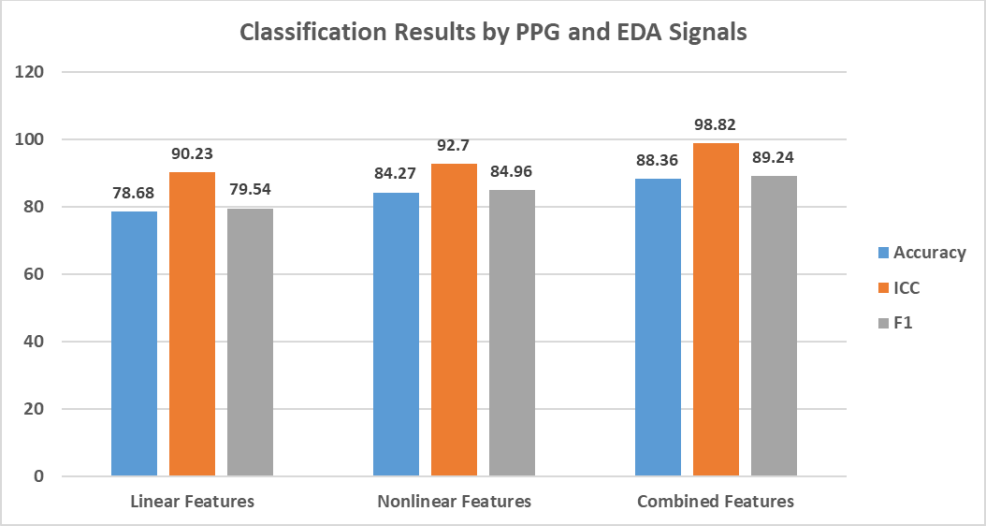

Fig. 7. Averaged classification results were obtained for different features extracted from PPG and EDA signals.

V. DISCUSSION

In the current study, we explored the possibility of detecting and classifying three levels of human stress (low, medium and high-stress levels) in 42 healthy people. Our findings showed that classification with linear and nonlinear features extracted from PPG and EDA signals is a good strategy for achieving an artificial intelligence-based automated system for detecting closed levels of human stress. Therefore, the nonlinear and linear dynamics of biological signals play a vital role in recognizing stress levels. This shows that the biological signals are not purely stochastic and random and follow a deterministic nonlinear behavior in response to different conditions. However, it should be noted that these results were obtained in laboratory conditions. All participants experienced a fixed setup with a noiseless environment, and different stress levels were induced through an executive cognitive task. However, this situation is totally different from real-life situations and the stress of everyday life, and this is the main limitation of this work. The use of wearable devices and virtual reality environments may alleviate this important limitation that future studies should consider.

Moreover, it should be noted that human stress may be unstable and temporary [31]. Therefore, it is very important to design a fast real-time system to detect stress levels in such situations. In addition, emotions and mental stress may be influenced by different physical and mental disorders. However, here, we only worked on healthy subjects. Consequently, our proposed system should be used with caution. On the other hand, our findings can be used in the field of psychiatry and psychology, and future studies should investigate the ability of our system to detect different levels of stress in psychiatric patients. Overall, our proposed automated stress detection system can be used in a wide range of settings to improve safety, health, and performance, including workplace safety, healthcare, education, sports, and transportation. For example, our stress detection system can be used in sports to monitor athletes' stress levels and provide feedback on how to manage stress during competition. This can help improve performance and reduce the risk of injury. Also, our stress detection system can be used in schools to monitor students' stress levels and provide support if necessary. This can help improve academic performance and reduce absenteeism.

Our proposed system showed good performance compared to previous studies. Healey and Picard proposed an automated system to distinguish three stress levels caused by a driving task through EMG, ECG, EDA and RSP signals and achieved an accuracy of 97% for this purpose [18]. However, the variety of biological signals in their work has led to a large increase in the cost of computations and the practical limitation of their proposed system. Zhai and Barreto reported an accuracy of 90% in distinguishing two stress levels using different biological signals and support vector machines [32]. This is despite the fact that we achieved the same accuracy as their work in our three-class problem. Furthermore, our proposed system outperformed the system introduced by Katsis et al., which achieved 79% accuracy in detecting three stress levels [21]. However, an important point that should be mentioned when comparing different systems is the lack of a comprehensive and public database for a more accurate evaluation and comparison of the systems proposed by researchers in this field.

VI. CONCLUSION

To sum up, we dealt with the crucial stages of an automated recognition system for three levels of human stress using biological signals of EDA and PPG, from signal recording to the classification step, and investigated the results from each stage of this system. Using the proposed system, we achieved a mean detection accuracy of 88%, which provides evidence to show autonomic nervous system differences among different stress levels. A range of biological features from linear and nonlinear analyzes was calculated to obtain the optimum stress-related features. Our findings showed that combining nonlinear and linear approaches for biological data analysis (PPG and EDA) could help develop a stress detection system. At the end, we call to action for a comprehensive, publicly accessible database of physiological signals to evaluate and compare stress detection systems rigorously.

***Abstract*—Urban environments are awash with myriad sounds, among which impulsive noises stand distinct due to their brief and often disruptive nature. As cities evolve and expand, the accurate classification and management of these impulsive sounds become paramount for urban planners, environmental scientists, and public health advocates. This paper introduces a novel framework leveraging the Bidirectional Long Short-Term Memory (BiLSTM) Network for the systematic categorization of impulsive urban sounds. Traditional methodologies often falter in recognizing the nuanced intricacies of such noises. In contrast, the presented BiLSTM-based approach adapts to the temporal variability intrinsic to these sounds, thereby enhancing classification accuracy. The research harnesses an expansive dataset, curated from various urban settings, to train and validate the model. Preliminary findings suggest that our BiLSTM framework outperforms existing models, with a marked increase in both specificity and sensitivity metrics. The outcome of this study holds profound implications for city acoustics management, noise pollution control, and urban health interventions. Moreover, the framework's adaptability paves the way for its application across diverse acoustic landscapes beyond the urban realm. Future endeavors should seek to further optimize the model by integrating more diverse soundscapes and addressing potential biases in data collection.**

I. Introduction

In the vibrant tapestry of urban life, sounds and noises play an integral role, shaping the auditory landscapes that city inhabitants navigate daily. The urban soundscape, a combination of ambient noises, human interactions, vehicular movements, and sudden, impulsive sounds, constitutes an integral aspect of urban living [1]. These sounds, particularly the impulsive varieties, serve as a double-edged sword [2]. On one hand, they contribute to the character and ambiance of a city, often evoking deep-seated memories and emotional responses among its residents. On the other hand, unchecked and discordant impulsive noises can deteriorate the quality of life, leading to stress, sleep disturbances, and even chronic health issues [3]. Consequently, the significance of identifying, classifying, and managing these sounds in urban spaces cannot be overstated.

While a plethora of research has focused on the broad soundscape of cities, the niche area of impulsive urban sounds has traditionally been underserved. Defined by their short, abrupt nature, these sounds—be it the honk of a car, the clang of a dropped tool, or the burst of fireworks—pose unique challenges to classification systems [4]. Traditional audio classification models, built primarily for longer and more consistent sounds, often struggle to capture the fleeting nuances of impulsive noises [5]. The rapid onset and offset of these sounds, combined with their varied frequency range, demand an approach that is both sensitive to temporal dynamics and adaptable to a broad acoustic spectrum.

Enter the realm of neural networks, which in recent years, has revolutionized the domain of sound classification. Among neural architectures, the Long Short-Term Memory (LSTM) network [6], a type of recurrent neural network, has shown promise in handling sequences and time-series data, making it a suitable contender for our auditory challenge. However, a unidirectional LSTM processes data in its input sequence order, potentially overlooking patterns that emerge from the reverse sequence of sounds [7]. Recognizing this limitation, and drawing inspiration from the bidirectional nature of human auditory processing where sounds are often understood in the context of both preceding and following sounds, this research innovatively employs the Bidirectional Long Short-Term Memory (BiLSTM) Network [8]. The BiLSTM, by virtue of processing an input sequence in both forward and backward directions, stands poised to capture the intricate patterns and characteristics intrinsic to impulsive urban sounds, offering a comprehensive understanding of their structure.

This paper, therefore, sets forth with a dual agenda. Firstly, it seeks to elucidate the significance and complexity of impulsive urban sounds, grounding its arguments in both auditory science and urban studies. Secondly, it embarks on a journey to explore the efficacy of the BiLSTM framework in classifying these sounds, aiming to bridge the gap between neural network research and urban acoustic management. In doing so, this research not only endeavors to advance the field

of auditory classification but also aspires to have a tangible impact on urban planning, noise pollution control measures, and public health interventions.

As we delve deeper into this exploration, it becomes imperative to understand the broader context within which urban sounds exist, the technological advancements in neural networks, and the potential applications of an effective classification system. Through this multi-faceted lens, this research hopes to offer a comprehensive view of the challenges and opportunities that lie at the intersection of urban acoustics and advanced neural architectures.

II. Related Works

Amid the bustling panorama of urban existence, the cacophony of sounds emerges not just as an incidental backdrop, but as an active participant shaping the dynamics of city life. The auditory fabric of urban centers is woven with diverse threads, ranging from the rhythmic footfalls on pavements to the occasional discordant blare of car horns [9]. Within this intricate web, impulsive urban sounds—transient, unexpected, and often sharp in nature—hold a unique place [10]. Their fleeting existence and unpredictable onset present both an auditory intrigue and a challenge that merit academic and scientific exploration.

As cityscapes continue to evolve, converging towards a future that's increasingly urbanized, the sonic environment they foster becomes an indispensable area of study. The implications of these sounds stretch across various dimensions: psychological, sociological, environmental, and even physiological [11]. For instance, while a distant church bell or a street performer's melody might evoke feelings of nostalgia or joy, the sudden screech of brakes or a loud explosion can trigger stress or anxiety [12]. The dichotomy of these reactions underscores the relevance of understanding and classifying urban sounds, especially those of an impulsive nature [13]. Given their impact on the well-being of city dwellers, mental health, and the broader urban experience, a systematic study becomes not just an academic endeavor but a societal imperative.

Historically, the academic arena has demonstrated a sustained interest in urban noises, resulting in extensive literature on the general soundscape of cities [14]. However, when it comes to the niche area of impulsive sounds, the scholarly attention seems somewhat disproportionate [15]. This relative dearth is surprising, given that impulsive noises, by virtue of their sudden onset and varied frequency profiles, pose unique challenges. Traditional auditory classification models, designed with an inclination towards consistent and prolonged sounds, falter when faced with the erratic nature of impulsive noises [16]. The fleeting presence and diverse acoustic characteristics of these sounds necessitate an approach that's not only nimble but also adept at capturing rapid temporal fluctuations [17].

Enter the world of advanced neural networks—a domain that has, in recent times, transformed numerous fields, including audio processing [18]. Among the neural architectures on offer, the Long Short-Term Memory (LSTM) network, a subtype of recurrent neural networks, has emerged as a front-runner for tasks involving sequence or time-series data [19]. Given its prowess in handling sequential data, LSTM offers a glimmer of hope for the impulsive sound conundrum. However, traditional LSTM, being unidirectional, processes sequences in the order they are presented, potentially missing out on valuable insights that could be gleaned from reverse order processing.

It's against this backdrop that this research introduces the Bidirectional Long Short-Term Memory (BiLSTM) [20] Network to the equation. Drawing parallels from human auditory processing, which inherently understands sounds based on both their preceding and succeeding context, the BiLSTM processes sequences bidirectionally—both forwards and backwards. This bidirectional approach promises a more holistic grasp of impulsive urban sounds, capturing nuances that might escape unidirectional models [21]. By processing sounds in this dual manner, the BiLSTM aspires to straddle the intricate patterns and temporal dynamics intrinsic to impulsive noises.

This paper embarks on a journey with twofold objectives. First, it aims to contextualize the importance and intricacies of impulsive urban sounds within the broader discourse of urban studies and auditory science [22]. It strives to illustrate why these sounds, often sidelined in scholarly pursuits, deserve focused attention. Second, the research delves into the technical and empirical exploration of the BiLSTM framework, investigating its potential as the much-needed solution to the challenges posed by impulsive sounds. Through this synthesis, the paper hopes to create a bridge—linking the often disparate worlds of neural network research and urban acoustic management.

As we venture further into this academic exploration, we're invited to reflect upon a myriad of interconnected themes: the transformative power of neural networks, the complex tapestry of urban soundscapes, and the potential societal ramifications of effective sound classification. Through this kaleidoscopic lens, this research endeavors to provide a comprehensive and nuanced perspective, setting the stage for groundbreaking revelations in the crossroads of urban acoustics and neural network technology.

III. Materials and Methods

In line with our initial conceptual framework, there is a two-fold requirement: first, to register the designated sound analysis apparatus, and second, to subject it to rigorous training [23]. This machine, once operational, deciphers the ingested auditory data, which can span a gamut of audio formats, a notable example being the mp3 format. Upon the reception of such an audio file, the machine subsequently crafts its associated spectrogram. A spectrogram, often interchangeably termed a sonogram (Fig. 1), is a graphical rendering that elucidates the relationship between the spectral density of a signal's power and its temporal progression [24]. Historically, spectrograms have found multifaceted applications across disciplines. They play a pivotal role in areas such as speech recognition, analysis of animal vocal patterns, diverse musical domains, radio and sonar technologies, linguistic signal processing, seismological research, and several other specialized fields.

A. Searching and Selecting Dataset

Each model training task requires a lot of input data, and the quality of our model will essentially depend on them. Therefore, the choice of dataset is an important part when building a model. Often the data also needs to be filtered or "cleaned up" in case some of the samples contain misrepresentations or false sounds for the class.

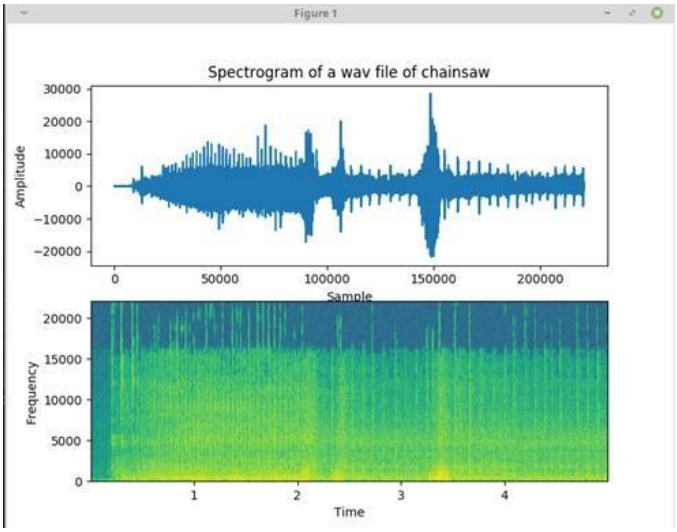

Fig. 1. Example of spectrogram of chainsaw.

We found two very interesting datasets, the first is the UrbanSounds-8K and second is UrbanAudioDataset. But firstly, let's see the first one.

UrbanSounds-8K. This dataset [25] contains about ~900 ".wav" sound files for each 10 classes such as:

- Air conditioners
- Car horns
- Children playing
- Dog barking
- Drilling
- Engine idling
- Gun shots
- Jackhammers
- Sirens
- Street music

Total 8732 audio files. This dataset, is pretty big (about 6,6 gigabytes) but as we know, the more data, the more we can train the model. That's why we believe that it will perfectly show the advantages and disadvantages of model preprocessing. And in the first part of our research we will use it.

Urban Audio Dataset. The second dataset [26] was collected from various resources and consist about 10000 samples for next eight classes:

- Crying
- Dog barking
- Emergency alarms
- Explosions
- Fire
- Glass breaking
- Screaming
- The sound of a weapon firing(gun shots)

However, the data in it requires normalization, since the data format is extremely different (with formats like: .mp3, .aiff, .flac, .wav, .m4a), also weights about 30 gigabytes! Therefore, we will use this dataset only after checking the main model. And this dataset is more suitable for our problem, since these sounds are more suitable for alerting danger. But again, we will talk about this dataset in more detail later in the next parts of the research.

B. Environment Selection

After the datasets, let's think about the hardware environment. Initially, the development was carried out on a virtual machine in the VirtualBox image on the Linux Mint system, which was sharpened for computer vision tasks, and in particular OpenCV. It fit the prototype, but due to the limitations of virtualization, it was decided to transfer the project to the main machine (host machine) on the Windows 10 operating system.

Now let's decide for the environment itself. Machine learning and deep learning in general are very widely used in the Python language due to ease of use, however, it is worth mentioning that for performance, you can try developing in C / C ++ if the issue of performance will play a key role. But we believe that Python 3.7 is enough for this task.

For analysis and research, we will use Jupyter Notebook. It is on it that we can write lines of code that we can interpret in different ways and thereby observe changes in individual cells of the program launch.

For the final part of development in production, we will be using PyCharm by JetBrains (Community Edition) and IntelliJ IDEA with Java Spring Framework for backend. But about interacting with application we will explain later in next parts.

C. Sound Processing

In this section, we will talk about the part about digital sounds. We decided that it was very important to fully understand how a computer can pick up sound, how we can work with it, and how to adapt it for classification. In this subsection, we will try to answer these questions.

Digital audio is the result of converting an analog audio signal into a digital audio format. There are a lot of audio formats at the moment, such as .ogg, .wav, .mp3, .flac and more. They differ in their storage and playback properties, but all alone cope with their task - they transmit an audio signal within a digital system. In our case, the sound will be displayed as a graph like in Fig. 2:

From which we can later obtain values after sampling when converting from an analog signal to digital. In other words, the digital sound that is already in the computer is already converted and we can work directly with it.

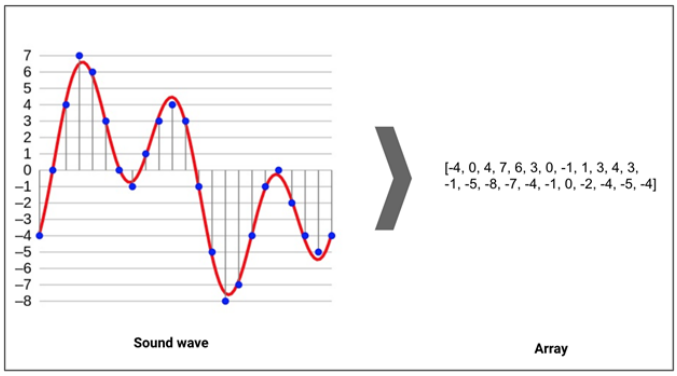

Fig. 2. Example of converting sound wave to array type.

D. Sound Analysis and Visualization

Audio has its own sound transmission channels, these channels called "Left-Right" output [27], in simple words, the output of the whole sound goes immediately to both the left ear and the right. This is called a mono channel. And the recording of such sound is carried out only from one input device, for example, a conventional microphone.

However, when we need to add more different kinds of sounds/effects, this is where stereo sound comes to us. Its fundamental difference lies in the fact that the received sound does not go to both Left-Right channels, but specifically to the Left and separately to the Right [28]. Thus, the sound in the channels acquires a certain volume in the sound. For a more comparative analysis, you can see their display in Fig. 3.

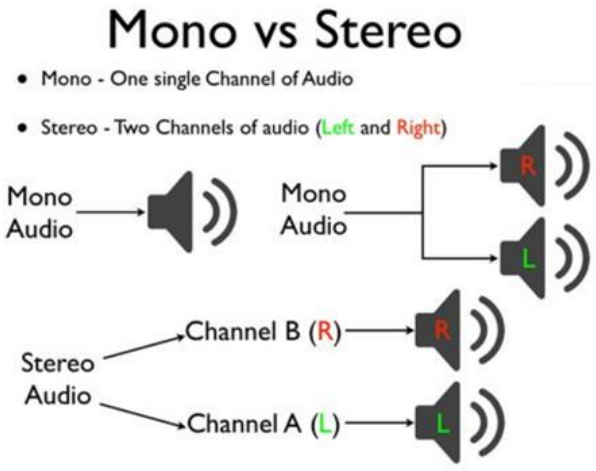

Fig. 3. Mono and stereo comparison.

And in order to see the difference for ourselves, we can take a different sound and compare their graphs, it is enough to display them through the Matplotlib library, which will allow us to do this [29]. To do this, we import and take another example with a mono channel for comparison, this will be a barking dog. Now let's display in Fig. 4:

In the graph, we can see that mono sound is displayed as one color, when the colors are displayed differently in stereo. Also, to check the channel, you can write a function that, using .shape, will show us a mono or stereo channel. This will especially help in the analysis of the second dataset.

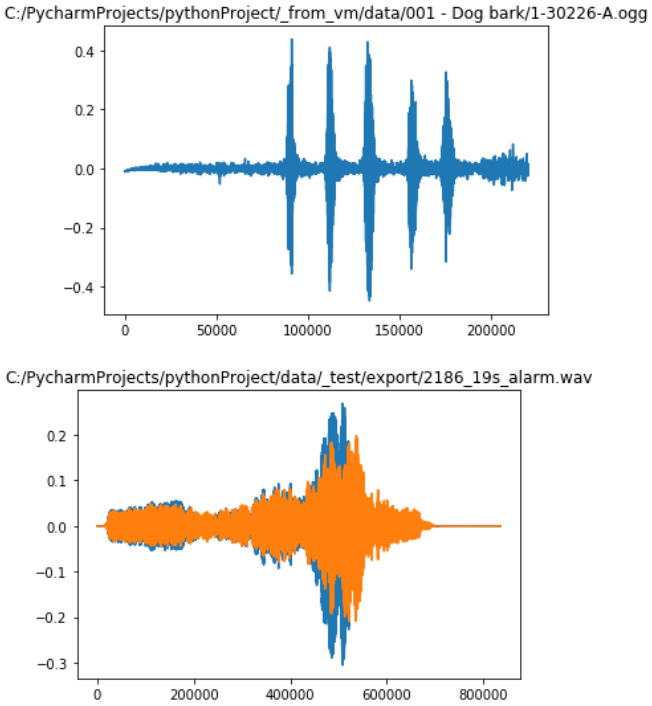

Fig. 4. Visualization of mono sound (upper), stereo sound (lower).

E. Proposed Model

There are deep learning techniques that can be applied in different areas as sound processing, images or video processing [30]. Urban environments, marked by their dynamic interactions and complexities, continuously emanate a diverse array of sounds, ranging from the benign murmurs of daily life to potentially dangerous noises that can indicate emergent situations or hazards [31]. Accurately discerning and classifying these dangerous sounds is not only paramount for the enhancement of urban safety but also imperative for proactive response mechanisms in smart cities. Traditional sound classification techniques often fall short in recognizing these transitory yet critical sounds due to their inherent limitations in capturing temporal relationships [32]. Enter the Bidirectional Long Short-Term Memory (BiLSTM) model, a sophisticated neural network architecture designed to navigate such challenges with unparalleled efficacy [33]. Fig. 5 demonstrates a flowchart of the proposed BiLSTM network for impulsive urban sound detection.

At its core, the Long Short-Term Memory (LSTM) is a form of Recurrent Neural Network (RNN) that addresses the vanishing gradient problem inherent in traditional RNNs. LSTMs are equipped with memory cells that can maintain information in memory for long periods, making them especially adept at tasks that require the understanding of long-term dependencies — a feature highly relevant to sound

sequences where past sounds can influence the characterization of present ones.

However, when dealing with dangerous urban sounds, which are often abrupt and embedded within larger, intricate auditory contexts, it becomes essential to understand the sound in relation to both its past and forthcoming sequences. This is where the bidirectional approach of the BiLSTM becomes invaluable. Instead of processing sequences in a unidirectional manner (from past to present), the BiLSTM simultaneously processes the data in both forward and backward directions. This bidirectional processing ensures that the model has access to information from both before and after a particular time step, enabling a more comprehensive understanding of the sound's context.

In the context of dangerous urban sound classification, this means that a sudden loud crash, which could signify a vehicular accident or a structural collapse, is not just evaluated based on preceding sounds, but also by the sounds that follow it. Such a dual-context perspective can be crucial in distinguishing between, say, a harmless crash in a construction site versus a car collision that requires immediate attention.

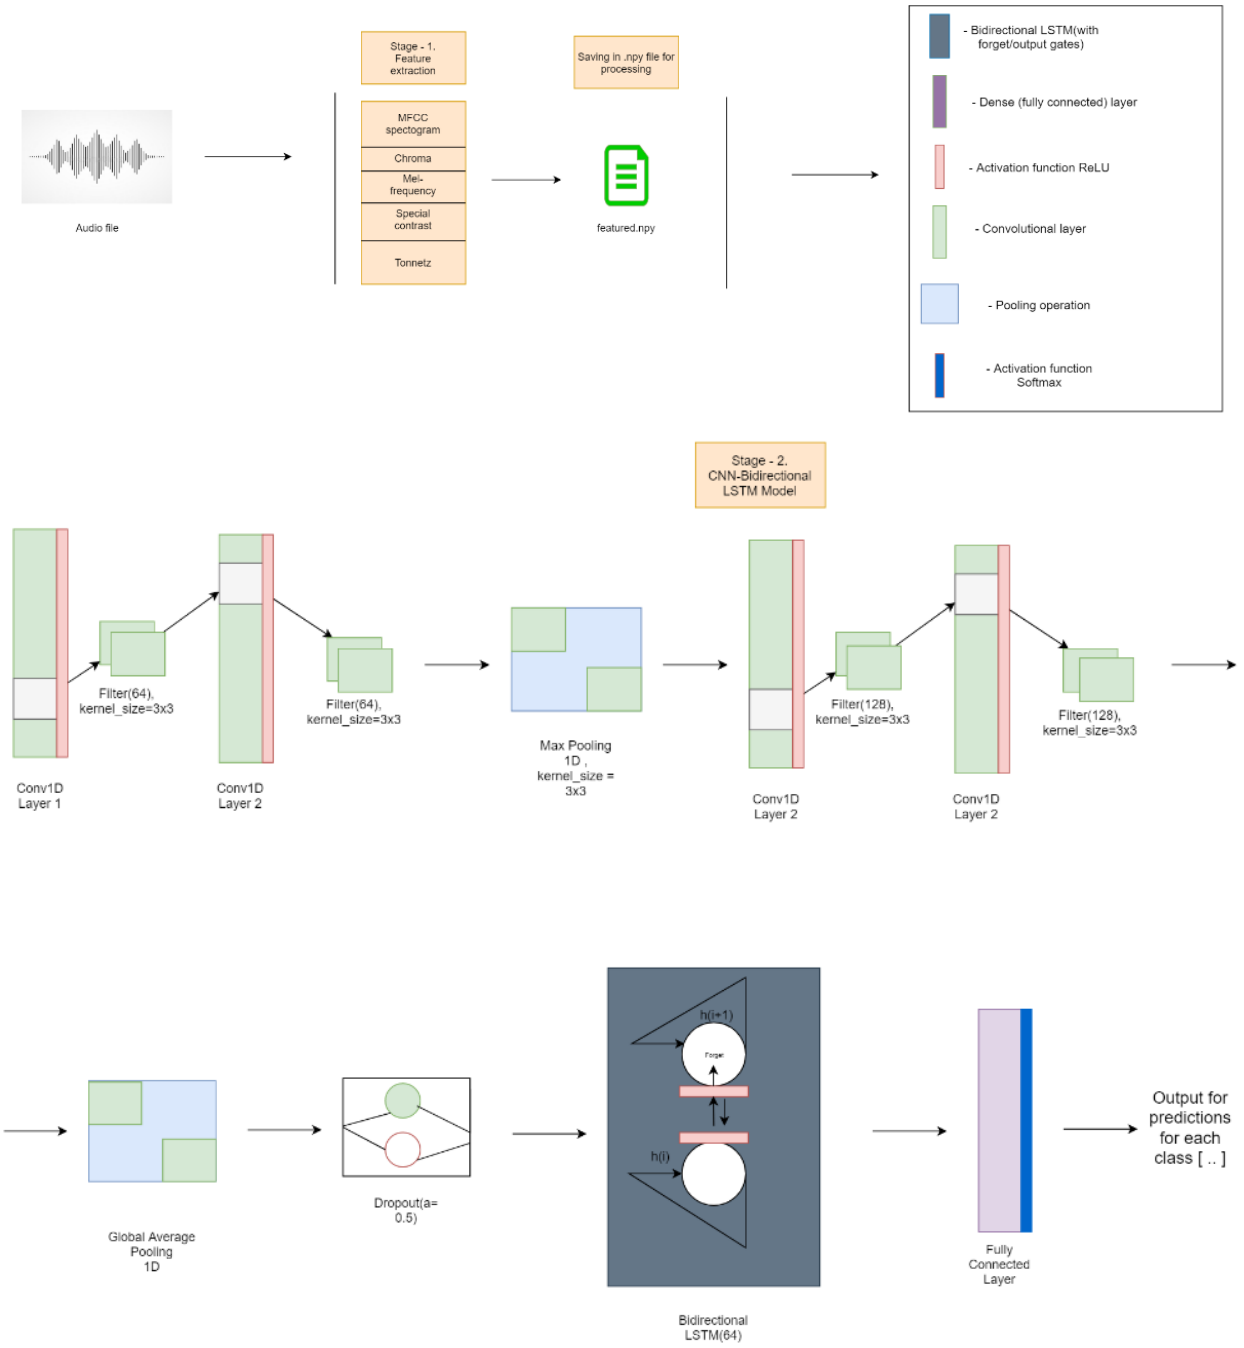

Fig. 5. Proposed Bidirectional LSTM network.

IV. Experimental Results

Furthermore, the inherent structure of the BiLSTM, with its memory gates, allows for meticulous filtering of sound data, ensuring that only relevant information is retained for classification. This selective retention is especially crucial for urban environments where the soundscape is cluttered, and the distinction between dangerous and non-dangerous sounds can be razor-thin.

A. Results of the Proposed Model

The proposed Bidirectional Long Short-Term Memory model offers a groundbreaking approach to dangerous urban sound classification. Its ability to capture intricate temporal relationships from both past and future contexts, coupled with its adeptness at managing long-term dependencies, positions the BiLSTM as a frontrunner in the ongoing quest for creating safer and smarter urban ecosystems. As urban centers across the globe grapple with the challenges of increasing density and complexity, such advanced neural network architectures emerge not just as academic curiosities, but as essential tools for ensuring the well-being and safety of their inhabitants.

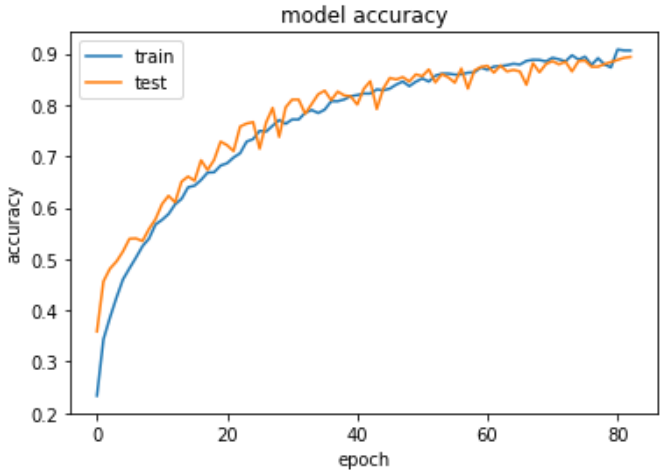

Fig. 6. Model training accuracy.

Further, this is a bidirectional LSTM network that immediately grows in parameters to as many as 352,330. This means that in theory there should be good results. The training time took about 871 seconds or about 14 minutes. Fig. 6 demonstrates the model training and test accuracy for 80 learning epochs.

Fig. 7 demonstrates model training loss in 80 learning epochs. The results show that, the proposed bidirectional LSTM network achieves to 90% accuracy, and 10% training loss, respectively.

Fig. 8 and Fig. 9 demonstrate test accuracy and test loss of the proposed model. Test results show that, the proposed model achieves 90% accuracy in model testing.

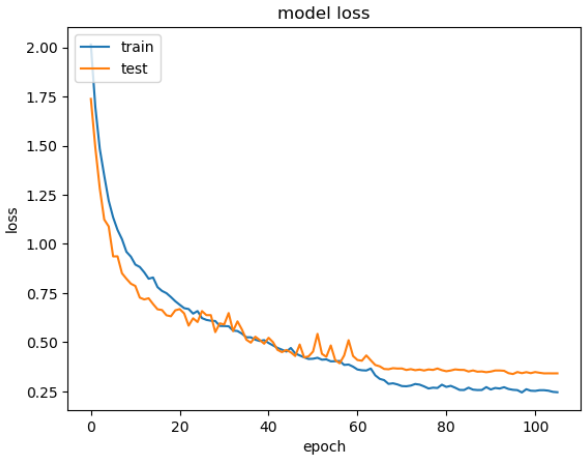

Fig. 9. Model test loss.

V. DISCUSSION

The intricacies and dynamics of urban environments demand a profound, nuanced understanding, especially when delving into the auditory spectrum of these landscapes. Our exploration into the Bidirectional Long Short-Term Memory (BiLSTM) model for classifying dangerous urban sounds opens an array of discussions, both in the realm of neural network architectures and urban acoustics.

One of the most compelling findings from this research is the marked superiority of the BiLSTM model in classifying impulsive, dangerous sounds as compared to traditional sound classification techniques. The bidirectional nature of the model, which processes sound sequences both in forward and reverse temporal orders, demonstrates an inherent advantage in capturing the context of impulsive noises [34]. By concurrently assessing preceding and subsequent sounds, the model offers a panoramic view of the auditory environment, a perspective pivotal in discerning potential dangers in bustling urban soundscapes.

However, while the BiLSTM demonstrates significant promise, it's essential to address its limitations. Training a BiLSTM model, particularly with expansive urban sound datasets, can be computationally demanding [35]. The simultaneous processing of forward and backward sequences necessitates robust computational resources, which may not be readily available in all application scenarios, especially in real-time urban monitoring systems [36]. As cities move toward the vision of smart urbanism, the real-time processing of data becomes crucial. Future research should, therefore, look into optimizing the BiLSTM structure without compromising its classification prowess.

Another aspect worth reflecting upon is the diversity of the urban soundscape dataset employed in this study [37]. While the dataset was expansive, it was primarily curated from a limited number of urban settings. Urban soundscapes can significantly vary based on factors like cultural practices, architectural designs, traffic patterns, and even weather conditions. For the BiLSTM model to be universally applicable, it's imperative to train it with a more globally representative dataset, encompassing the myriad variations of urban environments. This would enhance the model's adaptability, ensuring its efficacy across diverse urban landscapes.

Furthermore, the human auditory system, despite its biological limitations, possesses a remarkable ability to discern sounds based on learned experiences and cultural contexts [38]. The sudden clang of pots in one culture might be dismissed as a benign household activity, while in another, it could be an alert for danger. Incorporating such cultural nuances and learned experiences into the BiLSTM model presents a challenge and an opportunity. The integration of these elements might enhance the model's sensitivity to context-specific dangerous sounds, making it even more aligned with human auditory perception.

Lastly, the ethical considerations of continuous urban sound monitoring need to be highlighted. While the primary intent is safety and rapid response to dangerous situations, the omnipresent nature of sound monitoring systems can raise concerns related to privacy and surveillance. It becomes imperative for urban planners and policymakers to strike a balance, ensuring that the pursuit of safety doesn't infringe upon the privacy rights of city inhabitants.

In summation, this research underscores the transformative potential of the BiLSTM model in the realm of dangerous urban sound classification. The model's bidirectional processing, its adeptness at capturing temporal nuances, and its alignment with the holistic human perception of sounds make it an invaluable tool in the urban auditory toolkit. However, like all pioneering endeavors, this study raises as many questions as it seeks to answer. The computational demands of the model, the need for a more globally diverse dataset, the integration of cultural nuances, and the overarching ethical considerations form a rich tapestry of challenges and opportunities for future research.

As urban centers continue to burgeon and evolve, the imperative to understand, manage, and respond to their auditory landscapes becomes even more pronounced. The Bidirectional Long Short-Term Memory model, with its blend of technological sophistication and auditory acumen, emerges as a beacon in this journey, illuminating the path toward safer, smarter, and more responsive urban ecosystems. This research, albeit a single step, paves the way for a future where cities don't just listen but truly understand.

VI. CONCLUSION

In an era where urban expanses are rapidly growing, manifesting themselves as the epicenters of human civilization, understanding the multifaceted dimensions of these environments is imperative. The auditory realm of cities, teeming with a symphony of sounds both benign and dangerous, necessitates an analytical lens equipped with both precision and depth. This research, centered on the Bidirectional Long Short-Term Memory (BiLSTM) model, underscores this very sentiment, offering a pioneering approach to the classification of dangerous urban sounds.

Our exploration into the BiLSTM model has illuminated its profound potential. By processing sound sequences in both forward and reverse temporal frames, the model imitates the holistic human perception of sounds, transcending the limitations of traditional classification techniques. This bidirectional prowess not only captures the intricate nuances of dangerous sounds but also provides a broader context, pivotal for accurate classification in bustling urban settings.

However, as is characteristic of any academic endeavor, this study also opens avenues for further exploration. While the BiLSTM model is undeniably potent, its computational demands, adaptability across diverse urban landscapes, and the integration of cultural and learned auditory nuances present challenges warranting future research. Moreover, the ethical dimensions of continuous urban sound monitoring, with potential implications for privacy and surveillance, underscore the need for a balanced approach, harmonizing safety with individual rights.

In conclusion, this research signifies a seminal step in the realm of urban sound classification. The BiLSTM model

emerges not merely as a technological marvel but as a testament to the convergence of neural network architectures and urban auditory science. As cities continue their inexorable march towards the future, tools like the BiLSTM will play a pivotal role, ensuring that these urban giants are not just expanses of concrete and steel, but responsive, adaptive, and safe ecosystems for all their inhabitants.

ACKNOWLEDGMENT

This work was supported by the research project — Development of a system for detecting and alerting dangerous events based on the audio analysis and machine learning funded by the Ministry of Science and Higher Education of the Republic of Kazakhstan. Grant No. IRN AP19175674.

Research on Evaluation Method of Urban Human Settlement Environment Quality Based on Back Propagation Neural Network

Siyuan Zhang[1], Wenbo Song[2]
Jilin University of Architecture and Technology, Changchun, 130114, China[1]
Jilin Provincial Defense Mobilization Office, Changchun, 130051, China[2]

***Abstract*—In order to improve people's living experience, a method for evaluating the quality of urban human settlements based on back propagation neural network is proposed. Firstly, the initial evaluation index system is constructed, the initial evaluation index system is screened, and the final evaluation index system is constructed by using the remaining evaluation indexes. Then, the back propagation neural network is constructed to build an evaluation model, and the evaluation model is trained through the processes of network initialization, hidden layer output calculation and output layer output calculation. Finally, the improved genetic algorithm is used to optimize the back propagation neural network, improve the evaluation performance of the back propagation neural network, and realize the evaluation of human settlements quality. The experimental results show that the accuracy of the evaluation results of urban human settlements quality output by the trained back-propagation neural network model reaches 96.3%, which has a good effect.**

***Keywords*—Back propagation; neural network; urban human settlements; quality evaluation; morbidity index; genetic algorithm**

I. INTRODUCTION

The quality of the human settlement environment has consistently been a fundamental concern in urban research, as it directly impacts human well-being and urban development [1]. With the rapid growth of the global population in the 20th century, the degradation of the ecological environment resulting from industrial development has contributed to the widening regional disparities, and global scholars are increasingly concerned about the sustainable development of human settlements. The urban human settlement environment is a comprehensive regional concept. This refers to the dynamic interaction between the natural environment and human activities [2] and includes all fields of humanity, geography, economy and environment. It is the activity area of urban residents. Theoretically, the meaning of an urban residential environment should be the harmony between man and nature, the unity of material and spirit [3]. However, in civil engineering and geography, they have their own emphasis. In civil engineering, they tend to regard the urban residential environment as a small-scale operation object, which is more reflected in the study of urban architectural planning. In geography, the urban human settlement environment is more regarded as a large-scale geoinformation system [4], and urban structure is more discussed. Assessing urban human settlements holds great significance in terms of the survival and development of the population [5], as it offers essential parameters for the transformation of urban industrial structure and the optimization of human settlements.

Staats et al. [6], in the process of studying the environmental quality evaluation method, the number of parked cars and the number of street trees were taken as the evaluation criteria, and the former was divided into four levels: from no car to full capacity, and the latter was divided into three levels: from no tree to 50% density. The evaluation model is constructed using the neural network in the artificial intelligence method; the evaluation of environmental quality is achieved by analyzing two evaluation indicators. When utilizing this method, it has been observed that the neural network exhibits limited global search capability, making it susceptible to extreme local values and slow convergence. These factors consequently impact the computational efficiency and prediction accuracy of the neural network. Fomina et al. [7] analyzed the key factors and standards that have a significant impact on the quality of the living environment of the population in their research on urban environmental quality assessment methods and considered that ecological environment, urban planning, landscape and social factors are the main evaluation indicators, each set of factors are calculated quantitatively (based on a set of standards and indicators), at the same time, the category coefficient obtained according to the expert survey results is considered in the calculation process. In the application process of this method, some indicators have a weak impact on the evaluation results, which is only because the evaluators empirically think that these indicators are important, while subjective experience may not be objective and reliable, which leads to deviation in the final evaluation results. Longhini et al. [8], in the process of studying the environmental quality evaluation method, the evaluation index for the study is selected using the geochemical multi-index method, and the constructed evaluation model is used to achieve the purpose of environmental quality evaluation. Different indicators must be weighted according to the actual situation. In the process of using this method, the qualitative analysis method is used to obtain the evaluation results, which inevitably leads to a one-sided evaluation and cannot reflect the real situation. Sarkheil et al. [9] employed the fuzzy comprehensive evaluation method to construct the evaluation model. The research area selected for evaluating the environmental quality was the Pass economic energy Zone. It is worth noting that during the

implementation of this method, there was a significant correlation observed among the evaluation indicators utilized; that is, the degree of information overlap between the indicators may be high. If this overlapping information is not processed, it will be emphasized repeatedly in the comprehensive evaluation, thus distorting the comprehensive evaluation results.

Although the above research has made some progress, there are still problems, such as the index system is not scientific and comprehensive, the differences in index selection and weight distribution in evaluation methods, and the lack of unified standards and systems. Therefore, this article studies the evaluation method of urban residential environment quality based on the back-propagation neural network and applies the back-propagation neural network to the evaluation process of urban residential environment quality. The significance of evaluating the quality of urban human settlements lies in evaluating and improving the living environment conditions of residents, providing scientific basis for urban planning, construction and management, and promoting the sustainable development of cities. By evaluating the quality of human settlements, the health of residents can be guaranteed, the influence of harmful factors on human body can be reduced and the quality of life can be improved. The evaluation results can also reveal the advantages and disadvantages of the city, provide decision-making basis for urban planning and construction, and promote the comprehensive development of the city. Evaluating and improving the quality of human settlements can enhance residents' happiness and satisfaction, and increase social stability and social harmony. Therefore, the quality evaluation of urban human settlements is of great significance to both cities and residents. Through the study of this method, it provides a reference for quantifying the quality of urban residential environments and monitoring the livability of cities. The overall structure of the article is as follows:

1) Build the initial evaluation index system, screen the initial evaluation index system, and use the remaining evaluation indexes to build the final evaluation index system.

2) Then, a back propagation neural network is constructed to build an evaluation model, and the evaluation model is trained through network initialization, hidden layer output calculation and output layer output calculation.

3) Using the improved genetic algorithm to optimize the back propagation neural network, improve the evaluation performance of the back propagation neural network, and realize the quality evaluation of human settlements.

II. Quality Assessment of Urban Human Settlements

A. Selection of Evaluation Indicators Based on Pathological Index Cycle Analysis

There are many factors that affect the quality of urban human settlements, and these factors can be used as evaluation indicators of urban human settlements. However, these evaluation indicators are not only different from each other but also closely related. To accurately evaluate the quality of urban human settlements, it is necessary to choose suitable evaluation indicators to build a highly scientific, highly operational, qualitative and quantitative evaluation indicator system. These indicators were selected based on expert opinions and research findings from scholars in relevant fields. Among them, experts' opinions and researchers in related fields play an important role in the quality evaluation of urban human settlements. Experts and researchers in related fields can provide valuable opinions and suggestions to help determine the importance and applicability of evaluation indicators based on in-depth research on urban environment and accumulation of professional knowledge. When selecting the evaluation index of urban human settlements quality, expert opinions can be obtained through expert consultation, expert interview and expert evaluation. The experience and professional knowledge of experts and researchers in related fields are helpful to determine the evaluation index with high authority and credibility. They can evaluate different environmental factors, human settlement needs and socio-economic factors based on their understanding of environmental disciplines and related fields, so as to determine the appropriateness and importance of evaluation indicators.

Considering the potential presence of duplicate evaluation indicators in the initial system for assessing the environmental quality of urban human settlements, where there may be overlapping information among the indicators, it becomes necessary to employ the pathological index cycle analysis method to screen and refine the evaluation indicators in the system.

In order to prevent redundant evaluation indicators from being retained in the selection process of evaluation indicators, a set of urban human settlements environmental quality evaluation indicators $X_1, X_2, \cdots, X_n$, all are the remaining evaluation indicators after removing the indicators with poor criticality. The specific process of screening environmental qualitative assessment of people's urban habitation indicators on the basis of the pathological indicator cycle analysis is as follows:

1) Determine the matrix with Formula (1) X^T characteristic value of $\phi_1, \phi_2, \cdots, \phi_n$:

$$|X^T - \phi_i \times D_n| = 0 \tag{1}$$

In Formula (1) X^T and D_n respectively represent the sample data matrix corresponding to the urban human settlements environmental quality evaluation indicator set transpose matrix and identity matrix of X.

2) C_{I_n} is used as a pathological index, which is determined by Formula (2) C_{I_n}:

$$C_{I_n} = \sqrt{\frac{\phi_1^*}{\phi_n^*}} \times X^T \tag{2}$$

In Formula (2), ϕ_1^* and ϕ_n^* respectively represent the matrix the upper and lower eigenvalues of X^T.

C_{I_n} describes the quality evaluation indicators of urban human settlements $X_1, X_2, \cdots, X_n$. The overall redundancy level is positively proportional to the overall redundancy level of the evaluation index.

3) Determine the indicator of clearing document X_i remaining after $n-1$ a pathological index of human settlements quality evaluation indicators in cities $C_{I_{(n-1)i}}$. Determine the residual according to the process of process (1) and process (2) $n-1$ pathological index of human settlements quality evaluation indicators in cities $C_{I_{(n-1)i}}$.

4) Use Formula (3) to determine the evaluation index of urban human settlement environment quality X_i overall redundancy contribution of C_{i1}:

$$C_{i1} = C_{I_n} - C_{I_{(n-1)i}} \quad (3)$$

C_{i1} describes the removal of urban residential environment quality assessment indicators X_i remaining after $n-1$ a conditioned index of evaluation indicators $C_{I_{(n-1)i}}$, the same as clearing X_i the pathological index of all previous evaluation indicators C_{I_n}. The value is the same as the evaluation index X_i the overall redundancy contribution to all evaluation indicators is positively proportional. The larger the C_{i1} is, the more it should be cleared of X_i.

5) Eliminate the indicators with the largest overall redundancy contribution in all urban human settlements' environmental quality evaluation indicators. If

$$C_{j1} = max\{C_{i1} | 1 \le i \le n\} \quad (4)$$

Indicate the evaluation indicators of the quality of human settlements in n cities $X_1, X_2, \cdots, X_n$ within X_j the largest contribution to the overall redundancy of the evaluation indicator set, X_j needs to be cleared.

For the convenience of description, the above process is defined as the first round of screening of redundant evaluation indicators. Cycle the above process to clear the remaining $n-1$ evaluation index with the largest overall redundancy contribution among the evaluation indexes. Thus, after several iterations, the evaluation indicators with the largest overall redundancy among the remaining evaluation indicators are removed in each iteration until the following termination conditions for the removal of redundant indicators are met.

The termination conditions for the removal of redundant indicators are as follows: if the morbidity index of all remaining urban human settlements' environmental quality assessment indicators is less than or equal to 10, the screening of redundant indicators will be terminated; On the contrary, the redundant evaluation indicators are continuously screened according to the above process until the morbidity index of the remaining evaluation indicators is less than or equal to 10.

Through the above process, the redundant evaluation indicators in the initial urban human settlements' environmental quality evaluation indicator system can be eliminated, and the final urban human settlements' environmental quality evaluation indicator system can be constructed.

B. Construction of Evaluation Index System

Following the implementation of the pathological index cycle analysis method, the evaluation indicators within the initial system for assessing the environmental quality of people's urban habitation have been screened, and the final evaluation index system is constructed, as shown in Table I.

TABLE I. INDEX SYSTEM FOR EVALUATING THE QUALITY OF URBAN RESIDENTIAL ENVIRONMENT

Target layer	Indicator layer
Quality of the urban living environment	Relief
	THI
	Vegetation Index
	Hydrological index
	Traffic accessibility
	Per Capita GDP

The calculation method of each evaluation index in the evaluation index system is as follows:

1) Topographic relief: As the foundation of human survival and development, the terrain changes and geomorphic characteristics on the surface will have a significant impact on the result of the qualitative assessment of people's habitation [10]. Referring to the research results of relevant scholars, the topographic relief is described by Formula (5):

$$R_{DLS} = (max\, H - min\, H) \times \frac{P(A)}{A} \times C_{j1} \quad (5)$$

In Formula (5), $max\, H$ and $min\, H$ are the upper and lower limits of regional altitude, $P(A)$ and A respectively represent the flat area and total area in the region.

2) Temperature humidity index: Climate conditions have an important impact on human activities. The temperature and humidity index describes the degree of mugginess under windless conditions [11], and the formula is as shown below:

$$T_{HI} = t + R_{DLS} \times f \times 1.8t \quad (6)$$

In Formula (6), t stands for the average monthly temperature in Celsius; f stands for the average value of air relative humidity.

3) Vegetation index: The vegetation coverage within the region can not only be used as the main indicator to judge in the qualitative assessment of people's habitation but even as a ecological condition of human life [12]. The normalized vegetation index is calculated as follows:

$$N_{DVI} = (N_{IR} - R)(N_{IR} + R) \times T_{HI} \quad (7)$$

In Formula (7), N_{IR} and R respectively represent reflectance in a near-infrared band and red band.

4) Hydrological index: As the main resource for survival and development in the region [13], the quality of hydrological resources plays a crucial role in determining the quality of urban human settlements [14], and hydrological resources can be described by hydrological index:

$$W_{RI} = (\alpha \times P + \beta \times W_a) \times N_{DVI} \quad (8)$$

In Formula (8), P and α respectively represents the average annual precipitation and its weight in the region, W_a and β respectively represent the water area and its weight.

5) Traffic accessibility: The perfection of the traffic network within the region has a significant role in promoting the improvement of the quality of urban human settlements, so the traffic network has become the main indicator of the adaptability evaluation of regional human settlements, which can be described by the traffic accessibility within the region. The calculation formula is as follows:

$$D = \frac{L_i}{A_i} \times W_{RI} \quad (9)$$

In Formula (9), L_i and A_i respectively represent the total length of roads and the area of the region.

6) GDP per capita: The economic level within the region has a significant impact on the quality of urban human settlements, which can be described by the per capita GDP within the region. The calculation formula is as shown below:

$$P_{CCDP} = \frac{Z_{GDP}}{R_{pop}} \times D \quad (10)$$

In Formula (10), Z_{GDP} and R_{pop} respectively represent the gross domestic product and the total population within the region.

C. Construction of Evaluation Model Based on Back-Propagation Neural Network

1) Evaluation model of back-propagation neural network: An artificial neural network (ANN), referred to as a neural network (NN), is a mathematical model or computing model that imitates the structure and function of the biological neural network [15]. Its unique nonlinear adaptive information processing capability makes it particularly suitable for solving problems with complex internal mechanisms [16], prediction and other fields that have been successfully applied. The back-propagation (BP) neural network is a popular and extensively utilized model in the field of artificial neural networks. It typically consists of an input layer, one or more hidden layers, and an output layer. Fig. 1 shows the topology of a back-propagation neural network with a hidden layer.

The back-propagation neural network algorithm utilizes the gradient descent method as its underlying principle. During the learning process (training) of a neural network, back and forward propagation are utilized. Within the forward engendering stage, intake data is sequentially handled from the intake layer to the covered up one before being transferred to the outcome one. The neurons' state in each one specifically impacts the neurons' state within the subsequent one. Within the occasion that the outcome layer does not abdicate the required outcome, the back-propagation technique is employed. It recursively computes the difference (i.e., error) between the actual input and the expected input layer by layer [17]. The error signal is propagated back through the original connection pathway, and the weights between neurons in each layer are adjusted to minimize the error.

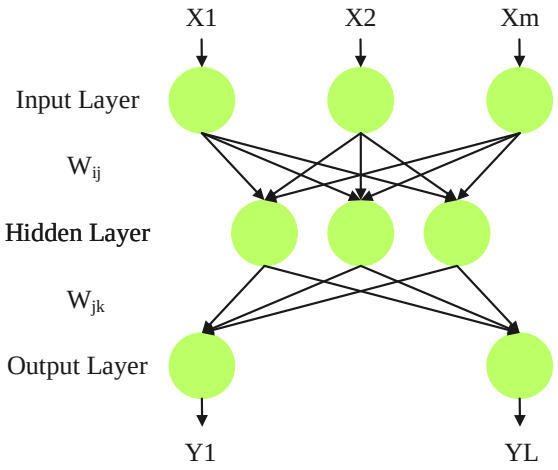

Fig. 1. Topological plan of the back-propagation neural system.

a) Foundation of preparing tests: Normalize the information within the evaluating measures (good quality, ordinary quality, light pollution and heavy pollution) of the six indicators listed in Table I, convert the specific values into [0,1] of the data in the interval, changes the absolute value of the physical system value into a relative value relationship. The urban residential environment quality grading metrics are used as training demos and intake to the network's intake hubs. Through the arbitrary number generation principles, 250 demos of every urban human settlement environmental quality index data were taken, and a total of 1000 samples were trained and modelled. MATLAB R2012b is used to establish the graphical user interface (GUI).

b) Neural network initialization: In the neural network model, we determine the hubs of the intake, hidden and outcome layers. Additionally, initializing the association weights among w_{ij} and w_{jk}; We also assign values to the hidden layer threshold a and output layer threshold b. These parameters are set along with the learning rate and neuron excitation function, select the input sequence (urban living environment quality evaluation index) and output sequence (urban living environment quality grading standard) of the system (X, Y) [18]. The hubs number within the covered up layer is evaluated utilizing an experimental equation.

$$Y_H = \sqrt{\theta_1 + \theta_2} \times P_{CCDP} \quad (11)$$

In Formula (11), θ_1 and θ_2 represent the number of neuron nodes in the input layer and the output layer, respectively.

c) Hidden layer output calculation: Using the input vector X, the association weights between the input layer w_{ij} and the hidden layer, as well as the hidden layer threshold a [19], we can compute the output of the hidden layer H; the calculation is shown in Formula (12), where f is the excitation function, and the excitation function is represented by the well-known Sigmoid function, as depicted in Formula (13).

$$H_j = Y_H \times f\left(\sum_{i=1}^{n} w_{ij} x_i - a_j\right), j = 1,2,\cdots,m \quad (12)$$

$$f(x) = \frac{1}{1+e^{-x}} \quad (13)$$

d) Output layer output calculation: Input according to the hidden layer H, hidden layer and output layer w_{jk} and output layer threshold b, calculate the predicted output of urban residential environment quality O, as shown in Formula (14).

$$O_k = f\left(\sum_{j=1}^{m} H_j \times w_{jk} - b_k\right), k = 1,2,\cdots,l \quad (14)$$

e) Error calculation: Considering the anticipated outcome O and desired outcome Y obtain estimation error e, as shown in Formula (15).

$$e_k = Y_k - O_k \quad (15)$$

f) Weight update: According to the prediction error$e$ to update connection weight w_{ij} and w_{jk}, the calculation formula is shown in Formula (16) and Formula (17). η is the learning rate.

$$w_{ij} = w_{ij} + \eta H_j\left(1 - H_j\right)x_i \sum_{k=1}^{l} w_{jk} e_k \quad (16)$$

$$w_{jk} = w_{jk} + \eta H_j e_k \quad (17)$$

g) Threshold update: According to the prediction error e to update threshold value a, b, the calculation formula is shown in Formula (18) and Formula (19), respectively.

$$a_j = a_j + \eta H_j\left(1 - H_j\right)\sum_{k=1}^{l} w_{jk} e_k \quad (18)$$

$$b_k = b_k + e_k \quad (19)$$

h) Judge whether the algorithm iteration ends: If the iteration is completed, it means that the training process of urban human settlements environmental quality assessment model based on back propagation neural network can be completed, and the show is established; In case the iteration isn't completed, return to the covered up layer yield evaluation part and begin a new preparing alteration procedure [20] until the method iteration is completed.

The evaluation model parameters mainly include the maximum number of training steps, performance parameters, the maximum number of confirmation failures, the number of hidden layer neuron nodes and other parameters [21]. These parameters can be manually modified as needed. At the same time, the initialization weight of the back-propagation neural network model is not unique. The final prediction result is the number of grades that appear most after the decision to repeat the training an odd number of times.

2) Optimization of back-propagation neural network algorithm: The back-propagation neural network exhibits robust capabilities in nonlinear mapping and complex logic operation ability, but the global search ability of the back-propagation neural network is relatively weak and is prone to local extreme values and slow convergence speed, which affects the backpropagation neural system's calculation efficiency and prediction accuracy. To enhance the global search capability of the back-propagation neural network within the assessment model for urban human settlement environmental quality, an improved genetic algorithm is employed for optimizing the network. Genetic algorithm is a search and optimization algorithm that simulates the natural evolution process. By simulating operations such as heredity, mutation and selection, the weight and structure of the network are gradually improved to make it better adapt to the evaluation task. In the process of optimization, the fitness function is defined, that is, the performance and fitness of the network are evaluated. By initializing the initial population composed of a group of genes, new individuals are generated by the operation of genetic algorithm, and they are evaluated according to the fitness function. Through iterative updating, individuals with high adaptability are gradually screened out. The improved genetic algorithm is used to optimize the back propagation neural network, which can improve the accuracy and generalization ability of the network by searching for better network weight and structure combination globally. The evaluation model of urban human settlement environmental quality can evaluate the urban environmental quality more accurately and provide a more scientific basis for urban planning, construction and management.

The conventional genetic algorithm often encounters challenges such as local optimization and slow convergence. To address this, an enhanced genetic algorithm with enhanced global search capability is proposed, building upon the traditional genetic algorithm. By employing an adaptive calculation strategy for crossover probability and mutation probability, the ability of the genetic algorithm to discover the global optimal solution is significantly improved. Compared with other evaluation methods, this improved genetic algorithm can overcome the problems that traditional genetic algorithm is easy to fall into local optimum and slow convergence, and has stronger global search ability. By adopting adaptive crossover probability and mutation probability calculation strategy, the improved genetic algorithm can flexibly adjust the parameters of genetic operation to adapt to the characteristics and difficulties of different problems. It can improve the extensive search ability of the algorithm in the solution space and reduce the dependence on the initial solution, thus effectively avoiding the problem of falling into the local optimal solution and being unable to find the global optimal solution.

a) Design of chromosome coding: The dimension of the chromosome gene vector in real coding is determined by the number of weights and thresholds present in the back-propagation neural network [22], and the formula is as follows:

$$X_i = (w_{11},\cdots,w_{ms},w_{11},\cdots,w_{sn},a_1,\cdots,a_s,b_1,\cdots,b_n) \quad (20)$$

b) Determination of fitness function: In the genetic algorithm, the fitness value of the individual is an important indicator to evaluate the excellent performance of the individual [23]; assuming that the fitness value of the ith individual is F_i, the back-propagation neural network yields a mean square error of $M_{SE}(X_i)$, the fitness function is taken as:

$$F_i = M_{SE}(X_i) \times a_j \times b_k \quad (21)$$

c) Select the design of the operation: Discarding the roulette wheel method in the traditional genetic algorithm, the formula of the probability of each individual being selected is:

$$p_i = \frac{\frac{l}{F_i}}{\frac{\sum_{i=1}^{N} l}{F_i}}, i = 1,2,\cdots,N \quad (22)$$

In Formula (22): $\frac{l}{F_i}$ represents the fitness value of the ith individual, l represents the adjustment factor.

d) Design of cross operation: An adaptive crossover probability is proposed for individuals with poor performance, appropriately increase the crossover probability of the individual to optimize its gene structure; For individuals with good performance, the crossover probability should be appropriately reduced to avoid damaging excellent genes. In addition, in order to ensure population diversity and the algorithm exhibits a fast search speed in the initial stage, followed by enhanced local search capability in the later stage, ultimately leading to convergence and avoiding oscillation at the extreme point [24]; this crossover probability should also be reduced with the iteration of the algorithm.

The calculation formula of individual crossover probability is:

$$p_{ci} = P\left(Pcmin_{cmax} \times \frac{t \times F_{min}}{T \times (F + F_{min}())}\right)_{cmax} \quad (23)$$

In Formula (23): t represents the current iteration number of the algorithm, T represents the total number of iterations of the algorithm, p_{ci} is the probability of the ith individual at the t-th crossing, F_{min} indicates the fitness value of the individual with the best performance of the population, P_{cmax} is the maximum crossing probability, which is 0.6, P_{cmin} represents the minimum crossing probability, which is 0.3.

Chromosome i X_i and the j chromosomes X_j on k and the bit crossing formula is:

$$\begin{cases} X_i^k = (1-\partial)X_i^k + \partial X_j^k \\ X_j^k = (1-\partial)X_j^k + \partial X_i^k \end{cases} \quad (24)$$

In Formula (24): ∂ represents a random number, and $0 \le \partial \le 1$.

e) Design of mutation operation: The mutation operation is implemented to preserve the global search capability in the initial iterations of the algorithm while also ensuring local search capability and stability during the later stages [25]. Consequently, the design assigns equal probabilities for individual mutation and crossover operations. These probabilities are determined based on the individual fitness value and the number of algorithm iterations [26]. The calculation formula is:

$$p_{mi} = P\left(Pmmin_{mmax} \times \frac{t \times F_{min}}{T \times (F_i + F_{min}())}\right)_{mmax} \quad (25)$$

In Formula (25): p_{mi} is the probability of the ith individual at the time of t variation, P_{mmax} represents the maximum probability of variation, 0.005, P_{mmin} represents the minimum probability of variation. Gene j on chromosome i X_i^j and the variation formula of is:

$$X_i^j = \begin{cases} X_i^j + \left(X_i^j - X_{i\max}^j\right) f(t), \lambda > 0.5 \\ X_i^j + \left(X_{i\min}^j - X_i^j\right) f(t), \lambda \le 0.5 \end{cases} \quad (26)$$

In Formula (26): X_{imax}^j express the upper bound of gene X_i^j, X_{imin}^j express the lower bound of gene X_i^j, t represents the current number of iterations, λ represents a random number, and $-1 \le \lambda \le 1$.

f) Determination of population size and iteration number: Since there are many undetermined parameters in the back-propagation neural network, the selected population size is 100 to ensure global optimization; The number of iterations is 500 to ensure the complete convergence of the algorithm. Fig. 2 illustrates the flowchart of the back-propagation neural network model that incorporates an improved genetic algorithm.

The steps to optimize the back-propagation neural network using the improved genetic algorithm are as follows:

Step 1: Pre-process the urban human settlements' environmental quality evaluation index data, determine the network structure of the back-propagation neural network, and determine the coding method;

Step 2: Determine the fitness function and repeatedly select, cross, and mutate the initial population until the fitness value of a chromosome reaches the preset standard;

Step 3: Compute the output of each node in the hidden layer and the output layer sequentially, followed by the calculation of the output error for each node in the output layer.

Step 4: If the output error does not meet the accuracy requirements, update the weights and thresholds of each layer based on the error back-propagation process, and utilize the updated weights and thresholds to calculate the output error. Repeat this process iteratively till the output error satisfies the desired precision criteria, and then the teaching is over.

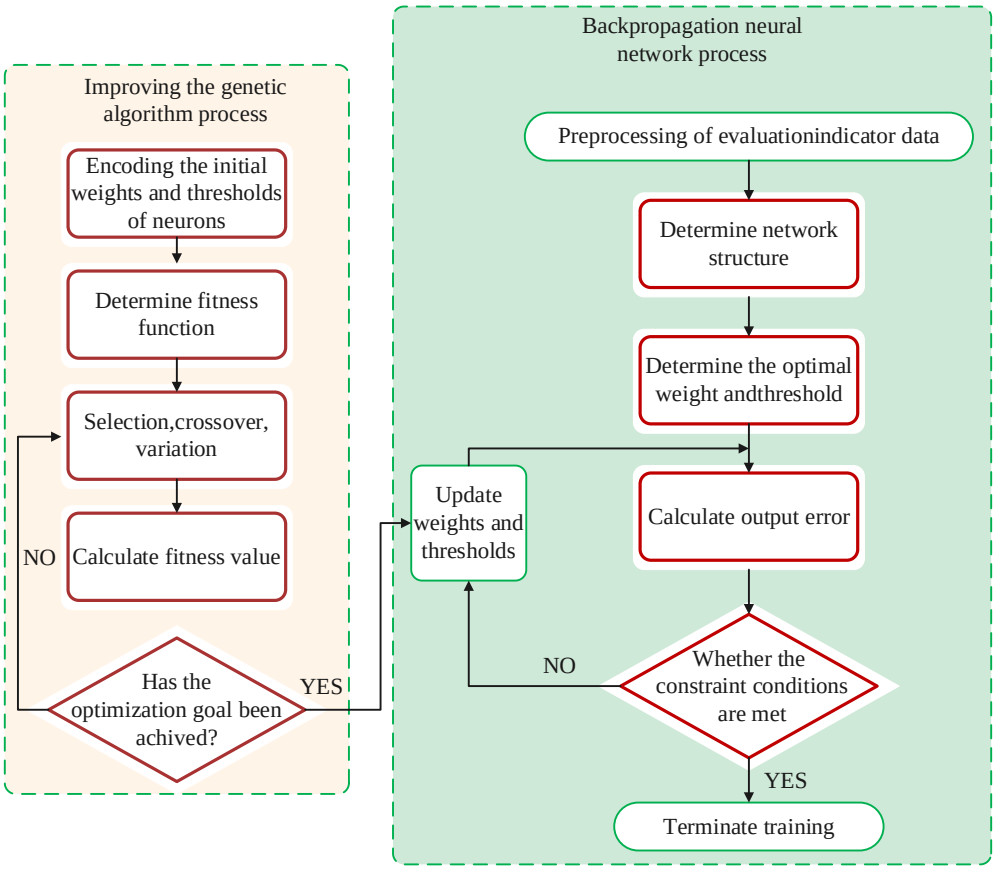

Fig. 2. Flow chart of back-propagation neural network model on the basis of improved genetic algorithm.

III. Experimental Results

This paper studies the urban residential environment quality assessment algorithm on the basis of the back-propagation neural network. In order to verify the application effect of this method in the urban residential environment quality assessment, a region is selected as the research object. The region contains nine cities, which are represented by A-I as shown in Fig. 3. The method in this paper is used to evaluate the urban residential environment quality in the study area. The results are as follows:

A. Data Source and Processing

The data used in the process of qualitative assessment of people's habitation of the research object using this method mainly include environmental data, population data, vector water network distribution data and basic geographic data. In the process of data collection, relevant data are obtained through various channels such as government statistics bureau, environmental monitoring department, professional research institutions and open data platforms. These data sources provide various indicators of urban environmental quality, such as air quality, water quality, noise level and green space coverage rate. In order to ensure the reliability and validity of the data, the data are verified and calibrated. Through data sampling and the integration of multiple data sources, the representativeness and reliability of data are improved, and residents' subjective feelings and evaluation on the quality of urban human settlements are obtained by means of field surveys and questionnaires, so as to increase the comprehensiveness and objectivity of the research. The data sources and corresponding processing processes are shown in Table II.

Based on the processing results of various types in Table II, the evaluation index data used in the process of urban human settlements' environmental quality assessment is obtained.

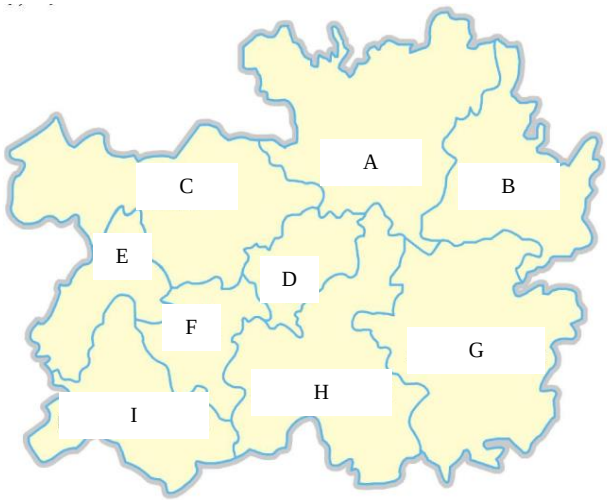

Fig. 3. Overview of the study area.

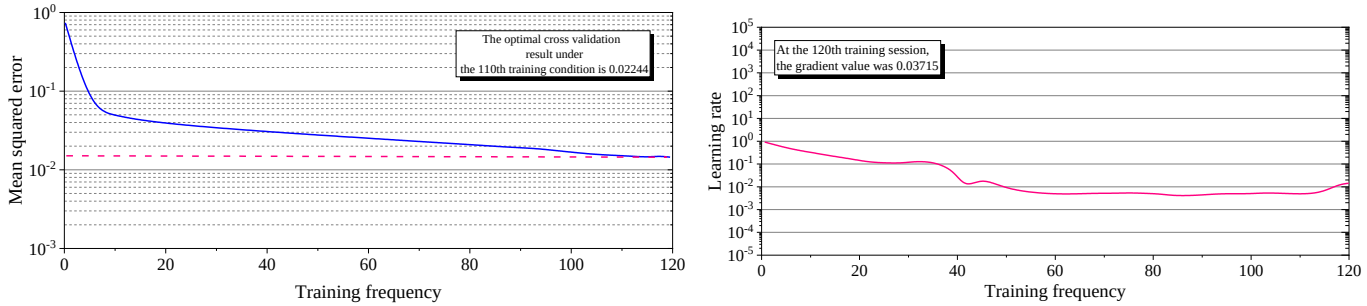
TABLE II. DATA SOURCES AND CORRESPONDING PROCESSING

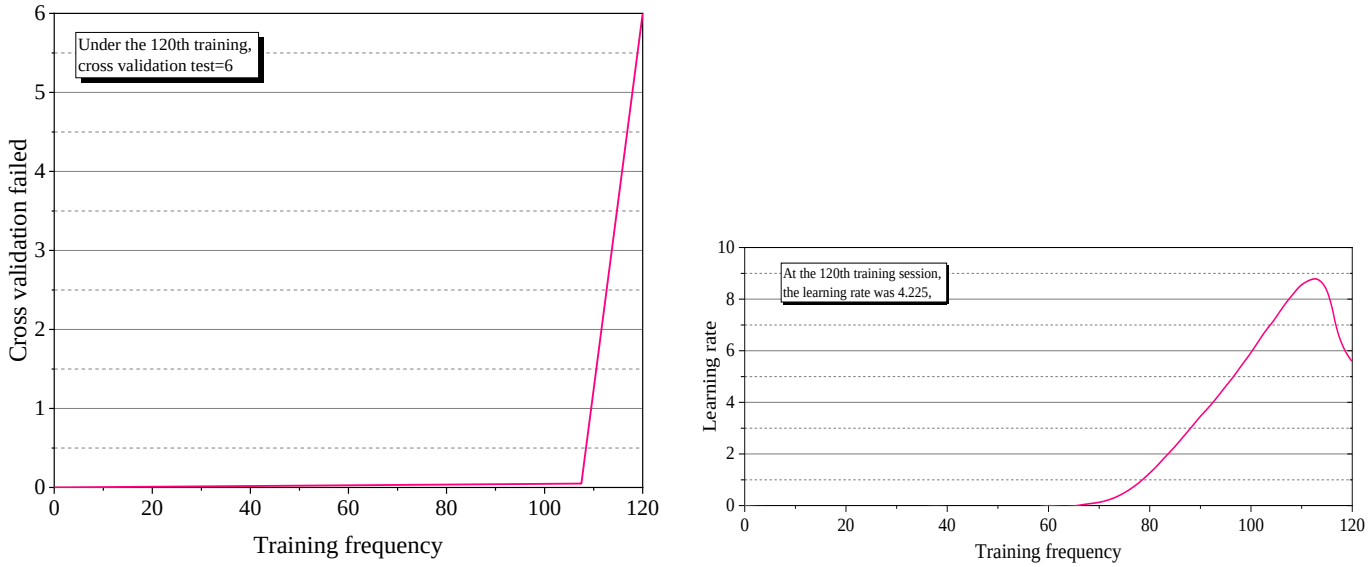
Data type	Relevant content	Main sources	Processing technology
Environmental data	Temperature, relative humidity, precipitation, etc	Regional Meteorological Station Resource Library	For various types of data, the Kriging method, spline method, and inverse gradient distance square method are used for interpolation processing to obtain regional meteorological element layers
	Digital Elevation Model	Global GTO-PO30	Adopting the conic projection of double standard weft lines with positive axis area to obtain 0.5km × Digital elevation model map of 0.5km area
	NDVI	Earth Science Data Sharing Center	-
Demographic data	Demographics	Regional Statistical Yearbook	-
Basic geographic data	Traffic distribution vector data	Data Center of the Chinese Academy of Sciences	Build a 0.5km × 0.5km grid, determine the water network density of the grid through spatial analysis, and convert it to a 0.5 km × Grid scale of 0.5 km
	Distribution data of social settlements	Earth Science Data Sharing Center	On the basis of the data gathered using the sharing centre and combined with the latest map implementation comparison and optimization
Economic data	Various economic data within the region	Regional Statistical Yearbook	-

B. Training and Parameter Adjustment

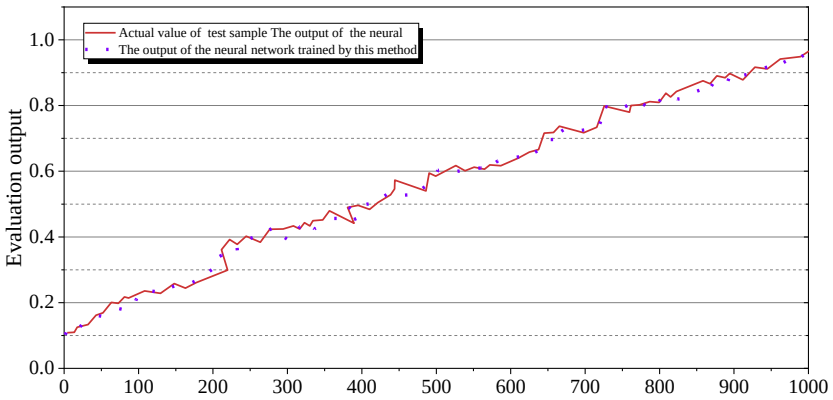
By utilizing the Nprtool toolbox in MATLAB R2012b software, the neural network is trained and evaluated, the data import, data pre-processing, establishment and training of neural networks, and the use of error mean square and confusion matrix are automatically completed to analyze the modelling effect of back-propagation neural networks used in this evaluation method. The back-propagation neural network is constructed with two-layer feedforward architecture. The transmision function employed in the covered up one is the sigmoid, while the entire network is trained using the variable gradient algorithm. 1000 training demos are consumed for training and learning. In which, the training set consists of 700 samples, the verification set comprises 150 samples, and the rest 150 demos are allocated to the set of test. After several iterations, the optimal number of neurons in the hidden layer for the back-propagation neural network is determined as 10, with a training target error set to 0. To mitigate overfitting, the maximum number of training iterations for the neural network is set at 1000. The maximum number of validation set failures is set to 6. The training process and parameters are shown in Fig. 4.



(a) Mean squared error Gradient analysis.



(b) Cross-validation failed learning rate.



(c) Output accuracy.

Fig. 4. Parameter adjustment process of back-propagation neural network training set.

It can be seen from Fig. 4 that the back-propagation neural network used in this method can stop training after 110 times of training, and the error is 0.02244. Among them, it can be seen that the gradient of the back-propagation neural network is declining in the training process, which conforms to the characteristics of back-propagation neural network error back-propagation. The accuracy of the evaluation results obtained by substituting the training data back into the neural network model is 96.3%.

C. Evaluation Results

The trained back-propagation neural system is for evaluating the quality of urban human settlements in nine cities within the study object, and the evaluation results are shown in Table III.

According to the analysis of Table III, the urban residential environment quality of nine cities in the study object was evaluated using the method in this paper, and the results showed that the quality of the urban residential environment in G city was excellent; The qualitative assessment of people's habitations in cities A, D, E and F is average; However, the qualitative assessment of people's habitations in cities B, C, H and I is slightly polluted. At the same time, the obtained results from this approach align perfectly with the actual conditions of each city, indicating the method's capability to complete the qualitative assessment of people's urban habitations accurately.

TABLE III. EVALUATION RESULTS OF THE STUDY OBJECT

City number	Evaluate Results	Actual situation
A	Average quality	Average quality
B	Slightly polluted	Slightly polluted
C	Slightly polluted	Slightly polluted
D	Average quality	Average quality
E	Average quality	Average quality
F	Average quality	Average quality
G	Superior in quality	Superior in quality
H	Slightly polluted	Slightly polluted
I	Slightly polluted	Slightly polluted

D. Analysis of the Improvement Effect of Urban Residential Environment Quality

This method is used to complete the qualitative assessment of people's habitations in all cities within the study object. The assessment outcomes gathered from the algorithm are utilized to optimize the quality of human settlements in various cities. Compare the fluctuation of human settlements' environmental quality assessment grades in different cities before and after the assessment using this method, and the results are shown in Fig. 5.

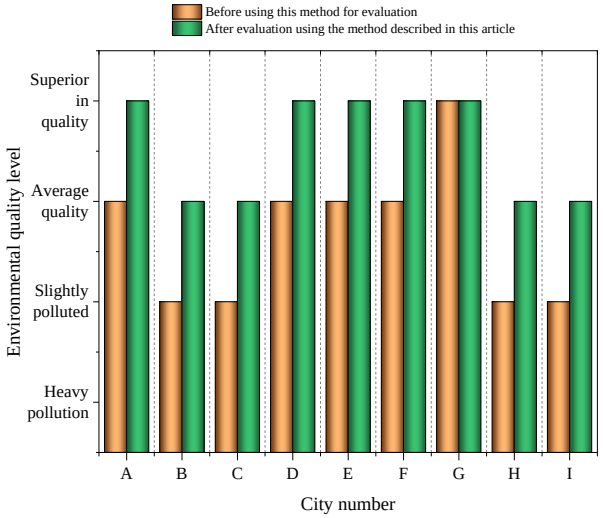


Fig. 5. Fluctuation of the assessment levels of people's habitations quality in different cities.

From the results in Fig. 5, it can be seen that after evaluating the quality of human settlements in different cities using this method, most cities have shown a certain degree of improvement after environmental optimization, further verifying the effectiveness and feasibility of this method in evaluating the quality of urban human settlements. Specifically, except for the relatively high initial evaluation results of City G, which do not require environmental optimization, all eight other cities have achieved further improvement after environmental optimization. This means that using the method presented in this article can accurately

identify areas that need improvement and provide corresponding optimization strategies, thereby improving the quality of urban living environment. This result further demonstrates that the method proposed in this paper has good evaluation performance and provides effective solutions for the quality of human settlements in different cities. It helps urban planners and policy makers to better understand the current state of human settlements in cities and take corresponding measures to improve their quality of life.

IV. Discussion

In the study of the evaluation method of urban human settlements based on back propagation neural network, this method is applied to evaluate and improve the urban environmental quality. By constructing an appropriate index system and training a back propagation neural network evaluation model with good generalization ability, the situation of urban human settlements can be accurately evaluated and scientific basis can be provided for urban planning and management.

Through this study, it is found that the evaluation method of urban human settlements quality based on back propagation neural network has some remarkable advantages. Firstly, this method can integrate multiple environmental factors and socio-economic factors, and comprehensively consider the comprehensiveness and complexity of urban human settlements. Secondly, the back propagation neural network has strong fitting ability and generalization ability, and performs well in dealing with nonlinear relations and predicting future trends. Finally, this method can be flexibly adjusted and optimized according to the actual needs and data, and has high operability and adaptability.

V. Conclusion

This research focuses on the qualitative assessment of people's urban habitations through a backpropagation neural system method. An assessment model is constructed using the back-propagation neural network, and an improved genetic algorithm is introduced to address the issues of local optimization and slow convergence commonly associated with the back-propagation neural network. Additionally, the optimization of the initial weights and thresholds of the network is addressed, ensuring the stability of the algorithm and overcoming the shortcomings of the back-propagation neural network algorithm. Through experiments, the following conclusions are obtained:

1) After 110 times of training, the BP neural network used in this method can stop training, and the error is 0.02244. According to the characteristics of back propagation neural network, the accuracy of evaluation results obtained by substituting training data into neural network model is 96.3%.

2) This method can accurately evaluate the quality of urban human settlements.

3) The method in this paper has good evaluation performance for the quality of human settlements, which can effectively promote the improvement of the quality of urban human settlements.

There are some limitations in the study of this method in practice, such as the lack of availability and completeness of data. Although there are many data sources to choose from, the data of some urban environmental indicators may be lacking or incomplete, which affects the accuracy and reliability of the evaluation model. Future research can solve this problem by improving the coverage and quality of data collection and monitoring systems, or by integrating multiple data sources. At the same time, the construction of evaluation index system is still a challenge. At present, there are still subjectivity and limitations in the selection of evaluation indicators and the distribution of weights, and there is still a lack of unified standards and systems. Further research can explore a more scientific, comprehensive and objective evaluation index system, taking into account social and economic factors, residents' subjective feelings and other factors, so as to evaluate the quality of urban human settlements more comprehensively.

Basketball Motion Recognition Model Analysis Based on Perspective Invariant Geometric Features in Skeleton Data Extraction

Jiaojiao Lu
Sport Institute, Yantai Institute of Science and Technology, Yantai 265600, China

***Abstract*—The study proposes a recognition method based on skeleton data to address the basketball action recognition, especially those posed by viewpoint changes in videos. The key of this method is to extract geometric features of viewpoint invariance and combine them with spatio-temporal feature fusion techniques. In addition, the study constructs a dynamic topological map of the human skeleton based on long and short-term neural networks to improve the model performance. The experimental results showed that the research method had an average accuracy of 97.85% for Top-5 metrics on the Kinetics dataset and 97.82% for Top-5 metrics on the NTU RGB+D dataset. It is significantly better than the other three state-of-the-art methods. According to the experimental results, it achieves efficient and stable basketball action recognition, which is significantly superior to existing methods. This research not only provides a more efficient method for basketball motion recognition, but also provides valuable references for other sports action recognition fields.**

***Keywords*—Skeleton data; perspective invariance; geometric features; basketball recognition; spatio-temporal feature fusion**

I. Introduction

Basketball, as a global sport, not only attracts countless spectators and enthusiasts, but also becomes the focus of in-depth discussions in academic research and business. With the development of technology, analyzing the importance of basketball matches from a technical perspective is becoming increasingly prominent [1]. Among them, basketball action recognition technology plays an important role in player skill analysis and training assistance [2]. However, traditional visual basketball action recognition methods rely on the analysis of continuous video frames. They are limited by background noise, complex environments, and especially the change of camera viewpoints, which makes the action recognition face great challenges [3]. Skeletal data provide a more abstract and concise representation of movements than traditional methods, and are more effective in resisting the effects of perspective changes [4]. However, due to the poor fusion effect of spatio-temporal features in skeleton data, the accuracy of existing recognition models is not ideal [5]. To address this problem, the study proposes a novel basketball sports recognition model, which is based on viewpoint invariant geometric features and aims to improve the accuracy and robustness of skeleton data recognition. In addition, the study also explores the method of constructing a dynamic topological map of the human skeleton to further improve the model performance. This study consists of five parts. The first part is an overview of this study. The second part is a summary of relevant research. The third part has two sections. Firstly, a dynamic topology map of the human skeleton is constructed. The second section introduces a basketball motion recognition method based on perspective invariant geometric features. In the fourth section, the proposed method is tested on a dataset and in a real environment. The results are analyzed. The fifth section is a summary and outlook for this study. This study develops a new basketball action recognition system. It not only utilizes skeleton data more efficiently, but also shows significant improvement in both recognition accuracy and robustness. It is expected that this study can provide strong technical support for basketball game analysis, teaching assistance and other related applications.

II. Related Works

In the action recognition, feature extraction and fusion are the foundation of accurate recognition. Therefore, a large number of scholars have conducted in-depth research on this field [6]. Zhou W et al. proposed a novel feature fusion network to improve the performance of object detection under low light and uneven lighting conditions. This study applied a cross modal fusion module to fuse the corresponding size features of target detection and thermal modes. Then, the bidirectional reverse fusion module was used to achieve bidirectional fusion of foreground and background information. In the experimental results, the proposed feature fusion network was superior to other advanced methods [7]. Zhang X et al. proposed a network that combined multi-scale hierarchical feature fusion and mixed convolutional attention to solve the single image defogging in image recognition. By fusing multi-scale layered features, the haze level and image structure information were accurately estimated, resulting in the restored image containing less residual haze. According to the experimental result, it exceeded the most advanced defogging algorithm [8]. Choi H et al. proposed a new multimodal image feature fusion module to solve the transmission line inspection. The output of the multi branch feature extraction block was aggregated into an attention vector in the channel attention block. Each input feature was recalibrated. According to the experimental result, it was superior to the single mode input [9].

With the emergence of various optimization techniques, the improved action recognition models are gradually receiving attention. To solve the distinguishable feature extraction in skeleton action recognition model, Song Y F et al.

embedded an advanced separable convolutional layer into the Multiple Input Branches network. The research constructed an efficient Graph Convolutional Network (GCN) baseline. A composite extension strategy was designed to synchronously extend the width and depth. In the NTU 60 dataset testing, the accuracy reached 92.1% [10]. Li M et al. proposed a symbiotic graph neural network for 3D skeleton motion recognition. The network structure included a basic part, an action recognition part, and a motion prediction part. In the backbone network, a multi-scale GCN based on joints and parts was used to extract key features. Compared with the current methods, the method had better performance on all four datasets [11]. Li C et al. proposed a new temporal and spatial recalibration method to address the complex changes in skeletal joints in motion recognition. The research constructed a novel temporal attention mechanism based on residual learning to calibrate the frames of skeleton data. Compared with the most advanced methods, the research method significantly improved performance. It had the best results on six action recognition datasets [12].

In summary, there have been many studies in the action recognition, especially in feature extraction and fusion. However, most of these studies have focused on improving the performance of object detection under specific environmental conditions, specific problems in image processing, or specific applications. These approaches are often not applicable to complex sports scenarios, especially in basketball action recognition. They fail to adequately address the challenges posed by changes in perspective [13]. This research fills this gap by proposing a new basketball motion recognition model. It focuses on extracting viewpoint-invariant geometric features from skeleton data and incorporates spatio-temporal feature fusion techniques. Compared with existing studies, the innovation of the study is follows. It proposes an action recognition method for complex sports scenarios, which specifically addresses the viewpoint invariance in basketball. Further, the study effectively improves the accuracy and robustness of the model by constructing a dynamic topological map of the human skeleton based on long and short-term neural networks. In contrast to existing research in GCNs, symbiotic graph neural networks, and temporal re-space recalibration methods, the study focuses on combining action recognition with perspective invariance. It is an area rarely covered in existing research. As a result, the study not only makes significant improvements in the efficiency and accuracy of basketball action recognition, but also provides a new perspective to explore the action recognition problem. It provides a valuable reference for research in this area.

III. Construction of Basketball Motion Recognition Model Based on Perspective Invariant Geometric Features in Skeleton Data Extraction

To achieve more efficient and stable basketball motion recognition results, the study optimizes the model from two aspects. Firstly, based on short-term and short-term memory neural networks, a dynamic topology map of the human skeleton is constructed to provide more accurate data support for the recognition model. Then, a new spatio-temporal feature fusion method is proposed based on the perspective invariant geometric features extracted from skeleton data. On this basis, the research constructs a basketball motion recognition model.

A. Dynamic Topology Map Construction of Human Skeleton

Basketball action recognition based on human skeleton data aims to identify the types of actions represented by human skeleton time series. Traditional recognition methods have two categories. One is based on manual features, which mainly capture the dynamic relationships of joints through manual design features. The second is based on deep learning. It conducts end-to-end modeling with recurrent neural networks to capture joint information [14]. In practical scenarios, an action consists of multiple video frames. It is difficult to accurately display the dependency relationship between joints and bones by manually creating a topology map. The individual training and parameters for each video frame not only require a large amount of computation, but may also lead to catastrophic forgetting. Therefore, the research adopts a continuous learning method. The Long Short-Term Memory (LSTM) is utilized to dynamically construct the topology map of the human skeleton to improve the recognition performance of the basketball motion recognition model. The human skeleton sequence is composed of continuous human skeleton frames. Each frame is a set of joint coordinates and coordinates confidence. The definition of the human skeleton sequence is shown in Eq. (1).

$$VT = \{VT_1, VT_2, ..., VT_T\} \tag{1}$$

In Eq. (1), T represents the number of human skeleton frames. VT_i represents the i-th human skeleton frame in the human skeleton sequence. VT_i is composed of joint points containing spatio-temporal information, as shown in Eq. (2).

$$VT_i = \{V_1, V_2, ..., V_N\} \quad (1 \le i \le T) \tag{2}$$

In Eq. (2), N represents the joint points in the human skeleton frame. The i-th joint point V_i in the human skeleton frame is shown in Eq. (3).

$$V_i (1 \le i \le N) = (x_i, y_i, score_i) \tag{3}$$

In Eq. (3), (x_i, y_i) represents the position information of the joint point. $score_i$ represents the confidence information of the joint position. Therefore, the dimension of the human skeleton sequence is (T, N, C). C is the position vector dimension. The dynamic topology diagram of the human skeleton is shown in Fig. 1.

In data preprocessing, firstly, normalize the joint feature vectors. Then, convert skeleton sequences from different positions to the same position to promote convergence. A relationship graph is a many to many graph structure that exists between nodes. Convert multiple diagrams into a set of relationship triplets, as shown in Eq. (4) [15].

$$\{(u, r, v)\} \subseteq V \times E \times V \tag{4}$$

In Eq. (4), u and v are entities. r represents a relationship between entities. Therefore, encode multiple human bone sequence datasets into relational triplet sequence

datasets. Based on the multi relationship features of human skeleton data, Eq. (5) defines a sequence of triples.

$$RT = \left\{ (VT_i, r_{ij}, VT_j) \middle| 1 \le i \le T, 1 \le j \le T \right\} \tag{5}$$

After obtaining the relational triplet dataset, the features need to be decoupled. The feature decoupling module extracts entities and feature embedding vectors from a triplet dataset. Then, based on the association between independent joints in each action, the video frames of the triplet sequence are decomposed into multiple features to learn the embedding vectors of the entities. At the same time, encode the action types to learn the embedding vectors of relationship features. Entity feature decouples a single video frame into multiple features. Then the embedded feature vectors of each joint feature are learned separately. Therefore, the entity $VT_i \in V$ represented by each single video frame is transformed into a set of multiple independent joint points, as shown in Eq. (6).

$$VT_L = \left[V_1, V_2, ..., V_N \right] \tag{6}$$

In Eq. (6), $VT_L \in R^d$. d represents the vector dimension. After performing one-hot encoding on the action type, the study uses embedded feature vectors to represent action analogies, thereby constructing a dynamic topology map. The vectors obtained from the feature decoupling module are used to construct skeleton topology maps for different action categories. Firstly, the K-means is applied to cluster the relationship feature vectors representing action categories. Then the dataset is grouped based on the clustering center. Next, based on the action categories encoded by one-hot, combined with the attention mechanism and the partial update strategy, the study constructs a topology diagram for each type of action. Eq. (7) defines the i-th training set.

$$T_i = \{ (u_1^{T_i}, u_1^{T_i}, v_1^{T_i}), ..., (u_m^{T_i}, u_m^{T_i}, v_m^{T_i}) \} \tag{7}$$

In Eq. (7), m represents the instance number of T_i. For a skeletal relationship triplet, the research uses the attention mechanism to extract the relevant joint features of continuous video frames VT_i and their relationship r_{ij}. Triple (VT_i, r_{ij}, VT_j) is assigned N attention weights. Eq. (8) shows the importance α_r^i of the i-th joint point in the current relationship r.

$$\alpha_r^i = \frac{exp(\alpha_r^i)}{\sum_{j=1}^{N} exp(\alpha_r^j)} \tag{8}$$

In Eq. (8), α_r^j represents the importance of the j-th joint point in the current relationship r. Then, the research adopts the video frame VT_i with the highest attention weight and the first i joint points. Different features are used to construct a relationship topology diagram for this action category, as shown in Fig. 2.

In Fig. 2, a single skeleton frame contains 18 embedded feature vectors. The red leg nodes are the first six joint features most relevant to this action. The model experiences forgetting when updating parameters. Therefore, the study introduces a partial update strategy to dynamically adjust the topology map. When connecting a new skeleton relationship triplet, the model first identifies the parts related to the new data in the existing skeleton relationship graph. However, this only updates highly relevant features. Due to the complex connections between nodes, new data may affect multiple existing nodes. Therefore, activate the nodes directly or indirectly connected to it. Based on feature similarity, perform selective updates and further optimize computational efficiency. Finally, perform local updates on joint features that are highly similar to the new data.

B. Basketball Movement Recognition Based on Perspective Invariant Geometric Features

In modern basketball, numerous factors can easily affect target action recognition, such as local occlusion, rapid movement, and noise caused by inherent unstable factors in cameras [16]. These factors can cause the collected joint points to shake, resulting in a large amount of noise. Fig. 3 displays the schematic diagram of human joint shaking.

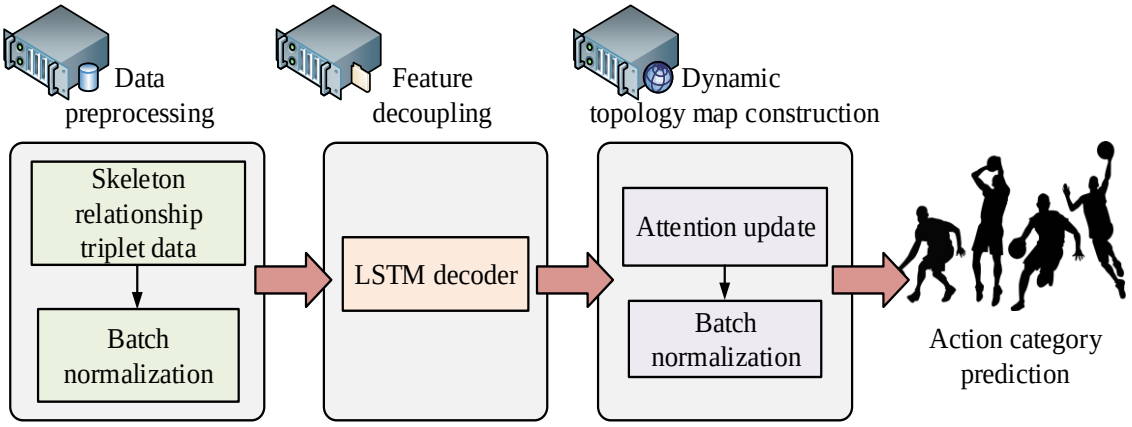

Fig. 1. The Process of human skeleton motion recognition based on dynamic topology graph.

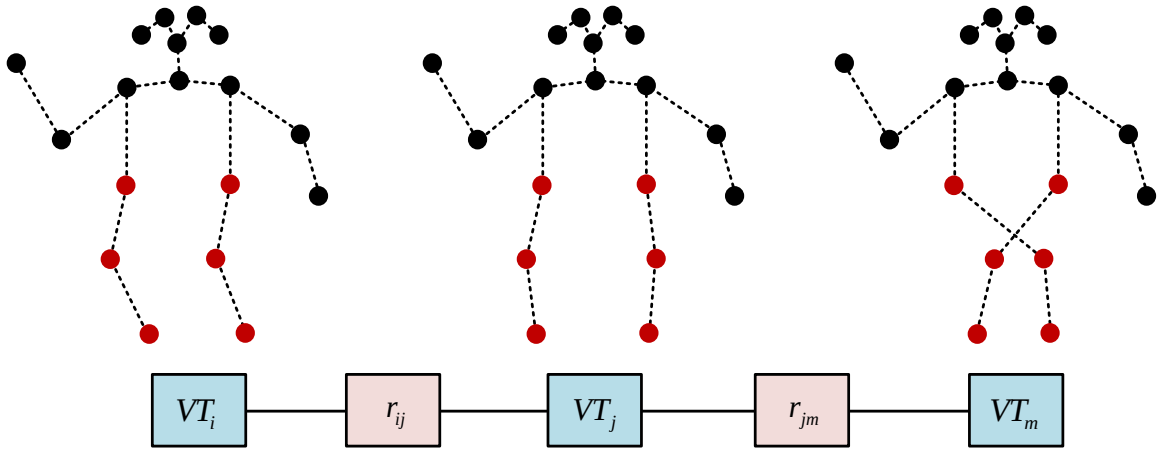

Fig. 2. Schematic diagram of feature encoding.

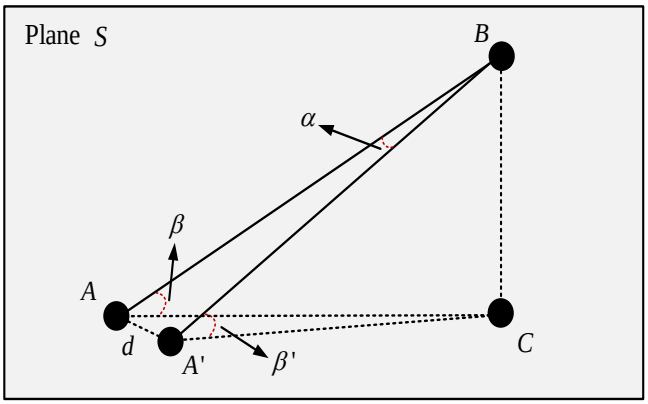

Fig. 3. Schematic diagram of human joint shaking.

In Fig. 3, when joint point A experiences shaking and moves to A', the shaking path is a periodic rotation around the joint BC. The rotation radius is AC, and the angle is α. The joint point A or conventional geometric characteristics used as network input may lead to system stability issues [17]. In addition, in cross perspective testing, apply two Kinect devices to calculate the three-dimensional coordinates of human bones. This calculation uses different projection centers, which may also introduce interference [18]. To address these challenges, a few feature representations that are not sensitive to three-dimensional spatial transformations of skeleton data are proposed. It is named the Planes of 3D Joint Motions Vector (P3DJMV). Cosine similarity is the primary distance comparison method for this research, primarily because it focuses on measuring directional similarity between vectors rather than the size. This property is particularly important for basketball motion recognition because the study focuses more on capturing and comparing features of the motion patterns rather than the absolute size of the action. In addition, cosine similarity typically performs well when dealing with high-dimensional data, which is particularly useful for research application scenarios that analyze complex motion data. Since it is based on directional similarity, cosine similarity naturally ignores differences in the size of the data. When comparing, it is possible to fairly handle different sizes of motion patterns. P3DJMV uses the cosine angle between vector $\underset{AB}{\rightarrow}$ and vector $\underset{AC}{\rightarrow}$ as the feature descriptor for skeleton data. In this way, even if point A shakes to point A', it will not follow the shaking due to point A shaking. In the plane S composed of A, B, and C, the angles β and β' are approximately equal. To explore the spatial variation of joint points, a feature representation based on node momentum (FRNM) is also designed, as shown in Fig. 4.

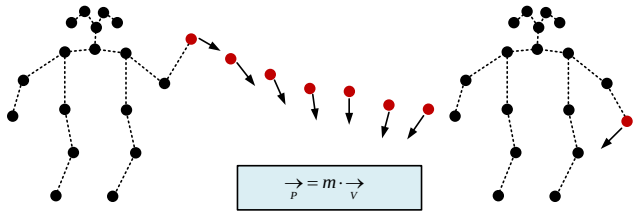

Fig. 4. Schematic diagram of feature FRNM.

Fig. 4 shows the FRNM visualization diagram of a basketball player's catch movement. The end node of the athlete's left hand is the target node, displaying its continuous changes in space. The arrow direction represents the motion direction of the target node. The length roughly reflects the motion speed. P3DJMV aims to simplify the three-dimensional spatial into a one-dimensional angular space, as displayed in Fig. 5.

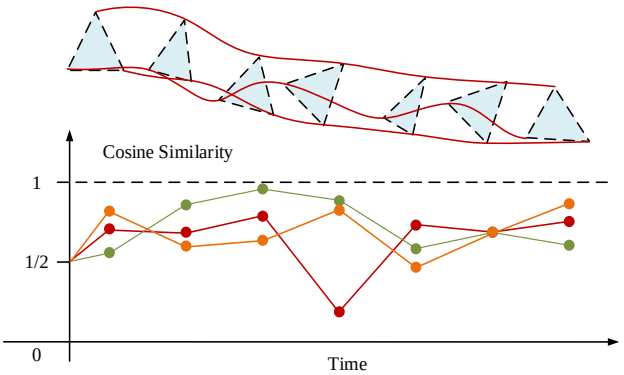

Fig. 5. P3DJMV feature visualization.

Unlike P3DJMV, FRNM essentially treats human joint points as a particle [19]. The particle mass is 1. Momentum represents the trajectory of particles. The human skeleton data contains 25 nodes. It is simplified to 20 nodes. Then, solve for the average and standard deviation of the entire dataset. The data meets the standard normal distribution through standardized processing. Afterwards, FRNM arranges groups from these 20 joints to extract possible planes, with a total of 1140 possibilities. Eq. (9) represents these planes expressions.

$$C_p = \{p_i, p_j, p_k\}, p \in N^+[1,1140]\ i, j, k \in N^+[1,20] \tag{9}$$

In Eq. (9), p_i, p_j, and p_k represent three joint points. p represents a plane. The three points p_i, p_j and p_k can obtain three vectors, as shown in Eq. (10).

$$\begin{cases} V_p(1) = (p_i^x - p_j^x, p_i^y - p_j^y, p_i^z - p_j^z) \\ V_p(2) = (p_i^x - p_k^x, p_i^y - p_k^y, p_i^z - p_k^z) \\ V_p(3) = (p_k^x - p_j^x, p_k^y - p_j^y, p_k^z - p_j^z) \end{cases} \tag{10}$$

In Eq. (10), the cosine value $V_p(1)$, $V_p(1)$, and $V_p(1)$ are shown in Eq. (11).

The P3DJMV is stacked in the tensor form of $F \times H \times W$. F represents the frames. H represents length. W represents the width. The node is abstractly represented as a physical particle. The mass is 1. The particle momentum is $\rho = mv$, and m is 1. If the trajectory of the physical particle is differentiated, then v can be obtained by differentiating the distance of the particle's motion per unit time, as shown in Eq. (12).

$$\begin{cases} A_p(1) = cos\alpha = \dfrac{V_p(1) \cdot V_p(2)}{V_p(1) * V_p(2)} \\ A_p(2) = cos\alpha = \dfrac{V_p(1) \cdot V_p(3)}{V_p(1) * V_p(3)} \\ A_p(3) = cos\alpha = \dfrac{V_p(3) \cdot V_p(2)}{V_p(3) * V_p(2)} \end{cases} \tag{11}$$

$$v = \lim_{\Delta t \to 0} \frac{y_{t+1} - y_{t-1}}{2\Delta t} \tag{12}$$

In Eq. (12), t represents the motion time. The FRNM is stacked as a geometric manifold $F \times H \times W$. F represents the frames. H represents length. W represents the width. Finally, P3DJMV and FRNM are fused and input into the prediction network. The research constructs the model based on 2D ResNet18. Its spatial down sampling remains unchanged. The first layer convolution is used to update the weights of each P3DJMV vector. In the spatio-temporal feature learning stage, each construction layer undergoes batch normalization and activation functions [20]. Finally, the two proposed features are fused after the fully connected layer. The research constructs a basketball motion recognition model based on perspective invariant geometric features extracted from skeleton data, as shown in Fig. 6.

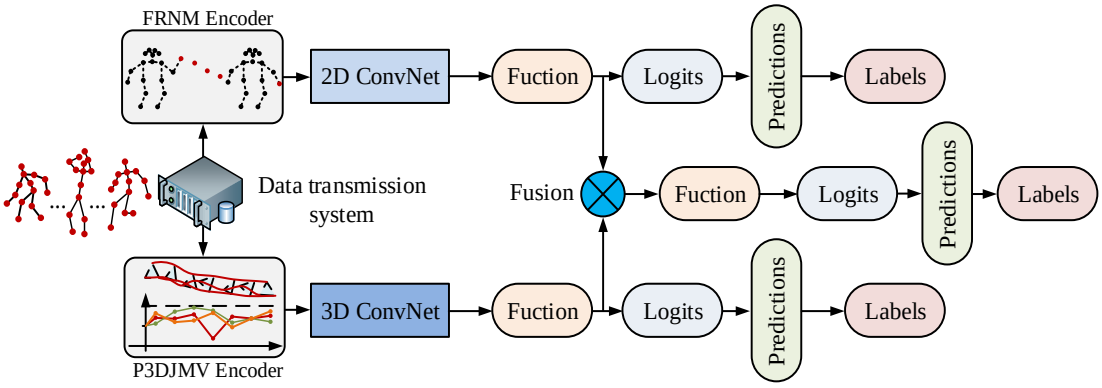

Fig. 6. Basketball movement recognition model based on skeleton data.

IV. Experimental Analysis

To improve the basketball motion recognition performance, the research proposed the basketball motion recognition model based on perspective invariant geometric features extracted from skeleton data. The dynamic topology map of the human skeleton was constructed to provide better output for recognition models. Then, a basketball motion recognition model based on perspective invariant geometric features was designed. To verify the effectiveness, test experiments were designed on datasets and real environments. The experimental results were analyzed.

A. Test Results in the Dataset

The dataset used in the experiment was two publicly available large-scale behavior recognition datasets, Kinetics and NTU RGB+D. Kinetic was a human behavior dataset that contained 300000 edited videos and 400 types of actions. The basketball movement segments were divided into training sets and validation sets. The second generation Kinetics depth sensor collection constituted the NTU RGB+D collection, with a total of 56000 edited action videos. To verify the validity of the research method, the experiments were conducted in the same environment. In the software architecture of the experimental system, this study

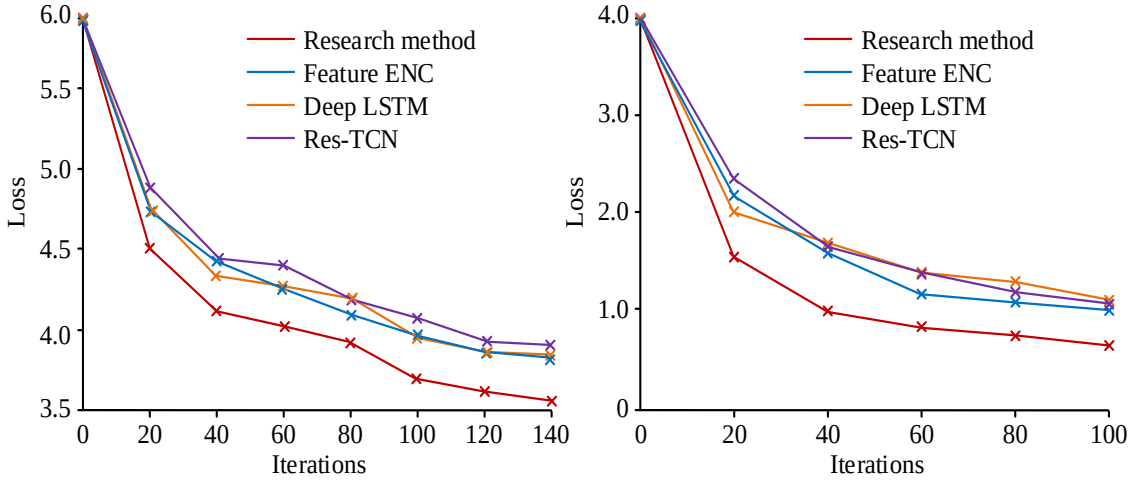
implemented five core modules, which were the Hikvision video capture module, the Noiton motion capture module, the Kinect somatosensory camera module, the Linux-based WiFi data acquisition module, and the synchronization control system used to coordinate these modules. Except for the Linux-based WiFi data acquisition module, all other modules ran on Windows 10 operating system. The research utilized the TCP/IP protocol to communicate with various collection subsystems, achieving data collection and storage operations. After precise testing, the system could ensure that the message synchronization error was within 100 milliseconds. In addition, the each acquisition module was flexible, which could work together on multiple hosts as well as operate independently. It enhanced the adaptability and reliability of the system. The experimental hardware environment was shown in Table I.

TABLE I. INTRODUCTION TO EXPERIMENTAL ENVIRONMENT

Name	Configuration Introduction
CPU	Intel Core i9-10920X CPU@3.50 GHz
GPU	NVIDIA1 GeForce RTX 3080Ti
Running memory	32GB
Operating system	Windows 10
Programming Language	Python
Development environment	Anaconda 3+python 3.6+pytorch 1.9

Top-1 and Top-5 classification accuracy were applied to evaluate recognition performance. The Top-1 indicator represented the probability that the first ranked category in the predicted category score vector was a true category. The Top-5 indicator represented the probability that the top five categories in the predicted category score vector contained the correct category. The proposed methods were compared with advanced methods, including Feature Encoding (Feature ENC) [21], Deep LSTM based on Recurrent Neural Network (RNN) [22], and Residual Temporal Convolutional Network (Res-TCN) based on Convolutional Neural Network (CNN) [23]. Among them, Feature ENC could effectively extract and encode key features, which improved the model's ability to recognize complex action patterns. The method demonstrated excellent performance in dealing with different types of action data, which was crucial for identifying diverse and complex basketball motions. Deep LSTM was suitable for dealing with time-series data. It combined the spatial feature extraction ability of CNN with the advantages of time series data processing. The residual network structure could avoid the gradient vanishing problem in deep network training, which represented the most advanced technology currently used to handle complex action sequences. The performance of different algorithms during training iterations was shown in Fig. 7.

Fig. 7 (a) showed the iterative loss curve on the Kinetics dataset. From the graph, the method proposed in the research showed significant differences from the other three methods after 20 iterations. The proposed method achieved lower loss values with faster iteration speed. When the iterations were 140, the loss of the research method was 3.52. The loss values for Feature ENC, Deep LSTM, and Res-TCN were3.85, 3.89, and 3.98, respectively. Fig. 7 (b) showed the iterative loss curve on the NTU RGB+D dataset. From the graph, the method demonstrated better performance after 20 iterations. When the iterations were 100, the loss value was 0.82. The other three methods were 1.18, 1.32, and 1.26, respectively. The results on the test set demonstrated the effectiveness of this method. The Top-1 indicator results of different algorithms were shown in Fig. 8.



(a) Kinetics dataset (b) NTU RGB+D dataset

Fig. 7. Curve of loss value with number of iterations.

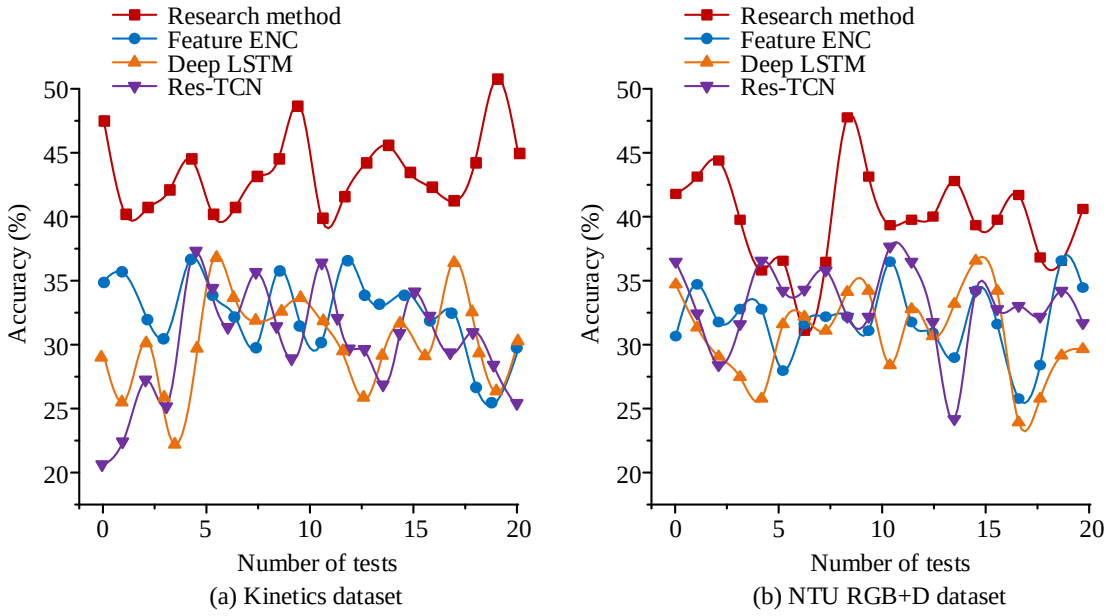


Fig. 8. Comparison results of Top-1 indicators.

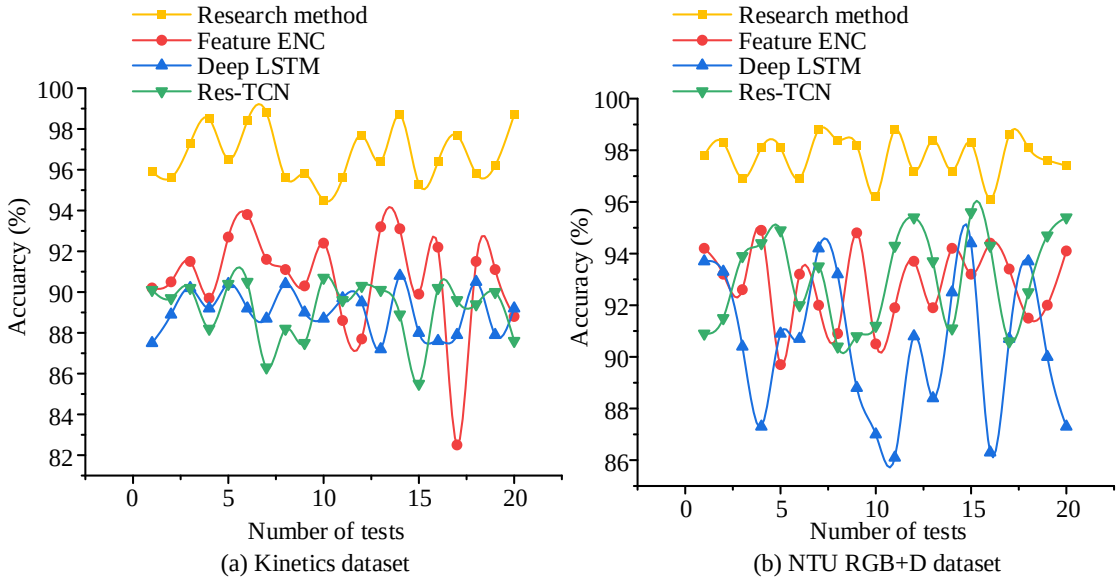

Fig. 9. Comparison results of Top-5 indicators.

Fig. 8 (a) showed the Top 1 standard accuracy. From the graph, the accuracy exceeded the other three methods. The average accuracy of the method in 20 tests was 43.52%, while the other three methods were 30.85%, 29.65%, and 27.34%, respectively. Fig. 8 (b) showed the Top 1 standard accuracy on the NTU RGB+D dataset. From the graph, the accuracy was higher than the other three methods in most tests. The average accuracy of the method in 20 tests was 40.52%. The other three methods were 34.12%, 32.07%, and 31.67%, respectively. From the experimental results, the research method had higher accuracy. The performance on the Kinetics dataset was superior to that on the NTU RGB+D dataset. The Top-5 indicator results of different algorithms were shown in Fig. 9.

Fig. 9 (a) showed the Top-5 standard accuracy on the Kinetics dataset. From the graph, the accuracy exceeded the other three methods. The average accuracy in 20 tests was 97.85%. The other three methods were 90.81%, 89.95%, and 89.27%, respectively. Fig. 9 (b) showed the Top-5 standard accuracy on the NTU RGB+D dataset. The accuracy also exceeded the other three methods. The average accuracy in 20 tests was 97.82%. The other three methods were 92.08%, 90.11%, and 91.73%, respectively. From the experimental results, compared to the current advanced three methods, the proposed method significantly improved the accuracy of the Top-5 evaluation index, verifying the effectiveness of this method.

B. Real Environment Application Analysis

To evaluate the performance of the basketball motion recognition model based on perspective invariant geometric features extracted from skeleton data in real environments, it performed motion recognition experiments on 80 volunteers. This study first used a confusion matrix to evaluate the performance of the basketball motion recognition model. The confusion matrix displayed the correspondence between the recognition results of each category and the actual results. It helped to understand the performance of basketball action recognition models in different categories, such as which categories were accurately identified and which categories were easily confused. By analyzing the confusion matrix, the researcher could identify and improve the weaknesses of the model, such as increasing the recognition rate or reducing misclassification. The research divided basketball motions into six categories, including shooting, dribbling, layups, passing, and grabbing the board. It performed 280 recognition tests for each action category. Fig. 10 displayed the test results.

Fig. 10 (a) showed the recognition results of the research method. The average correct recognition quantity for each category was 269.6. The expected correct recognition quantity was 280. Therefore, the average accuracy of the research method was 96.3%. Fig. 10 (b) displayed the recognition results of Feature ENC. The average correct recognition quantity for each category of Feature ENC was 247.8. The expected correct recognition quantity was 280. Therefore, the average accuracy of Feature ENC was 88.5%. Fig. 10 (c) showed the recognition results of Deep LSTM. The average correct recognition number for each category in Deep LSTM was 249.2. The expected correct recognition number was 280. The average accuracy of Deep LSTM was 89.0%. Fig. 10 (d) showed the recognition results of Res-TCN. The average correct recognition number for each category in Res-TCN was 240.4. The expected correct recognition number was 280. The average accuracy of the research method was 85.86%. From Fig. 10, the correctly identified color bands in research methods had darker colors, while the incorrectly identified color bands had lighter colors. This indicated that it still outperformed the other three advanced methods in real-world testing. To further validate the performance of the proposed model, the study increased the number of experiments to 20 and used recall rate as an indicator. The recall rate was the proportion of positive category samples (e.g., a specific basketball action) correctly recognized by the model to all actual positive category samples. This metric was particularly important for evaluating the recognition ability. The results were shown in Fig. 11.

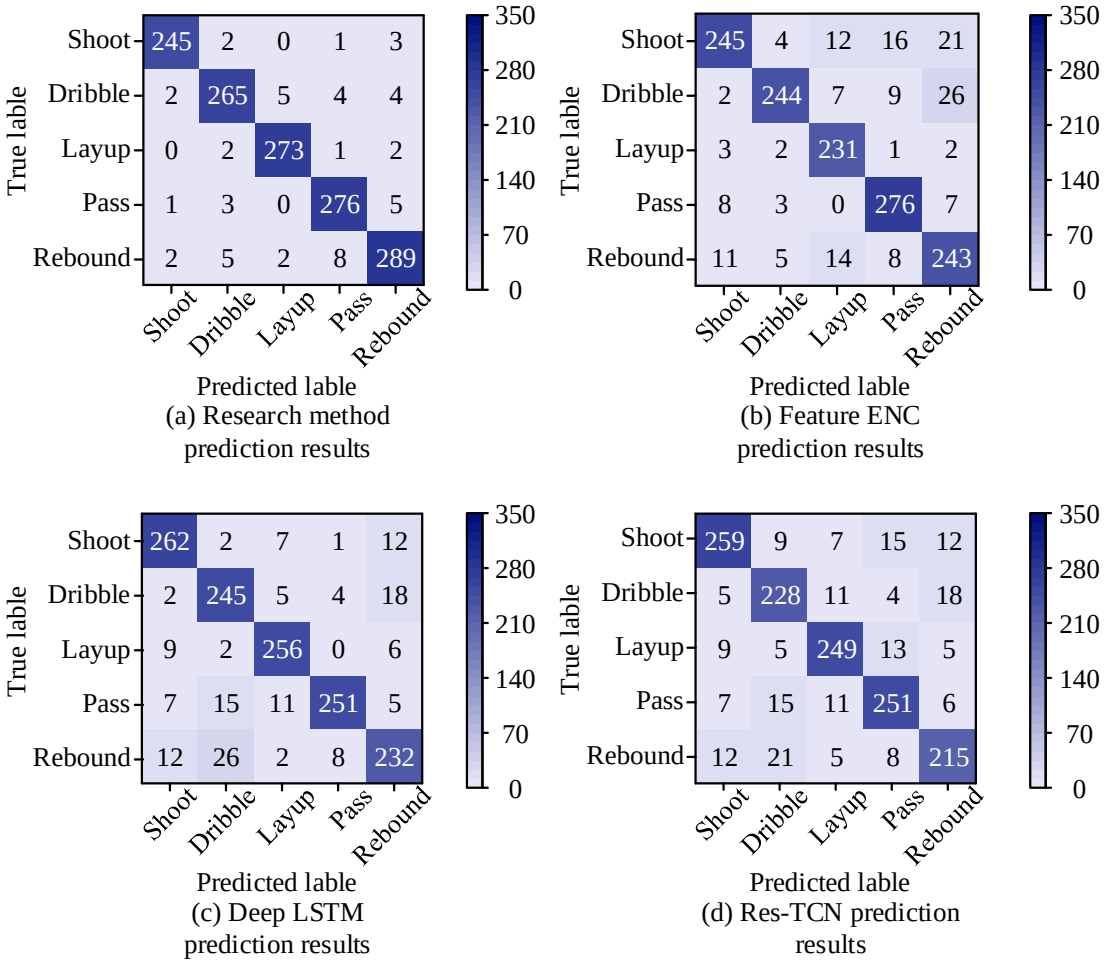

Fig. 10. Results of basketball motion recognition using different methods.

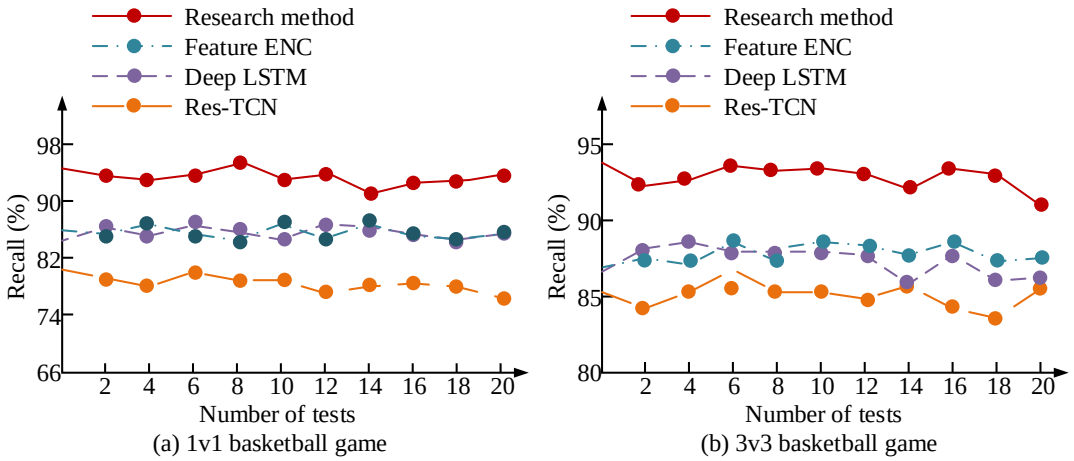

Fig. 11. Comparison of recall of different methods.

Fig. 11(a) showed the action recognition results in 1-to-1 basketball game. The recall of the research method was significantly higher than that of the other three methods. In 20 tests, the average recall rate was 96.35%, while the average recall rate of the other three methods was below 90%. Fig. 11(b) showed the action recognition results in 3-to-3 basketball game. The average recall of the research method reached 94.02% in 20 tests. The average recall of the other three methods was below 90%. From the recall experiments, the recognition performance of the constructed model was significantly better than other methods in different environments. Finally, to verify the computational complexity, the research compared the running times of the four recognition models. The results were shown in Fig. 12.

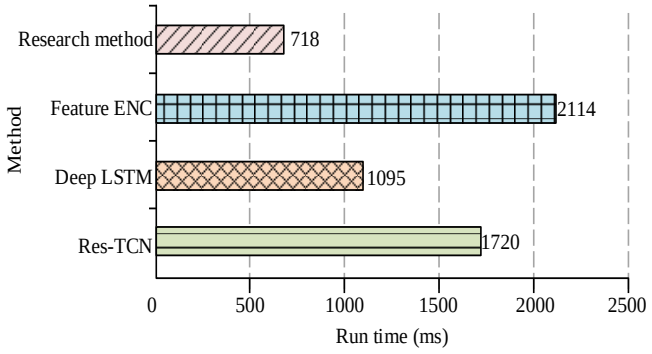

Fig. 12. Comparison of runtime of different recognition methods.

In Fig. 12, the running time of the research method was 718ms. The Feature ENC was 2114ms. TheDeep LSTM was 1095ms. The Res-TCN was 1720ms. Compared to the other methods, the running time of the proposed method was decreased by 66.03%, 34.43%, and 58.26%. According to the results, the basketball motion recognition model based on perspective invariant geometric features extracted from skeleton data had faster recognition speed.

V. Conclusion

To improve the utilization of human bone data and build a more accurate and efficient basketball motion recognition model, the study first constructs a dynamic topology map of human skeleton. Then it serves as input to the recognition model, thereby removing interference from environmental information. Then, based on the perspective invariance in skeleton data extraction, the study proposes two feature representation methods, namely the 3D joint motion vector plane and the feature representation method based on node momentum. By fusing two feature representations, the spatio-temporal feature fusion of skeleton data is achieved, thus constructing a new basketball motion recognition model. In real-world testing, the proposed method had an average accuracy of 96.3% for each category. The average accuracy of Feature ENC was 88.5%. The average accuracy of Deep LSTM was 89.0%. The average accuracy of Res-TCN was 85.86%. The results validated the effectiveness of this research. It demonstrated excellent performance in experiments. However, this research experiment uses single-mode data. Therefore, the recognition effect of multimodal data has not been verified yet. In the future, this method will be further optimized. Combined with other advanced machine learning technologies, this method will be improved to achieve better performance in a wider range of application scenarios.

Application of Data Mining Technology with Improved Clustering Algorithm in Library Personalized Book Recommendation System

Xiao Lin*, Wenjuan Guan, Ying Zhang
Library, Minjiang University, Fuzhou 350108, China

***Abstract*—The information construction work of university libraries is becoming increasingly perfect. However, the massive amount of data poses significant challenges to the personalized recommendation of books. Cluster analysis has always been an important research topic in data mining technology, and it has a wide range of application fields. Clustering algorithm is a fundamental operation in big data processing, and it also has good application value in personalized recommendation of library books. To improve the personalized service quality of libraries, this study proposes a clustering algorithm based on density noise application spatial clustering. This study introduced a distance optimization strategy and Warhill algorithm to the proposed algorithm, to improve the difficulties in selecting initial parameter neighborhoods and density thresholds in traditional models, as well as computational complexity. Afterwards, this study will integrate the improved algorithm with the density peak algorithm to further improve the operational efficiency of the model. The performance verification of the model demonstrated superior clustering performance. The average accuracy of the proposed model's recommendation is 98.97%, indicating superiority. The practical application results have confirmed that there is a significant similarity between the books read by the readers and the books read by the target readers, and the effectiveness and feasibility of the proposed model have been verified. Therefore, the proposed model can contribute to the personalized recommendation function of libraries and has certain practical significance.**

***Keywords*—Peak density; distance optimization; warhill algorithm; collaborative filtering; book recommendations**

I. Introduction

At present, the informatization work of university libraries has made great progress, but there are still problems such as too long time spent in retrieving information and documents [1]. There are a lot of library resources in university library, and there are a lot of data, which is easy to cause college students to blindly choose books in university library or do not know which books are suitable for them to read. Therefore, more and more attention is paid to the personalized recommendation of university library. At the same time, the development of artificial intelligence has brought new opportunities to the topic. Among them, the traditional intelligent data analysis methods mainly collect and analyze users' browsing records and information, excavate and analyze the collection of documents and resources, and realize the utilization of library resources [2]. However, large amounts of data often have more complex structures and types, which makes it difficult for traditional data analysis methods to meet these needs [3]. Cluster analysis is the most commonly used method in data mining [4]. Through cluster analysis, data with high similarity can be classified into the same category, so that the difference between similar data is small, and the difference between different data is large. In addition, the existing book recommendation algorithms generally have the disadvantages of low recommendation accuracy and poor applicability in university libraries [5]. Therefore, in order to help college students more accurately find their own suitable books in college libraries, this study is based on cluster analysis in data mining. This paper proposes a Density-Based Spatial Clustering of Applications with Noise, The Clustering model of DBSCAN and Density Peak Clustering Algorithm (DPC) is proposed to optimize the personalized recommendation performance of books in university libraries. The innovations of this study lie in: (1) The distance optimization strategy was proposed, which improved DBSCAN and improved the difficulty in selecting its initial parameters. (2) Warhill was introduced to reduce the computational complexity of the model. (3) The improved DBSCAN was integrated with DPC to further improve the operational efficiency of the model. (4) The constructed model was applied in the personalized book recommendation service of library. This study consists of four parts: (1) Firstly, a review was conducted on the current development status of technologies used in the article. (2) The construction process of the model was discussed in detail. (3) The model performance and practical application effects were verified. (4) The full text was summarized and prospects were made for the future.

II. Related Works

The application of CA is quite extensive and has always been a hot topic of discussion among scholars. DPC is unable to identify cluster centers and non-center point error allocation, which can cause a chain reaction. Therefore, DingS et al. proposed an improved method. This method can reduce the density difference of non-uniformly distributed datasets and use low density points as boundaries on the foundation of cluster center and surrounding points' similarity density. The proposed model can make algorithm's clustering accuracy improved while controlling running time [6]. CuiZ and other researchers proposed an improved subspace clustering model to address the shortcomings of subspace clustering methods that cannot balance the sparsity and connectivity of coefficient matrices in high-dimensional image data. This model can preserve the coefficients between the sample and its neighbors,

and prune the spatial connections within the subspace. The proposed model can effectively handle noise data in the Internet of Things and has good clustering accuracy [7]. KarimM and other scholars have conducted a detailed discussion on deep learning based clustering algorithms and pointed out different clustering quality indicators. This study utilizes the clustering methods discussed for text mining in bioimaging, cancer genomics, and biomedical texts. The final conclusion helps to provide new solutions for emerging bioinformatics problems [8]. Incomplete multi view CA methods can lead to intensive computation and complex storage. In response, researchers such as LiuX have proposed an efficient incomplete multi view method. This method utilizes consensus clustering matrix to interpolate the generated incomplete base matrix to optimize the clustering performance of the model. This study validates the performance of the proposed model in terms of clustering accuracy, evolution of consensus clustering matrix, and convergence [9]. Based on the application of CA in data mining, ZouH elaborated in detail on the basic concept, classic algorithms, and implementation process of CA through literature comparison and analysis methods. The study ultimately conducted numerical simulations, confirming the strong universality of the proposed method. It can be applied to data analysis in multiple fields and has strong theoretical value [10].

Personalized recommendation services have received increasing attention in recent years, and many scholars have contributed to this. Researchers such as ArabiH have found that contextual information such as emotions, location, and time can help improve service recommendations. Therefore, they proposed a context aware recommendation system. The system implements personalized settings based on multiple user characteristics and product functions. It utilizes users' personality traits, demographic details, geographical location, and comment emotions to generate personalized recommendations. This algorithm was ultimately proven to greatly optimize recommendation performance [11]. Scholars such as HuixiangX use K-means and utilize the relationships between users, tags, and books for group recommendations. The proposed strategy first clusters users and books, and calculates the cosine similarity between the two groups. Afterwards, it sorted and clustered the books, and tested the personalized recommendation effect. The proposed model improves the recommendation effect of books and provides better book resources for the target group [12]. SarmaD et al. constructed an effective online book recommendation system to address the irrationality of existing recommendation system rating techniques. The system uses the K-means cosine distance function to measure distance to find similarity between book clusters and grade books. The experiment used 10 datasets to validate the proposed model, indicating that the constructed recommendation system has high accuracy [13]. ZhouY has designed an information recommendation book management system based on an improved Apriori data mining algorithm, which integrates borrower and book data information. After cleaning, transforming, and integrating the relevant data, the Apriori algorithm is used to generate an association rule database. The implementation process of association matching is carried out by the personalized recommendation sub module based on the borrower and the books selected in the association rule database. The proposed model has good recommendation performance [14]. KwakW and NohY analyzed their domestic and international trends, policies, and cases based on the development background of artificial intelligence, and proposed the future direction of artificial intelligence services for libraries. This study suggests that in the future, libraries will further optimize artificial intelligence and provide personalized book recommendations to users based on their usage records [15].

To sum up, cluster analysis plays an important role in personalized recommendation. Although cluster-based algorithms have always been favored and improved by scholars, there are still some problems that need to be continuously studied and perfected by scholars. In addition, the existing recommendation services widely exist in e-commerce, short video and other platforms, and there is still a large research space for personalized recommendation of college books. In addition, the existing book recommendation algorithms also have the disadvantages of low recommendation accuracy and poor applicability in university libraries. Therefore, this study proposes a clustering algorithm combining DBSCAN and DPC, and applies it to the book recommendation system, aiming at contributing to the personalized recommendation service of libraries.

III. A Book Recommendation Model Based on Improved DBSCAN and DPC

Traditional DBSCAN has many limitations. Therefore, this section first optimizes and improves it. Then it is integrated with DPC to better achieve the clustering performance and book recommendation effect.

A. Construction and Improvement Strategy of DBSCAN

DBSCAN is the most classic density based CA. DBSCAN adopts the concept of neighborhood and utilizes the spatial distribution characteristics of point sets to cluster the dataset [16]. The basic idea is to determine the number of neighboring data points under a certain threshold, centered around a single data point. Using sparse points as the boundary, low density data points are used as the classification boundary, and high density points are used as another class [17]. Compared with other clustering algorithms, DBSCAN can find clusters of different sizes and shapes under conditions of noise interference. The full name of DBSCAN is "Density-Based Spatial Clustering of Applications with Noise", which is characterized by its ability to effectively process noisy data. Compared with conventional CA, DBSCAN not only handles non convex data well, but also fits convex datasets well. DBSCAN includes elements such as neighborhood, density threshold, core points, boundary points, and outliers. It is assumed that the sample dataset is $S=\{x_1,x_2,\cdots,x_n\}$, $x_i \in S$, and the neighborhood is δ. All sample points in the neighborhood form a subsample set and meet the conditions shown in Eq. (1).

$$N_\delta(x_j)=\left\{x_j \in S \middle| dis\tan ce(x_i,x_j)\le\delta\right\} \quad (1)$$

Eq. (1) represents the conditions that need to be met for the

sub sample set in the hypersphere region with a radius of δ. The density threshold in DBSCAN can be manually set. According to the relevant elements of DBSCAN, there are three relationships between data points in the overall algorithm: density direction, density reachability, and density connection [18-19]. Among them, the meaning of density direction is: for two samples that exist in the domain, if one is the core object, the other sample is called density direct access by that sample. The meaning of density reachability is: for x_i and x_j, if there is a sample sequence $\left\{p_t \middle| t=1,2,\ldots,T\right\}$ that satisfies $p_1=x_i, p_T=x_j$, and p_{t+1} is directly reachable by p_t density, then x_j is said to be reachable by x_i density. At this point, the samples in the sequence are all core points, which means that the density can satisfy transitivity but not symmetry. The meaning of density connection is: for x_i and x_j, if there is a core point x_k, so that both x_i and x_j can be reached by x_k density, then x_i and x_j are called density connections. Fig. 1 shows the schematic diagram of DBSCAN. x_1 and x_2 are the core points. x_3 and x_4 are boundary points. x_2 is directly accessible through x_1 density. x_3 is directly reached by x_2 density. x_4 can be achieved by x_1 density. x_4 and x_3 are density connected.

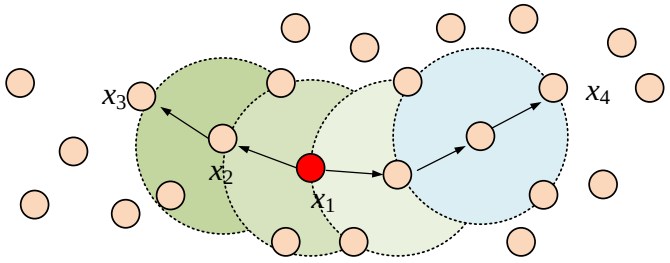

Fig. 1. DBSCAN clustering process.

Compared with other clustering methods, DBSCAN has the following advantages. Firstly, it can handle dense data of any shape. Due to its ability to find and remove noise throughout the entire search process, the clustering process is not affected by sample set noise. Its clustering does not require specifying the number of clusters in advance, and the clustering results are unbiased. However, the classic DBSCAN also has significant drawbacks that cannot be ignored. In DBSCAN, it is difficult to choose the initial parameter neighborhood and density threshold. DBSCAN is not suitable for samples with uneven distribution and large distances, in which case the clustering results are not ideal. For high-dimensional sample sets, the convergence speed of clustering algorithms is slow and cannot achieve accurate clustering results [20-21]. Therefore, this study first proposes optimization for the parameter selection process of DBSCAN, namely a DBSCAN model based on distance optimization (D-DBSCAN). D-DBSCAN can automatically select neighborhood values based on the characteristics of initial density threshold and data distribution density. Assuming the sample set is $S=\left\{x_1,x_2,\cdots,x_n\right\}$, there is Eq. (2).

$$N\left(x_i\right)=\left\{x_j\in S \middle| 0<d\left(x_i,x_j\right)<\delta\right\} \tag{2}$$

Eq. (2) indicates that for $x_i\in S$, the density of x_i is the number of data points owned within the domain δ. Eq. (3) is the distance coefficient.

$$\theta=N\left(x_j\right)/N\left(x_i\right) \tag{3}$$

In Eq. (3), θ is the distance coefficient, which specifically means that for the sample point x_j within the neighborhood of core point x_i, it is called the distance coefficient of x_j to x_i. Eq. (4) is the distance matrix between samples.

$$D=\left\{D_{ij} \middle| i,j\in R,\ i\neq j\right\} \tag{4}$$

In Eq. (4), D_{ij} represents the distance between samples x_i and x_j. The average distance of the points with the closest density threshold to x_i was calculated and added to the distance set U to calculate the overall average $\overline{U}$ of U. The neighborhood radius was set as the average distance $\overline{U}$, and all core points were identified and added to the core object set Ω. Subsequently, a core point x_i was randomly selected as the clustering center to form a new cluster C_i. All sample points in the δ neighborhood near x_i were identified, and the neighborhood radius δ was adjusted by calculating distance coefficient θ between the sample and core points. By repeating the above operation to find all sample points with achievable density and adding them to C_i, the final result was obtained in Eq. (5).

$$C=\left\{C_1,C_2,\cdots,C_n\right\} \tag{5}$$

Thus, D-DBSCAN can effectively improve the selection of initial parameters. To further reduce the complexity of D-DBSCAN calculation, Warhill was introduced to construct W-D-DBSCAN. Warhill can calculate reachable matrices to reduce the complexity of the model. It is assumed that Eq. (6) is a directed graph.

$$G=\left\langle V,E\right\rangle \tag{6}$$

In Eq. (6), V represents the node set. E refers to an adjacent points set. The node set is $V=\left\langle v_1,v_2,\cdots,v_n\right\rangle$. The matrix is $A=\left(a_{ij}\right)_{m\times n}$.

$$a_{ij}=\begin{cases}1, & v_i\ adjoin\ v_j\\ 0, & v_i\ is\ not\ adjacent\ to\ v_j\end{cases} \tag{7}$$

A directed graph can directly reflect two elements' connection. An adjacency matrix refers to nodes' connection in the directed graph. The two nodes that can be directly reached are regarded as 1. Otherwise, they are regarded as 0. It is

assumed that $G=\langle V,E\rangle$ is a simple directed graph. The node set is $V=\langle v_1,v_2,\cdots,v_n\rangle$. The matrix is $F=\left(f_{ij}\right)_{n\times n}$.

$$f_{ij}=\begin{cases}1, \text{There is a non-zero directed path from } v_i \text{ to } v_j\\ 0, \ others\end{cases} \quad (8)$$

If there is a reachable path between two elements, they are connected and reachable, marked as 1, otherwise marked as 0. In a directed graph, the connectivity between nodes can be directly reflected by a line with an arrow. However, it is difficult to determine the connectivity between two independent nodes, and a matrix of direct connectivity must be used. Usually, Warshall is used to convert adjacency matrices into reachable matrices. $dis[i,j]$ stands for the distance. A matrix $A_{n\times n}$ was established for dataset D and $dis[i,j]$ between data objects i,j was calculated in Eq. (9).

$$A[i,j]=\begin{cases}1, dis[i,j]\le Eps\\ 0, dis[i,j]>Eps\end{cases} \quad (9)$$

In Eq. (9), Eps represents the initial threshold. The adjacency matrix's reachable matrix obtained by Warhill is regarded as transitive closure or density connected sets which are the maximum. Fig. 2 shows the flowchart of W-D-DBSCAN. The density connected set obtained by Warhill is to achieve clustering. Compared with traditional density clustering, its clustering process is simpler.

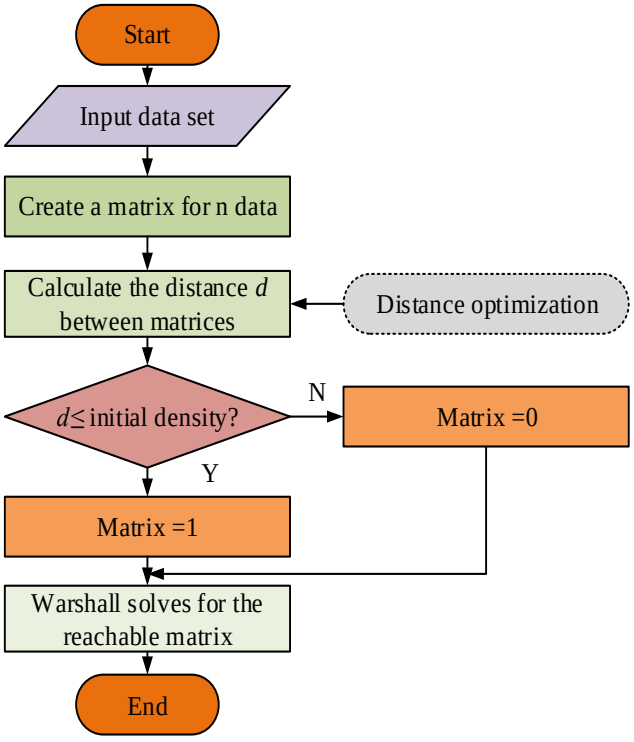

Fig. 2. Flow of the W-D-DBSCAN algorithm.

B. A Book Recommendation Model Integrating D-W-DBSCAN and DPC

DPC is a data clustering method based on maximum connectivity, which not only effectively distinguishes noise, but also has strong robustness for various convex and non-convex data [22-23]. DPC assumes that the centroid of data targets set is surrounded by a low-density data, and this low-density data is assigned to the nearest, less dense centroid data. DPC improves the efficiency of the algorithm and has good clustering performance by manually drawing decision maps and selecting data objects with high relative distance and density for clustering. On this basis, a new method of clustering quality centers based on DPC is proposed. This study adopts a combination of W-D-DBSCAN and DPC, namely the W-D-DBSCAN DPC model, to solve the problem that the centroid selected by DPC on the decision graph cannot be applicable to all data. This method first uses the maximum region density value as the centroid. Secondly, W-D-DBSCAN was used for clustering. Then, samples with high local density were searched out from the remaining samples, and the samples were clustered using W-D-DBSCAN as the center. The above methods were used to search for centroids and cluster them until all data were classified or local noise appeared, indicating the completion of clustering. This method can effectively solve the manual intervention problem in traditional DPC methods, while also reducing the computational complexity of W-D-DBSCAN.

Assuming any data object is i, the local density was calculated for it in Eq. (10).

$$\rho_i=\sum_j \chi\left(d_{ij}-d_c\right) \quad (10)$$

In Eq. (10), ρ_i represents local density. d_c represents truncation distance. d_{ij} represents relative distance. The relative distance between other data and data i was calculated using Euclidean distance in Eq. (11).

$$\sigma_i=\min_{J:\rho_j>\rho_i}\left(d_{ij}-d_c\right) \quad (11)$$

In Eq. (11), d_{ij} represents i and j's Euclidean distance. Through Eq. (11), the relative distance of data i refers to: if i is the largest data object of ρ_i, then σ_i represents the $\max_j\left(d_{ij}\right)$ between other data and data i. If i has no the highest local density, its relative distance is in the data with lower local density than the data, and it is closest to i. Fig. 3 shows the clustering process of W-D-DBSCAN-DPC [24].

In Fig. 3, the comprehensive model first calculates the local density. Then, they are compared to get the maximum local density, with data 7 of this maximum local density as the centroid. Starting from 7, W-D-DBSCAN was used to divide 1, 2, 3, 4, 5, and 6 into centroid data, completing the classification of the first type of cluster. Then, the local density of the remaining dataset was continued to be calculated. And the maximum local density was obtained through comparison again. Using the highest local density value of 10 as the centroid, W-D-DBSCAN was used to

cluster samples 8, 9, 11, and 12, and data 8, 9, 11, and 12 were divided into centroids 10. This process continues until the remaining data does not belong to a category, marked as noise, and clustering ends [25].

This study applies W-D-DBSCAN-DPC to the clustering process of library readers. By categorizing different categories of readers, the first category in the database is the book that the reader is most interested in. Therefore, recommending the first category of books to readers is a desirable approach. The recommendation algorithm of W-D-DBSCAN-DPC effectively solves the traditional "cold start". This method will help improve the performance of recommendation systems and alleviate the pressure of big data processing. Fig. 4 shows the system diagram of the library book recommendation system. W-D-DBSCAN-DPC is used to classify readers with high similarity. By compressing the existing massive reader data into analyzing and recommending the same type of reader data, the recommendation efficiency was improved. The collaborative filtering algorithm is used to generate the Top-n nearest neighbor set of readers, thereby completing recommendations.

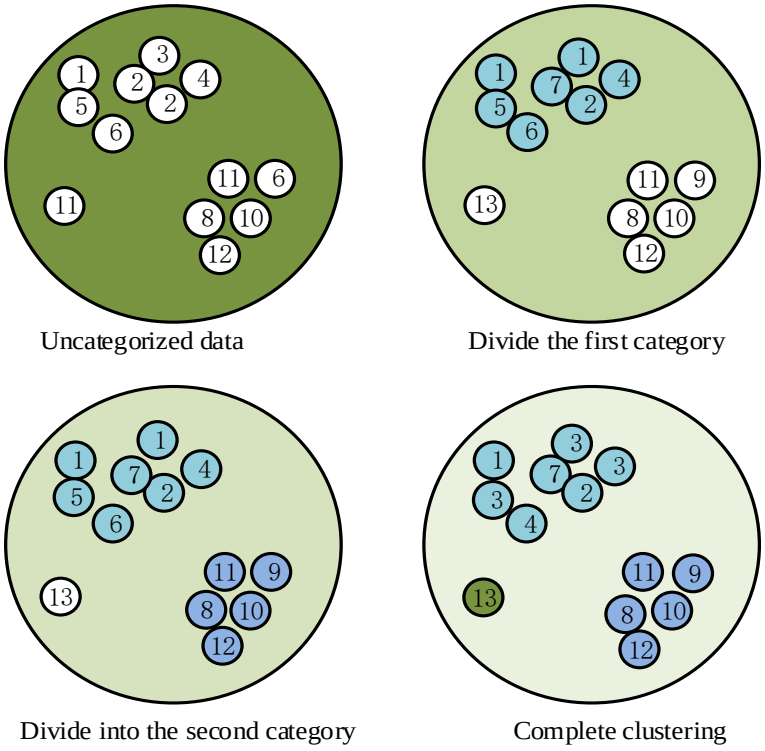

Fig. 3. Clustering process of W-D-DBSCAN-DPC.

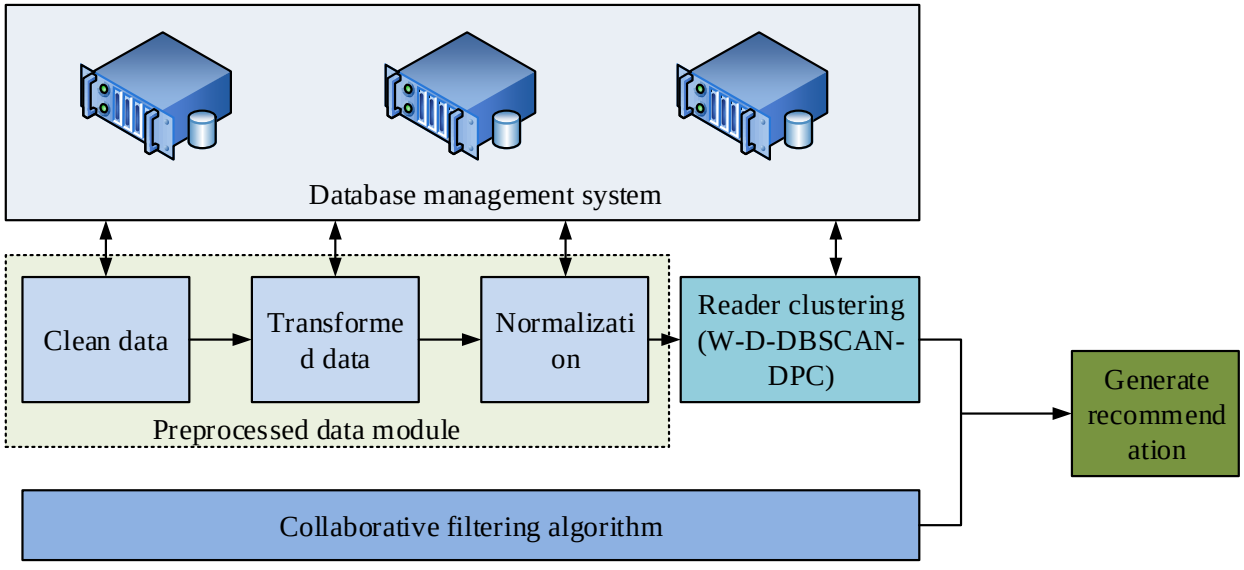

Fig. 4. Library book recommendation system.

This study used W-D-DBSCAN-DPC to cluster readers, identify the most popular books, and recommend them to new readers to solve the "cold start" problem. Adopting this method for users with a reading history reduces the range of data that the recommendation algorithm needs to process and reduces the problems that users may encounter during the reading process. If the target reader has a historical borrowing record, then based on its clustering results, a collaborative filtering algorithm is used to obtain the Top-n neighbor set for other readers of the same type and recommend them. The similarity between the target reader and the reader is calculated by Eq. (12).

$$sim(i,j)=\frac{\sum_{u\in U_{ij}}\left(R_{u,j}-\overline{R_i}\right)\left(R_{u,j}-\overline{R_j}\right)}{\sqrt{\sum_{u\in U_{ij}}\left(R_{u,j}-\overline{R_i}\right)}\sqrt{\sum_{u\in U_{ij}}\left(R_{u,j}-\overline{R_j}\right)}} \quad (12)$$

In Eq. (12), $sim(i,j)$ represents the similarity between readers i,j. U_{ij} represents the book categories that readers i,j are both interested in. $\overline{R_i}$, $\overline{R_j}$ represent the average values of readers i,j's interest in all books. By using Eq. (12), the similarity between the target reader and the reader can be obtained, and the similarity sequence can be obtained by sorting their similarity. Then, the Top-n neighbor set is generated from the high similarity readers. Therefore, the book recommendation model based on W-D-DBSCAN-DPC has been constructed.

To evaluate the clustering effect, Accuracy (ACC), Purity, and contour coefficient were introduced as evaluation indicators in this study. Eq. (13) is the calculation of ACC.

$$ACC=\left(\sum_{i=1}^{n}\delta\left(\hat{C}_i map\left(C_i\right)\right)\right)/n \quad (13)$$

In Eq. (13), C_i represents the category label of the proposed algorithm. $\hat{C}_i$ represents the true label of data object. $map(x)$ represents a mapping function. A high ACC value indicates high clustering quality. Eq. (14) represents the calculation of Purity.

$$purity=\frac{1}{N}\sum_{i=1}^{k}x_i \quad (14)$$

In Eq. (14), N represents the number of datasets. k represents the number of clusters in the dataset. x_i represents the number of correctly clustered data objects. Purity is within 0-1, which is closer to 1, the data clustering accuracy is higher. Eq. (15) is the calculation of contour coefficient.

$$S(X)=\frac{b(x)-a(x)}{\max\left(a(x),b(x)\right)} \quad (15)$$

In Eq. (15), $a(x)$ represents the average distance of other samples within the same cluster of sample x. $b(x)$ represents the average distance between sample x and all sample points within the nearest cluster. The range of contour coefficient values is $[-1,1]$, which is closer to 1, the clustering effect is better.

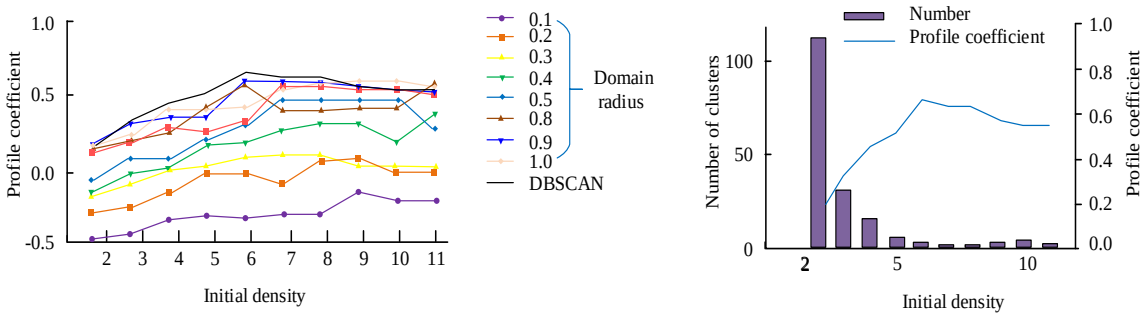
IV. Performance Verification of Book Recommendation Model Application Based on W-D-DBSCAN-DPC

This study first analyzes the clustering performance of W-D-DBSCAN-DPC. For this purpose, sufficient datasets were selected for the study and detailed discussions were conducted. In addition, the actual application effect of book recommendation was verified using a certain university as an example.

A. Performance Verification of W-D-DBSCAN-DPC Model

This study first verifies the clustering performance of the W-D-DBSCAN-DPC model. This study selected three datasets, namely Spiral, Lineblobs, and Aggregation, for validation. Spiral is a set of non-convex spiral datasets. Lineblobs is a set of smiling face datasets. Aggregation includes both spherical and non-spherical datasets. The proposed W-D-DBSCAN-DPC is implemented in C language and visualized using MATLAB. The proposed algorithm was evaluated and analyzed by comparing clustering results at different scales. To evaluate the clustering effect and determine the optimal number of clusters, this study used traditional DBSCAN and D-DBSCAN to cluster the dataset, and obtained the contour coefficients corresponding to different number of clusters in Fig. 5.

In Fig. 5 (a), DBSCAN requires continuous search of two parameters, namely initial value and neighborhood radius, in order to find the optimal solution. D-DBSCAN only needs to find the optimal solution under different initial density conditions, without adjusting the neighborhood radius. Fig. 5 (b) shows the number of class clusters and contour coefficients corresponding to different initial densities. At an initial density of 6, the D-DBSCAN contour coefficient reached its optimal value of 0.668. The contour coefficient of the DBSCAN method is 0.612. Compared with DBSCAN, the clustering performance of D-DBSCAN has improved by 9.17%. These results verify the effectiveness of distance optimization.



(a) DBSCAN profile coefficients at different initial densities and domain parameters

(b) D-DBSCAN Specifies the value of d-dbscan at different initial densities

Fig. 5. D-DBSCAN performance verification results.

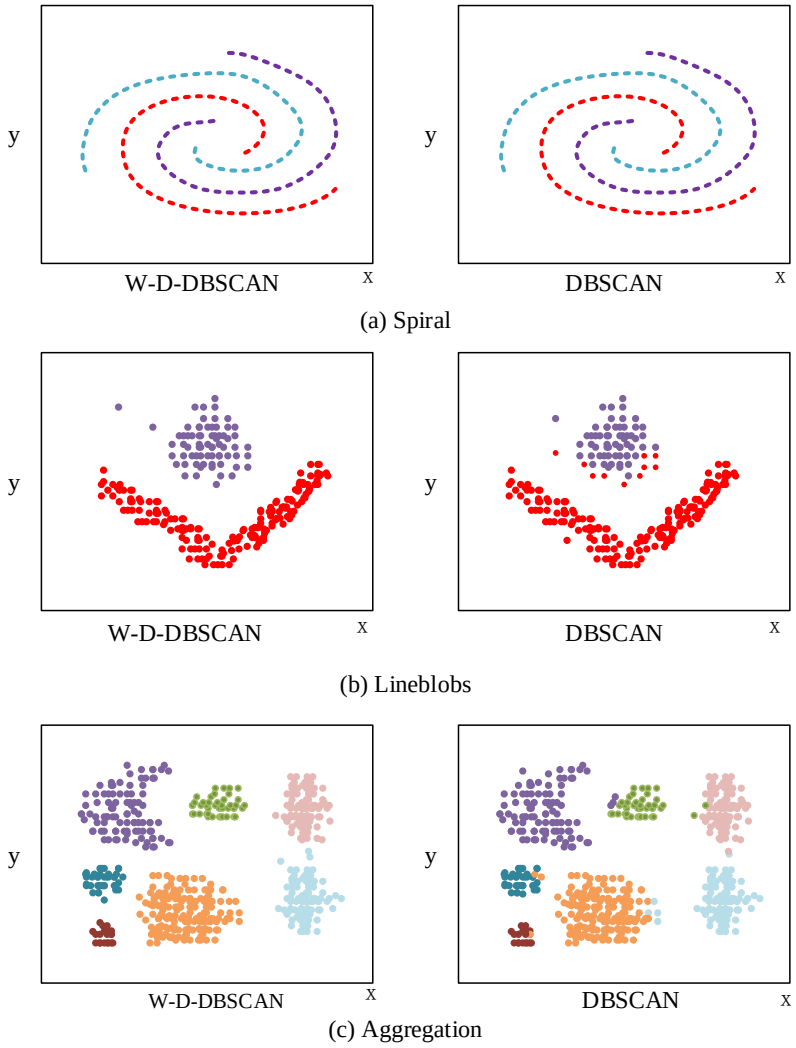


Fig. 6. Clustering results of D-DBSCAN and W-D-DBSCAN.

In Fig. 6, they are the clustering results of three datasets using two methods, D-DBSCAN and W-D-DBSCAN. In the figure, two algorithms' clustering effects on three types of datasets are relatively similar. Because W-D-DBSCAN continues the advantages of D-DBSCAN and can achieve clustering on any dataset.

Fig. 7 shows the comparison results of the runtime between D-DBSCAN and W-D-DBSCAN algorithms on a spiral dataset. The spiral dataset was generated into datasets with different shapes, sizes, and densities. And experiments were conducted on these datasets using D-DBSCAN and W-D-DBSCAN. In Fig. 7, W-D-DBSCAN has a shorter

runtime. As a result, W-D-DBSCAN effectively reduces the complexity of the model and improves its running speed.

To highlight the excellent performance of W-D-DBSCAN-DPC, this study selected four clustering algorithms: DPC, FCM, and K-means for comparative analysis. Fig. 8 shows the clustering performance of four algorithms on three datasets. In Fig. 8(a), K-means cannot cluster non-convex datasets, while the spiral shape of Spiral dataset is non-convex, resulting in clustering errors. In Fig. 8(b), the clustering results of W-D-DBSCAN-DPC and DPC are basically correct because they consider the transfer relationship between data. In Fig. 8(c), the clustering performance of W-D-DBSCAN-DPC is superior to other three algorithms.

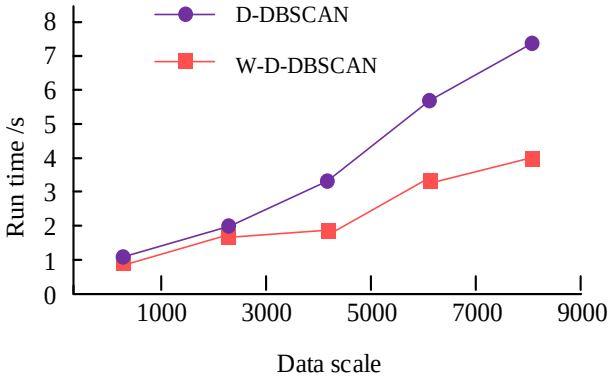

Fig. 7. Comparison of running time of the two algorithms on spiral data set.

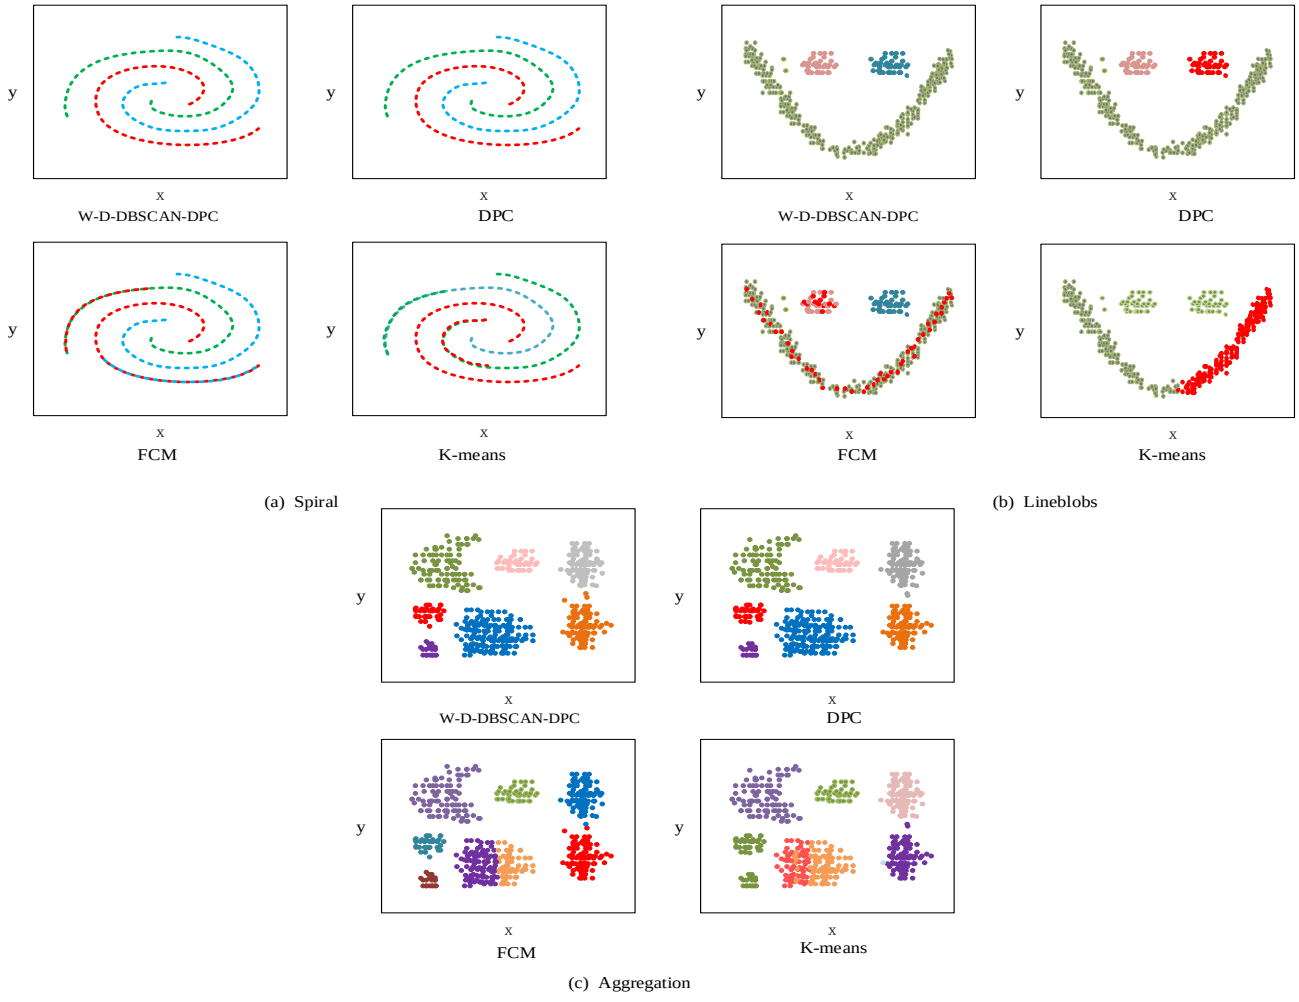

Fig. 8. Clustering effect of four algorithms on three data sets.

TABLE I. PURITY VALUES OF THE FOUR ALGORITHMS

Data set	W-D-DBSCAN-DPC	DPC	FCM	K-means
Iris	0.94	0.91	0.89	0.79
Tae	0.66	0.64	0.55	0.56
Cmc	0.78	0.73	0.63	0.56
Seeds	0.92	0.89	0.88	0.78

To further test the performance of W-D-DBSCAN-DPC, quantitative analysis was conducted on the aforementioned artificial dataset and UCI dataset. Four sets of data were randomly selected from UCI database for experiments on DPC, FCM, and K-means. Table I is four algorithms' purity values. The purity values on four datasets, W-D-DBSCAN-DPC, are the highest, indicating better clustering performance. Its clustering performance in Tae and Cmc datasets is relatively poor because one of these datasets has a large feature value, which affects the clustering results.

To demonstrate the effectiveness of the proposed W-D-DBSCAN-DPC recommendation algorithm in recommendation, the above three algorithms are used as comparative recommendation algorithms for this experiment. Fig. 9 shows the recommendation accuracy obtained by four algorithms on three types of datasets. The average accuracy of W-D-DBSCAN-DPC is 98.97%, while DPC, FCM, and K-means are 95.67%, 93.23%, and 90.34%, respectively. Thus, the superiority of W-D-DBSCAN-DPC was verified.

Fig. 10 shows the comparison results of recall rates obtained by four algorithms on three types of datasets. The average performance of W-D-DBSCAN-DPC is also superior to other algorithms, further verifying its superior performance.

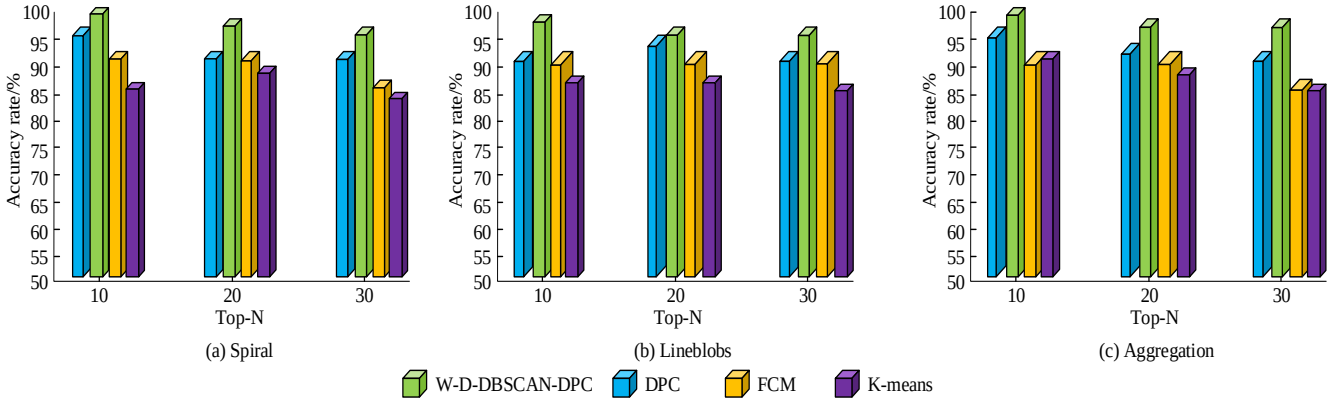

Fig. 9. Recommendation accuracy rates of four algorithms on three types of data sets.

(a) The category and number of books borrowed by a target audience

(b) Top-10 Type and number of nearest neighbors

Fig. 11. W-D-DBSCAN-DPC recommended result.

B. Practical Application Effect of Book Recommendation Model Based on W-D-DBSCAN-DPC

This study divides the existing book materials in the library into 22 categories and uses them as reader feature vectors. The experiment extracted borrowing information from the data center of a certain university library for 21st year college students, of which 8011 were borrowing information from the university library. By processing these materials, some reader's interest and preference data can be obtained.

This experiment proved that W-D-DBSCAN-DPC was used for clustering, combined with recommendation algorithms, and finally the Top-n algorithm was used for classification. Fig. 11(a) is a summary of the types of books borrowed and the number of target readers. According to the distribution, when recommending four books to the target audience, two literary books, one local science book, and one language and text book can be recommended. Fig. 11(b) shows the borrowing classification and quantity of readers in the Top-10 neighbor set. These results confirm that among the top 10 neighboring readers of the target audience, in addition to books related to language, geography, literature, etc., there are also books related to history, economy, art, etc. Therefore, according to Fig. 11(b), books on history, economics, art, etc. can be appropriately recommended to target readers. In addition, there is a significant similarity in the types of books read by Top-10 readers and the books read by the target readers, thus verifying the effectiveness and feasibility of this algorithm.

V. Discussion

The problem of "blind selection" or "unable to find suitable books" is common among contemporary college students in the library. Therefore, this topic tries to combine the clustering algorithm with the recommendation system organically, and build a system suitable for university book recommendation. Firstly, the data are collected and classified. On this basis, the user's historical reading records are clustered and classified, and finally the user's Top-n nearest neighbor set is calculated, and books are recommended to it, so as to help students find books suitable for themselves. Density clustering has always been a hot topic in the field of data mining, and the density peak clustering algorithm has pushed the study of density method to a hot trend [26-28]. Starting from cluster analysis and recommendation system, this study introduced the theoretical analysis, research status and common methods of related methods in detail, so as to make sufficient preparation for the follow-up work. This study mainly discusses the density peak and density clustering algorithm. It is found that in the density clustering algorithm, data objects are grouped by density linkage, but the calculation process of density linkage is complicated, and it needs to determine the core point, density reachability, direct density reachability, etc. Density peaks the method of selecting the center of mass on a decision graph is not suitable for all data. The main contents of this research are as follows: (1) Propose distance optimization strategies to improve DBSCAN and improve the difficulty in selecting its initial parameters. (2) Warshall algorithm was introduced to reduce the computational complexity of the model. (3) Merge the improved DBSCAN with DPC to further improve the operating efficiency of the model. (4) Apply the model to the personalized book recommendation service of the library.

Experimental results show that, compared with the traditional DBSCAN algorithm, W-D-DBSCAN-DPC algorithm can find clusters with different shapes and adaptively select appropriate neighborhood radius, which is more suitable for complex student book preferences [29-30]. Finally, according to the results of student book recommendation, different student groups show strong differences in daily borrowing activities. It can be concluded that the reader feature vector based on the borrowing information of college students in the library has a strong correlation with the reading preference of students, which provides more reference and research ideas for college library managers.

VI. Conclusion

The increasing amount of information data in university libraries has brought a lot of inconvenience to the daily lives of teachers and students. This study proposes a W-D-DBSCAN-DPC to enhance the personalized service quality of libraries. The performance of the model was verified: the optimal contour coefficient for D-DBSCAN was 0.668, while for DBSCAN, it was 0.612. Compared with DBSCAN, D-DBSCAN clustering performance improved by 9.17%, verifying the effectiveness of distance optimization. W-D-DBSCAN has a shorter runtime compared to D-DBSCAN, verifying the effectiveness of Warhill. The comparative analysis of four clustering algorithms, W-D-DBSCAN-DPC, DPC, FCM, and K-means, shows that W-D-DBSCAN-DPC's clustering results are basically correct, and its clustering effect is better than other three algorithms. W-D-DBSCAN-DPC has the highest purity values on the four datasets, indicating better clustering performance. The average accuracy recommended by W-D-DBSCAN-DPC is 98.97%, while DPC, FCM, and K-means are 95.67%, 93.23%, and 90.34%, respectively, confirming the superiority of W-D-DBSCAN-DPC. The practical application has confirmed that there is a significant similarity between the books read by Top-10 readers and the books read by the target readers, verifying the effectiveness and feasibility of this algorithm. The drawback is that the threshold in Warhill has not been controlled, resulting in some interference that can be optimized in the future.

***Abstract*—The cleaning services industry in Malaysia faces significant challenges in effectively managing its workforce. Workforce planning, a critical procedure that aligns employee skills with suitable positions at the right time, is becoming increasingly essential across various organizations, including postal delivery and cleaning services. However, the absence of proper workforce planning from management teams has emerged as a primary concern in this sector. This study identifies an opportunity to improve the workforce planning in the cleaning industry by employing an optimization approach that aims to minimize hiring costs. The main objective of this study is to minimize hiring costs in cleaning services operations at a public university in Malaysia. To achieve this, an optimization model based on integer programming was proposed to represent the current situation. Data collection involved interviews and company reports for the purpose of understanding the current conditions comprehensively. Factors influencing hiring costs were meticulously selected, considering the organization's specific situation. Model evaluation was conducted through what-if analysis, which allowed the evaluation of solutions provided by the modified models in three what-if scenarios. The findings indicated that the proposed modified model could assist organizations in improving the workforce planning by optimizing the allocation of resources, reducing hiring costs, and enhancing cleaner performance. This study offers valuable insights for the management of cleaning services, paving the way for more effective and efficient workforce planning practices in the industry.**

Keywords*—Workforce planning; cleaning services industry; optimization approach; integer programming

I. INTRODUCTION

In a company or an organization, it is important for the management to plan the workforce. Workforce planning is a procedure that assigns employees with the appropriate skills to suitable positions at the right time [1, 2, 3]. The workforce planning issue is pervasive across various industries, such as services, healthcare, education, military, transportation, and many more. These industries are listed in Table I, with the related studies highlighted by different authors.

Previous studies identified and discussed the issues in workforce planning in different industries. For instance, in the services industry, workforce planning challenges were discussed in study [4], where service technicians from various locations must go to the clients' locations, resulting in escalated costs and inefficiencies. These frequent travels not only imposed financial burdens but also hindered service delivery effectiveness due to time constraints. To address these concerns, the researchers introduced a workforce planning model designed to mitigate travel costs for service technicians, concurrently enhancing the overall efficiency of operations. In fact, other industries, such as healthcare, education, military, and transportation, are facing similar workforce issues. Therefore, as these workforce planning issues impact various industries, it will be beneficial to study further especially related to the service industry, since the nature of service is wide and intangible, which will be complex to measure.

TABLE I. RELATED STUDIES ON WORKFORCE PLANNING ISSUES IN DIFFERENT INDUSTRIES

Industry	Workforce Planning Issues	Author
Services	Service technicians located at different locations are required to travel along to the customers' locations.	[4]
Healthcare	Traveling issues happened for the medical staff, including transporting the medicines and medical equipment between warehouses and patients.	[5]
	The systemic delay happened in the hospital consultation service.	[6]
	Scheduling nurses on three shifts per day based on various preferences and constraints.	[7], [8]
Education	Allocating academic staff in quest of optimum knowledge transfer.	[9]
Military	To deploy the right employees in the right place at the right time.	[10]
	To meet the demands of the current force structure under conditions of uncertainty in officer retention.	[11]
Transportation	A pilot can be hired as a first officer or a captain, the company need to determine whether how many persons of pilot need to be hired.	[12]

A cleaning services operation is one of the popular services in the service industry. This service is provided by a contractor to an individual's or an organization's place or property. They typically take on these undesirables but necessary duties, as opposed to a person or employee who would be less than happy about the chance to deal with the dust or waste [13, 14, 15]. The cleaning services industry in Malaysia is facing

numerous challenges when it comes to effectively managing its workforce. One significant challenge is determining the ideal number of cleaners required to complete cleaning tasks within a specified timeframe. In this case, a specific timeframe refers to the required working time of the cleaners assigned by the organization. The specific timeframe ensures that the cleaners complete their tasks within a designated period, allowing for efficient scheduling and resource allocation. However, this often leads to overstaffing, resulting in increased of hiring costs, or understaffing, which can adversely affect the quality of cleaning services provided. Moreover, the existing workforce's performance in the cleaning services operation is unsatisfactory, translating into higher costs for the management team, who must hire additional workers to compensate for the inefficiencies [16]. This will finally lead to general issues in the workforce for a cleaning service operation, i.e. the high turnover rate [17]. The management team's absence of proper workforce planning seems to be the primary cause of this issue. As such, there is an opportunity to improve the workforce planning in the cleaning industry by utilizing a systematic approach to minimize hiring costs and maximize cleaners' performance. Consequently, this study was aimed to minimize the hiring cost at a cleaning services operation responsible for taking care of property-related matters and maintenance in a public university in Malaysia. A campus environment that is hygienic, healthy and pleasant plays a crucial role in shaping the learning experience and the academic performance of students [18]. As a big campus, the university requires cleaning services to manage the whole campus environment well. However, it is all aware that the cleaning service at the university can still be improved in order to achieve a satisfyingly clean and comfortable study area.

The paper is structured into distinct sections to address workforce planning challenges within the cleaning services industry comprehensively. The initial segment outlines the industry's issues and the absence of adequate planning, setting the study's goal: minimizing hiring costs within a university's cleaning services operation. Subsequently, various methodologies and influential factors in workforce planning are explored in the Literature Review which is given in Section II. The Research Methodology in Section III details the study's phases, from problem definition to model evaluation. Finally, the Findings in Section IV present the results of evaluating different scenarios and examining their impact on hiring costs and operational efficiency and lastly Section V concludes the paper. Each section contributes to a comprehensive understanding of optimizing workforce planning in cleaning services.

II. Literature Review

Workforce planning involves analyzing current and future workforce needs as a way of ensuring that it has the right people with the right skills in the right place and at the right time. The significance of workforce planning for organizations has been emphasized in numerous studies. Workforce planning is a continuous process that aids organizations in aligning their workforce with their business objectives and priorities [19]. Additionally, it is closely linked to the broader business planning process. There are three categories of the workforce planning methods, judgmental, mathematical, and a combination of the two [20]. Mathematical methods for the workforce planning fall under the realm of operations research. In a review of the current state of the workforce planning, an imbalance in the field was noted [21].

A. Factors in Workforce Planning

A range of factors with a significant impact must be considered for workforce planning to be effective. Factors affecting workforce planning, such as skills, demand and time windows, have been identified from previous studies and tabulated in Table II.

Workforce retention rates	[11]
Preference for the working period	[4]
Maximum tasks assigned to the worker	[4]
Workforce holidays	[12]

The table provides a clear overview of the most commonly cited factors in the workforce planning problem by researchers. The results suggest that a significant number of studies prioritize the "skill requirement" as a primary constraint in the workforce planning, indicating the importance of having a skilled workforce to meet organizational goals. Additionally, workforce demand is a critical factor that organizations must consider in their planning. As the second most commonly cited factor, it highlights the importance of accurately estimating the needs of future workforce. Organizations must ensure they have enough resources to meet the required workload while avoiding under or overstaffing, which can lead to an increase in operational costs.

Moreover, time windows are also crucial in the workforce planning, as they help organizations allocate resources efficiently within a specified timeframe. Organizations must ensure that they have enough staff available during peak periods and that they can accommodate fluctuations in demand. Overall, the information presented in the table emphasizes the importance of considering these constraints in the workforce planning. Organizations must prioritize these factors while establishing their workforce planning strategies to ensure they

have the right people with the necessary skills available at the right time to achieve their objectives.

B. Method for Improving Workforce Planning

In the research on workforce planning, the authors proposed several innovative methods to address its associated challenges. The authors' work sheds light on the importance of having a robust workforce planning strategy that considers various factors, such as workforce demand forecasting, skill requirements, time windows, etc. The details of these methods are comprehensively discussed and analysed in Table III.

TABLE III. METHOD FOR IMPROVING WORKFORCE PLANNING

Method	Author
Linear programming	[22]
Mixed integer linear programming	[4], [5], [12]
Integer programming	[31]
Goal programming	[9], [11]
Genetic algorithm	[9], [23]
System dynamics	[8], [23]
Discrete-Event Simulation Model	[11]
Stochastic programming	[30]
Robust optimization	[11]

Optimization is often the preferred method for solving the workforce planning issues in cleaning service operations. This is because it can help minimize costs and increase efficiency while ensuring all cleaning tasks are completed on time. An optimization approach is a mathematical method used in a variety of fields to identify the best option from a list of feasible solutions. It involves working through various solutions to maximize or minimize an objective, frequently under certain constraints. These approaches include methods such as linear and nonlinear programming as well as integer programming. Linear programming is a mathematical technique used to optimize complex problems by determining the best solution to a given set of constraints. It is particularly useful in the workforce planning because it can help organizations allocate their resources efficiently to meet the required workload. The research in [22] applied it in the workforce planning and to reduce manufacturing costs at the same time. Mixed-integer linear programming (MILP) is an extension of linear programming that allows for the inclusion of integer variables in addition to continuous variables. It is useful in the workforce planning because it can help organizations allocate their resources optimally while considering additional constraints, such as the availability of part-time workers or the minimum number of shifts an employee need to work. For instance, MILP is employed in addressing the workforce planning problems that involve task duration as a continuous variable in the constraints, as highlighted by [4, 5]. In another study conducted by study [12] demonstrated the effectiveness of MILP in addressing the workforce planning problems that involve pilot holidays as a continuous variable in the constraints. The study showed that MILP was able to produce a highly effective performance in this regard.

Meanwhile, for a complex problem, Genetic Algorithm (GA) can be used to address the workforce planning problems in a dynamic environment where demand, resources and other constraints are continuously changing [9]. It can also be used to optimize multiple objectives simultaneously such as maximizing productivity while minimizing labour costs. In a study by [23], GA seeks the optimal workforce flow between different ranks. However, it is important to note that GA has limitations, where there is a chance that GA will become trapped in local optima, making it difficult to find the overall optimal solution, which is normally addressed as a near-optimal solution.

Other than optimization, Goal Programming is another popular mathematical programming technique that can help organizations optimize their workforce planning strategies by simultaneously considering multiple objectives or goals. According to [9], the study involves constraints like physical resource planning, for instance, library, laboratory, etc., which must be considered simultaneously. Therefore, it is suitable to use goal programming in solving the problem.

In addition, System dynamics (SD) and Discrete-Event Simulation (DES) are also frequently used in the workforce planning issues. SD is a modeling approach that is useful in workforce planning because it allows for the analysis of complex systems with feedback loops, time delays, and other dynamic factors. The SD model helps simulate the workforce's career progressions from recruitment to interim separation and retirement [6], [23]. Meanwhile, DES is useful in workforce planning because it allows for the analysis of complex systems with a large number of discrete events that occur over time. In workforce planning, DES models can be used to simulate the behavior of the workforce planning system under different scenarios and policies. Although effective for evaluating complicated workforce planning, SD has a limitation when constructing an accurate SD model requires a thorough comprehension of the underlying dynamics of the system, which can be resource-intensive and time-consuming. Similarly, DES has limitations despite being good at capturing discrete events in workforce planning. When simulating complex systems with numerous events, DES models can become computationally difficult and time-consuming, thus restricting their application in real-time decision-making scenarios.

Additionally, as per [30], Stochastic Programming (SP) provides a range of modeling methods to incorporate uncertainty into manpower planning problems. Moreover, Robust Optimization (RO) techniques offer valuable insights as they do not require specific probability distributions for uncertain parameters. These methods might be useful for workforce planning; however, they also bring disadvantages. For instance, SP, while addressing uncertainty in manpower planning, can sometimes lead to complex mathematical formulations that are computationally intensive and challenging to solve, particularly for large-scale workforce scenarios. Including probabilistic components could also need a significant amount of historical data for precise parameter

estimates, providing limits in circumstances when the data is limited or unreliable. Similarly, RO can sometimes produce overly conservative solutions, potentially underutilizing resources or failing to capture the full range of possible outcomes, despite their advantages in handling uncertainty without exact probability distributions. Particularly in situations where finding a balance between robustness and optimization is essential, the practical implementation of RO might require careful evaluation of the trade-off between robustness and optimization performance.

In conclusion, there are numerous methods available for solving workforce planning problems. However, it is essential to select a method that is best suited to meet the constraints and requirements of the specific problem at hand. In this study, the use of integer programming (IP) is considered appropriate. This mathematical optimization approach enables the optimization of the objective function while adhering to constraints in terms of integer values only. The decision variables in the optimization problem can only assume integer values, making IP particularly useful when variables are restricted to discrete values. In the services industry, IP is not commonly used in solving problems. However, IP has been used in other industries such as research by [31], who investigated a hospital contact center that proposed a workforce planning framework using IP to optimize staffing. The decision variables are restricted to be integers in this method, which is the number of agents assigned to each shift. Another research in the education industry was conducted by [32] to allocate students to preferred lecturers for supervision of internships among undergraduate students. Since all the decision variables are integers, IP was the most suitable method to consider. The exact algorithms used in these models help solve the problem efficiently and accurately.

Returning to this study, the decision variable is an integer, i.e. the number of cleaners assigned. Thus, by utilizing IP, the optimal combination of variables satisfies the constraints while achieving the highest possible objective value, which is to minimize hiring costs, can be achieved.

III. Research Methodology

This study aims to develop an IP model for cleaning services operations in order to improve their current workforce planning. This section discusses on how this research is conducted in achieving the objective. The research is designed in a few phases of research activities that help to ensure progress throughout the study. These phases are problem definition, data collection, data analysis, results, and discussion, as shown in Table IV. The detail of each step is briefly discussed in the following subsection.

A. Phase 1: Problem Definition

In the current scenario, cleaners are being assigned by the cleaning services operation based on the location of buildings. This means they will only be placed at one location to concentrate and clean for the duration of the day. These cleaners will work regardless of the type of cleaning task, but only in the assigned building. The cleaners are compensated as full-time workers with work duration of nine hours per day and receive monthly wages. As an initial study, three academic buildings have been considered as the main focus of this study, which involves 25 cleaners. These buildings are the newest buildings in the university and thus appear to be the most organized and systematic. The number of cleaners is quite large when comparing the size of the building to the number of employees, which causes a high turnover rate. Therefore, this cleaning service tries to search for possibilities to reduce the rate and increase profit. Therefore, in order to improve the rate, this research experimented with different scenarios.

TABLE IV. Method for Improving Workforce Planning

Phase	Methods and Techniques
Phase 1: Problem Definition	1. Spotting the real-world problem. 2. Setting the research topic, objectives, and overall project plan. 3. Review of the literature.
Phase 2: Data Collection	1. Gather the potential factors that affect the workforce planning. 2. Interview sessions with the company representative. 3. Reviewing company reports.
Phase 3: Data Analysis	1. Select the suitable factors. 2. Develop an optimization model for the workforce planning. 3. Construct an objective function. 4. Construct mathematical formulation for the constraints.
Phase 4: Model Evaluation	1. Performing model evaluation based on what-if analysis using Microsoft Excel Solver 2. Giving suggestions to the cleaning services operation's management based on the findings.

B. Phase 2: Data Collection

The data collection process for this project involves two main sources: interview sessions with company representatives and analysis of company reports. Interviews provided valuable insights into the current situation of an organizational structure, job requirements, staffing levels, skills, competencies and task types within the cleaning services operation. These insights guide identifying areas for improvement and developing strategies to address the workforce planning challenges. Company reports offer critical data on workforce size, experience levels, pay scales, performance metrics, and other factors influencing the workforce planning. Analyzing this data helps organizations understand their current workforce state, identify skill gaps and make informed decisions for more effective planning while considering the available financial resources. The company report serves as a reference to comprehend company issues and financial performance, aiding in determining available resources for the workforce planning efforts.

C. Phase 3: Data Analysis

In this phase of the study, the focus shifts to selecting critical factors that will play a pivotal role in shaping the objective function of the workforce planning model. With these factors in mind, the study proceeds to construct an IP model that captures the essence of the workforce planning problem. The model integrates the factors seamlessly, facilitating the development of mathematical equations and constraints that reflect the real-world considerations of the cleaning services operation.

1) Factors selection: This study carefully selected several factors to be used as constraints in formulating an objective function. These factors have been chosen based on previous research, as discussed in Section II(A), and how well they align with the specific problem being investigated in this cleaning services operation. Table V shows the factors to be considered in the model formulation of the study.

TABLE V. FACTORS TO BE CONSIDERED

Factors	Definition
Size of the cleaning area	The total size of the area to be cleaned in the campus of the university.
Task duration	The given time frame for the cleaners to complete the task.
Scheduling	To ensure that the given cleaners are available in the time period.
Experience level	To ensure the cleaners efficiently perform the cleaning task within the given time.

Considering the size of the cleaning area as one of the important factors in the workforce planning affects the number of cleaners needed to clean up the area efficiently. A larger facility typically requires more cleaners to handle the workload, while a smaller facility may require fewer cleaners. Task duration is another important factor in the workforce planning for a cleaning service operation because it directly impacts the amount of time that a cleaner will need to spend on a particular task. In this study, the cleaners are given a time frame and are obliged to complete all the tasks allocated to them within the particular time frame.

In addition, effective scheduling helps to optimize the use of available staff and resources, reducing hiring costs and ensuring that the cleaning services are delivered on time and to the required standard. Moreover, experience level is important in the workforce planning for cleaning services operations to ensure that the premises are cleaned and maintained to the desired standard. Cleaning tasks requiring specialised skills or a high level of experience are more likely to be successfully completed by cleaners with sufficient experience within the allotted time frame. This is because it helps cleaners know how to do different cleaning tasks effectively, solve problems, and train new cleaners, resulting in better quality services that meet customer expectations and promote business growth for instance, carpet cleaning, computer lab cleaning, plant care, etc.

2) Model formulation: The problem for this study is now being addressed through an IP model, which incorporates the four factors discussed previously. Subsequently, the mathematical model is developed along with the corresponding constraints.

Indices:

Cleaner: $\{1, \ldots, i, \ldots, I\}$

Task: $\{1, \ldots, j, \ldots, J\}$

Time period: $\{1, \ldots, t, \ldots, T\}$

Parameters:

Cij: The cost of assigning cleaner i to task j at time t

Sj: The size of the area to be cleaned for task j

Ai: The maximum area that cleaner i can clean in one time period

Rj: The required experience level for task j

Ei: The experience level of cleaner i

Variables:

$Xijt = 1$ if cleaner i is assigned to task j at time period t, and $Xijt = 0$ otherwise.

Objectives:

In this model, we consider the objective of minimizing hiring costs, which can be formulated as:

$$\text{Minimize } \sum i\in I \sum j\in J \sum t\in T \; Cijt \; Xijt \quad (1)$$

Constraints:

$$\sum i\in I \sum t\in T \; Xijt \geq 1, \text{ for all } j\in J \quad (2)$$

$$\sum j\in J \; Xijt \leq 1, \text{ for all } i\in I, \; t\in T \quad (3)$$

$$Xijt \geq 0, \text{ for all } i\in I, \; j\in J, \; t\in T \quad (4)$$

This model is formulated to present the current scenario in the cleaning services operation, in which the cleaners are assigned to each building according to the total size of the cleaning area regardless of the skill requirements for the cleaners.

The objective function for this study is shown in Eq. (1). The aim is to minimize the hiring cost of the cleaning services. It is calculated by multiplying the hiring cost by the number of cleaners. Eq. (2) ensures that each task must be assigned to at least one cleaner during its entire duration. Eq. (3) ensures that each cleaner can perform at most one task during each period. Eq. (4) limits all the variables to a non-negative value. This model is then analysed to obtain the solution of the existing scenario.

D. Phase 4: Model Evaluation

In this study, the model evaluation was conducted using what-if analysis. What-if analysis is a process by which we adjust the model and then examine how those modifications will impact the model's results. In a study, there will typically be what-if analysis reflecting several situations. To better solve the problem, it would be good to see how the current results compare to the modified scenario. By conducting what-if analysis, it can gain insights into the potential outcomes and make informed decisions based on the model's sensitivity to different variables. This approach allows us to explore various scenarios and understand the implications of different adjustments on the overall results. This study has three modified scenarios: Model 2, Model 3, and Model 4. The current situation in Model 1 involves the cleaners working nine hours daily for a wage of 1,500 MYR per month. Consequently, the other three scenarios are as follows.

1) Model 2: What if the cleaner is assigned according to the size of the cleaning area?

A book on Setting Household Standards states that it takes four hours to clean 2000 sqft, which is an average of 500 sqft per hour [33]. However, the current assignment in the cleaning services operation is only focused on assigning the cleaners to the building areas without taking any consideration. In this modified scenario, the fewest cleaners possible are used to keep the building clean. Model 2 is the modification of the current Model 1 by adding the new constraint it to ensure the whole building is clean as shown in Eq. (5)

$$\sum j \in J \; Sj \; Xijt \leq Ai, \text{ for all } i \in I, \; t \in T \quad (5)$$

This equation is to ensure that each cleaner should clean at least a given size of area. To ensure that the cleaners can complete the assigned workload, the cleaning area multiplied by the number of cleaners should be larger than the total size of the cleaning area.

2) Model 3: What if the cleaners work in a part-time mode?

Model 3 is an improvement idea modified from the previous model. In this scenario, the cleaners are considered to be part-time workers, and therefore they will work for four hours and receive 30 MYR as their wages per day. The cleaner is assumed to clean 2000 sqft per day. It is possible to decrease the hiring cost due to the number of cleaners needed. Besides, according to the cleaning services operation, the cleaners might need only four hours to clean the building area. Therefore, cutting down the paid wages might help in minimizing the cost.

3) Model 4: What if the cleaner is assigned according to the task type?

In this scenario, similarly, the cleaners are considered to be part-time workers, and they will work for four hours and receive 30 MYR as their wages per day. This scenario was modified in Model 4 to retain all the current cleaners. In this scenario, the cleaners are assigned according to task type without considering the size of the cleaning area.

There are four different task types that make up the cleaning tasks: "General cleaning and maintenance," "Washroom maintenance," "Specialize cleaning," and "Plant care." Table VI shows the cleaning tasks included in the given task types. Each cleaner's performance level was gathered and converted to a range of experience levels. This is due to no available data on the cleaners' experience level. In this study, cleaners with more experience were assumed to perform their jobs more effectively. This assumption allows us to assign suitable cleaners to the given types of task.

Depending on their current experience level, the cleaners will be assigned a task type; for example, if their experience level is below 2, they will be given the task type "General cleaning and maintenance." Then, if they have an experience level of 2, the task will be "Washroom maintenance," and an experience level of 3, "Special cleaning," respectively. However, "Plant care" will only be assigned to cleaners with experience levels above 4, which can call for more patience and competence.

Since every hired cleaner should get one assigned task, therefore a new constraint as shown in Eq. (6), is modified from Eq. (3) in this model.

$$\sum j \in J \; Xijt = 1, \text{for all } i \in I, \; t \in T \quad (6)$$

Eq. (6) ensures that each cleaner must be assigned one task during the given time period. At the same time, a new equation, as shown below, is added to this model in order to ensure that the cleaner manage to fulfill their given task in the given time span as they have relevant skills for their given task.

$$Xijt = 0, \forall i \in I, \forall j \in J, \forall t \in T \text{ where } Rj > Ei \quad (7)$$

TABLE VI. TASK TYPES AND THE CLEANING TASKS

Task Type	Cleaning Task
General cleaning and maintenance	Cleaning desks and chairs, dusting furniture and fixtures, emptying trash bins, sweeping and mopping the floor, cleaning corridors, cleaning stairwells, cleaning windows and mirrors
Washroom maintenance	Cleaning the washroom and refill the supply
Specialized cleaning	Cleaning lift, cleaning computer set, cleaning carpet
Plant care	Trimming and pruning the plants, fertilizing the plants, watering the plant

Eq. (7) enforces that only cleaners with sufficient experience levels can be assigned to the tasks that require specific skills, which ensures that the tasks are completed properly. If the required experience level for task j is higher than the experience level of cleaner *i*, then cleaner *i* cannot be assigned to task *j* during the time period *t*.

IV. FINDINGS

This section discusses the results and findings obtained from the developed models. The model evaluation will be made by comparing the current model with all the modified models.

A. Discussion for Model 1 (Current scenario)

Model 1 was created to reflect the current situation of cleaning services operation. The size of the cleaning area and the task types were not taken into consideration when cleaners were assigned according to buildings. The three academic buildings taken into consideration, named as buildings X, Y and Z, received these cleaners randomly, assigned by the cleaning services operation. These cleaners would do any task types in the assigned building during nine working hours. Their performance level was monitored by the supervisor from the cleaning services operation. The number of cleaners involved in the current existing scenario and their performance are shown in Table VII. These data are provided by the cleaning services operation and will be compared later to the modified scenario.

The number of hired cleaners is multiplied by their monthly wages to determine the hiring cost for this model. In this model, there are 25 cleaners assigned, and their monthly pay is 1,500 MYR. In this situation, the total cost of hiring is 37,500 MYR. Reducing hiring costs is necessary since the high hiring costs strain the cleaning services operation.

B. Model Evaluation

Model evaluation is an important phase in this study, involving the comparison of the current model with modified models. The objective is to evaluate each model's advantages and limitations in order to find a better solution that suits the organization's needs. By assessing the models' performance in different scenarios, management will gain insights into how well the models address the problem. Microsoft Excel's Data Solver is used to run these models, with a computer powered by AMD Ryzen 7 5800X along with 16GB RAM.

TABLE VII. NUMBER OF CLEANERS INVOLVED AND THEIR PERFORMANCE IN THE CURRENT SCENARIO

Cleaner	Performance	Cleaner	Performance
Cleaner 1	80%	Cleaner 14	70%
Cleaner 2	95%	Cleaner 15	90%
Cleaner 3	70%	Cleaner 16	80%
Cleaner 4	75%	Cleaner 17	70%
Cleaner 5	70%	Cleaner 18	70%
Cleaner 6	85%	Cleaner 19	85%
Cleaner 7	80%	Cleaner 20	70%
Cleaner 8	85%	Cleaner 21	70%
Cleaner 9	90%	Cleaner 22	75%
Cleaner 10	70%	Cleaner 23	90%
Cleaner 11	80%	Cleaner 24	70%
Cleaner 12	80%	Cleaner 25	80%
Cleaner 13	85%		

Discussion for Model 2: Due to the high cost of the cleaning services operation to hire cleaners in the current scenario, Model 1 is used as a guideline to modify and come out with a new model in different scenarios. In this scenario, the size of the cleaning area is considered while assigning cleaners. The allocated cleaners must clean at least 14463 sqft for Building X, 12006 sqft for Building Y and 7320 sqft for Building Z. It took about 49 minutes to come up with the optimal solution, as shown in Table VIII.

TABLE VIII. THE ASSIGNMENT OF CLEANER IN MODEL 2

Cleaner	Assigned Location	Cleaner	Assigned Location
Cleaner 1	Building X	Cleaner 14	Not assigned
Cleaner 2	Not assigned	Cleaner 15	Not assigned
Cleaner 3	Not assigned	Cleaner 16	Building Z
Cleaner 4	Not assigned	Cleaner 17	Not assigned
Cleaner 5	Not assigned	Cleaner 18	Not assigned
Cleaner 6	Not assigned	Cleaner 19	Building Y
Cleaner 7	Not assigned	Cleaner 20	Building X
Cleaner 8	Not assigned	Cleaner 21	Building Y
Cleaner 9	Not assigned	Cleaner 22	Building X
Cleaner 10	Not assigned	Cleaner 23	Building Z
Cleaner 11	Not assigned	Cleaner 24	Building X
Cleaner 12	Not assigned	Cleaner 25	Building Y
Cleaner 13	Not assigned		

According to the result, four cleaners were assigned to Building X, three were assigned to Building Y, and two were assigned to Building Z. In a nutshell, total of nine cleaners were assigned to do the cleaning tasks at these buildings. If this model was used, the cleaning services operation would have to pay a monthly hiring cost of 13,500 MYR. Due to the decreased number of cleaners, this value is lower than the existing model. The result is graphically displayed in Fig. 1.

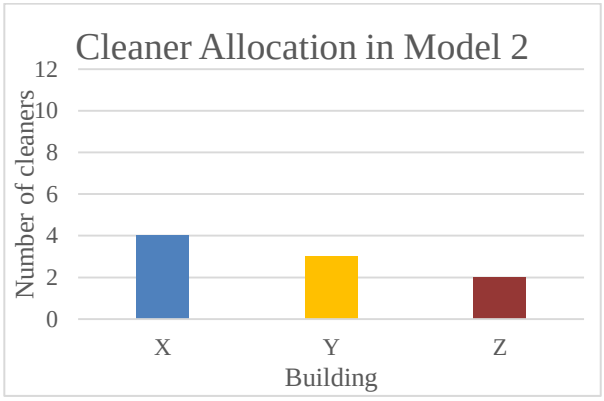

Fig. 1. Cleaner allocation in building based on Model 2.

1) Discussion for Model 3: Based on the interview with the cleaning services operator, the cleaners might only spend four hours cleaning the building despite being obligated to work nine hours every day. Therefore, it would be wise if we could reduce their working hours so that they could increase their level of efficiency. The optimal solution required a long running duration of 19 days. The assignment of cleaners in Model 3 is shown in Table IX.

TABLE IX. THE ASSIGNMENT OF CLEANER IN MODEL 3

Cleaner	Assigned Location	Cleaner	Assigned Location
Cleaner 1	Building X	Cleaner 14	Building X
Cleaner 2	Building Z	Cleaner 15	Building X
Cleaner 3	Building Z	Cleaner 16	Not assigned
Cleaner 4	Building Y	Cleaner 17	Building Y
Cleaner 5	Building Z	Cleaner 18	Not assigned
Cleaner 6	Building X	Cleaner 19	Not assigned
Cleaner 7	Building Y	Cleaner 20	Building Y
Cleaner 8	Building X	Cleaner 21	Not assigned
Cleaner 9	Building X	Cleaner 22	Not assigned
Cleaner 10	Not assigned	Cleaner 23	Building Y
Cleaner 11	Building Z	Cleaner 24	Building X
Cleaner 12	Building Y	Cleaner 25	Building Y
Cleaner 13	Building X		

Based on the result from Model 3, eight cleaners were assigned to the Building X. Besides, seven cleaners were assigned to Building Y while four cleaners were assigned to the Building Z. In this model, a total of 19 cleaners were assigned to carry out the cleaning tasks. The cleaning services operation might spend 570 MYR on the daily hiring cost for these three buildings. Since cleaners would work for 26 days per month, the total hiring cost in this model is 14,820 MYR, which is lower than the current hiring cost. However,

compared to Model 2, the hiring cost would be a little higher because this model might require more cleaners. Fig. 2 presents the cleaner allocation in Model 3.

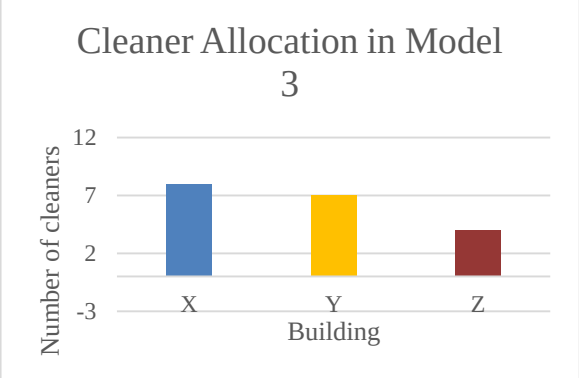

Fig. 2. Cleaner allocation in building based on Model 3.

2) Discussion for Model 4: As in the previous scenario of Model 3, all the cleaners remain considered as part-time workers in this scenario and will work four hours per day for 30 MYR. This scenario aims to enhance the cleaners' performance level, where they are assigned based on specific tasks. Cleaners should perform more effectively when carrying out a task that they are familiar with; thus, cleaners may result in higher performance levels since they are more expert with the task at hand. Therefore, the cleaners are assigned to a given task type based on their experience level in this model. Additionally, the cleaning services operator gets to maintain all the hired cleaners by employing this scenario. The assignment of cleaners in Model 4 are shown in Table X.

Based on the result from Model 4, 11 cleaners were assigned to "General cleaning and maintenance". Besides, 6 cleaners were assigned to "Washroom maintenance" while 4 cleaners were assigned to "Specialized cleaning". At the same time, the 4 cleaners with the highest performance level were assigned to "Plant care". In this scenario, all the hired cleaners would remain with the cleaning services operation and be assigned with cleaning tasks. They might spend 750 MYR on the daily hiring cost for these three buildings. Since cleaners will work for 26 days per month, the total hiring cost in this model is 19,500 MYR, which is lower than the current hiring cost. However, compared to Model 2 and Model 3, the hiring cost will be the highest as it tends to remain all cleaners in the organization. 52 minutes of time is taken to run this model and finding the optimal solution. The cleaner allocation in this Model 4 is clearly presented in Fig. 3.

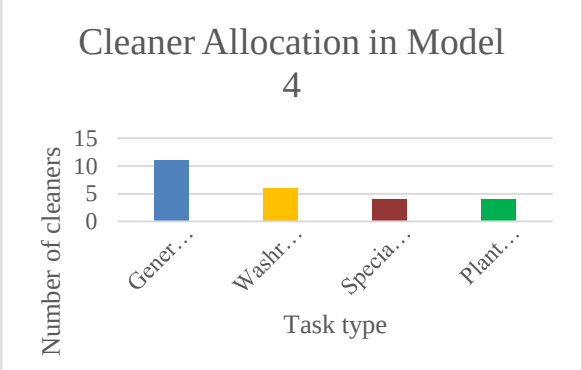

Fig. 3. Cleaner allocation in building based on Model 4.

TABLE X. THE ASSIGNMENT OF CLEANER IN MODEL 4

Cleaner	Experience level	Task type
Cleaner 1	2	Washroom maintenance
Cleaner 2	5	Plant care
Cleaner 3	0	General cleaning and maintenance
Cleaner 4	1	General cleaning and maintenance
Cleaner 5	0	General cleaning and maintenance
Cleaner 6	3	Specialized cleaning
Cleaner 7	2	Washroom maintenance
Cleaner 8	3	Specialized cleaning
Cleaner 9	4	Plant care
Cleaner 10	0	General cleaning and maintenance
Cleaner 11	2	Washroom maintenance
Cleaner 12	2	Washroom maintenance
Cleaner 13	3	Specialized cleaning
Cleaner 14	0	General cleaning and maintenance
Cleaner 15	4	Plant care
Cleaner 16	2	Washroom maintenance
Cleaner 17	0	General cleaning and maintenance
Cleaner 18	0	General cleaning and maintenance
Cleaner 19	3	Specialized cleaning
Cleaner 20	0	General cleaning and maintenance
Cleaner 21	0	General cleaning and maintenance
Cleaner 22	1	General cleaning and maintenance
Cleaner 23	4	Plant care
Cleaner 24	0	General cleaning and maintenance
Cleaner 25	2	Washroom maintenance

3) Model comparison: In this section, the result of all the models is compared and shown in Table XI.

TABLE XII. COMPARISON OF RESULTS

Model	Scenario	Number of Cleaners	Hiring Cost (MYR)
1	Cleaners are assigned randomly to the building.	25	37,500
2	What if the cleaner is assigned according to the size of the cleaning area?	9	13,500
3	What if the cleaner works in a part-time mode?	19	14,820
4	What if the cleaner is assigned according to the task type?	25	19,500

Originally, Model 1 required a high hiring cost of 37,500 MYR with 25 cleaners. Then, the first what-is scenario of Model 2 maintains normal working hours but reduces hiring costs by assigning nine cleaners based on cleaning area size, resulting in a 13,500 MYR cost. Meanwhile, Model 3 aims to enhance performance by minimizing cleaner working hours and employing 19 part-time cleaners for four hours daily at 14,820 MYR/month. On the other hand, Model 4 enhances cleaner performance via task specialization, retaining all cleaners. However, it has the highest cost at 19,500 MYR. It can be seen that these models offer distinct approaches, where Model 2 focuses on area size, Model 3 on efficiency, and Model 4 on specialization.

V. CONCLUSION

This study explores the workforce planning issues in cleaning service operations and provides helpful recommendations. Integer programming (IP) was used to create an optimization model to minimize hiring costs with a focus on three academic buildings in a public university in Malaysia. The current model with three different scenarios was investigated according to several identified factors, such as cleaning area size, task duration, scheduling, and experience level. Each model focused on a different approach and came out with improved hiring costs. Based on the analysis of scenarios, cleaning services operations can choose any model suited to their budget and future planning. However, of all models, Model 3 is recommended due to its lower cost and part-time working hours, which can benefit students and organizational efficiency.

This study contributes significantly to knowledge and practice, though limited by scope and time constraints. As a way to address constraints and improve model evaluation and effectiveness, the research highlights the necessity for heuristic methodologies in future work, especially involving the broader scenarios such as the whole building in a university. In fact, more input factors need to be added to future models for more reliable results.

ACKNOWLEDGMENT

This research was supported by Universiti Utara Malaysia through University Grant (S/O Code 21417). We would like to thank the Research and Innovation Management Centre for facilitating the management of this research work.

Tailored Expert Finding Systems for Vietnamese SMEs: A Five-step Framework

Thi Thu Le[1], Xuan Lam Pham[2*], Thanh Huong Nguyen[3]
Department of Research Methodology, Thuongmai University, Hanoi, Vietnam[1]
Department of Information Technology, School of Information Technology in Economics, National Economics University[2, 3]

***Abstract*—This study addresses the underexplored area of EFSs (EFS) tailored for business applications, with a specific focus on supporting Small and Medium Enterprises (SMEs). The principal objective of this research is to develop an EFS designed to cater to the needs of Vietnamese SMEs. The study methodology involves conducting in-depth interviews with Vietnamese SMEs to ascertain their requirements for Vietnamese EFSs. Subsequently, the research proposes an architectural model for the EFS and proceeds to develop the corresponding system. The EFS operates by collecting and analyzing data from diverse online sources to identify Vietnamese experts and individuals of Vietnamese origin who can provide valuable insights and support to enterprises operating in Vietnam. This research framework is guided by five key Husain (2019)'s issues: 1) Expertise evidence selection, 2) Expert representation, 3) Model building, 4) Model evaluation, and 5) Interaction design. By addressing these issues, the study aims to contribute to the development of an effective EFS tailored to the specific needs of Vietnamese SMEs in their quest to find and engage experts for business growth and innovation.**

Keywords*—Expert Finding System (EFS); Small and Medium-sized Enterprises (SMEs); experts; Vietnamese expert resources; business expertise identification

I. INTRODUCTION

SMEs play a key role in Vietnam and Asia's economic development, constituting up to 98% of businesses in Asia and providing about 66% of private-sector jobs from 2007 to 2012 [1]. Howerver, SMEs have to deal with a multitude of challenges, especially the issue of recruiting high-quality labor resources [2]. They employ various personnel sourcing methods, including costly headhunter services and specialized training companies [3]. Alternatively, businesses can utilize recruitment websites and job exchange platforms, but these predominantly cater to common job positions, offering limited information about experts [4, 5]. Another option is independent online searches via platforms like Google and Bing, which yield articles and related information rather than lists of suitable candidates. Specialized social networking sites like LinkedIn and academic networks such as ResearchGate and Academia provide detailed expert profiles. However, expert data is often private and not easily accessible, hindering effective comparisons and selections [4]. Lastly, personal referrals are highly dependent on social networks, varying in effectiveness. To address these issues, one solution is leveraging technology for human resources and production efficiency [6, 7]. Technology enables SMEs to access crucial information quickly for decision-making and strategic management. In Vietnam, the labor force mainly consists of unskilled, low-skilled, and medium-skilled workers, with only 10 million qualified workers, representing 21% of the total labor force [8]. Consequently, this shortage results in intense competition among SMEs to attract and retain qualified experts who can drive innovation and growth [9].

An Expert Finding System (EFS) for business in recruitment is a highly effective solution that leverages advanced technology and data analytics to identify and connect with top talent in a more efficient and targeted manner Husain, et al. [10]. By analyzing candidates' skills, experiences, and qualifications alongside the specific needs and requirements of the job, this system streamlines the recruitment process, reducing time and cost while ensuring that the best-fit candidates are brought to the forefront. This study is a significant attempt to address an often-overlooked aspect of EFS in the domain of business applications, with a specialized focus on supporting SMEs operating in Vietnam. The primary aim of this research is to develop an EFS system matched precisely to the needs of Vietnamese SMEs. This study employed an in-depth interview methodology to gain insights into Vietnamese SMEs' requirements for expert human resources. Subsequently, the study advances with the proposal of an architectural model for the EFS, followed by the actual development of the system. This EFS functions by collating and analyzing data from diverse online sources to pinpoint Vietnamese experts and individuals of Vietnamese origin who possess the expertise necessary to aid enterprises in Vietnam. Guided by the five pivotal issues identified by Husain, et al. [10], including expertise evidence selection, expert representation, model building, model evaluation, and interaction design, this research hopes to contribute significantly to the evolution of an effective EFS, custom-tailored to meet the unique demands of Vietnamese SMEs.

In particular, this research will examine two main research questions:

- Question 1: How do Vietnamese Small and Medium Enterprises (SMEs) perceive their need for expert human resources, and what are the key challenges they face in identifying and engaging experts to support their business growth and innovation and their requirements for Vietnamese EFSs?
- Question 2: How can an Expert Finding System (EFS) be optimized for Vietnamese SMEs by effectively addressing the five key issues outlined by Husain, et al. [10], enabling efficient identification and engagement

of Vietnamese experts and individuals of Vietnamese origin to support SMEs in Vietnam?

The remainder of this study is organized as follows. Section II explores work concerning the Expert Finding System. The Methodology in Section III describes the research design, survey participant information, and system design. The Results in Section IV presents the outcomes of the in-depth interview and the proposed framework of the Expert Finding System for Vietnamese SMEs. Finally, the last section i.e. Section V provides a summary of the results, discusses them, and indicates future work.

II. Expert Finding Systems

The development and deployment of EFS, have enabled users to discover and search for experts and high-quality human resources in various fields for collaboration or knowledge acquisition [11]. Singh in [12] conducted a study highlighting the essential need for organizations to swiftly identify experts in different domains. However, this task presents challenges due to limited and unevenly distributed information about experts. Furthermore, the requirements of those seeking experts are often unclear, and past expert performance lacks sufficient visibility, making it difficult to assess and quantify expertise. The dynamic nature of experts, who may switch jobs and research areas, further complicates expert identification. Additionally, many complex problems require the collective intelligence of diverse experts, underscoring the necessity of developing an expert finding information system to expedite problem-solving and enhance organizational efficiency [12].

Various studies have explored EFSs to address enterprise challenges and global issues [11, 13]. The development of these systems involves the discovery of experts in specialized fields, an examination of existing systems in these domains, and the proposal of models to guide future system design and development decisions [13]. Organizations can also leverage commercial services and solutions to identify experts and evaluate EFSs, taking into account their unique characteristics and the most effective implementation methods [11]. Moreover, In SMEs' pursuit of expert human resources, recent research indicates that social globalization positively influences gender equality in employment opportunities [14].

In Singh [12] study, the essential attributes of an ideal EFS are outlined. This comprehensive framework envisions a system that operates efficiently and effectively. Furthermore, it underscores the significance of categorizing expertise through a subject classification scheme, ensuring that users can easily access and navigate the wealth of knowledge available. Moreover, it strongly emphasizes the quantification of expertise, enabling the system to rank experts, thus aiding users in identifying the most suitable individuals for their specific needs. Ensuring the reliability of information sources is another aspect, ensuring the integrity and accuracy of the system's output. Moreover, the framework envisions fostering expert communities, facilitating collaboration and knowledge sharing among professionals. Lastly, the system is geared towards identifying locally available experts, enhancing accessibility and relevance for users seeking expertise within their geographic vicinity.

Furthermore, apart from research on EFSs for organizations, some studies delve into technical aspects related to collecting and processing expert information and algorithms for accurate expert identification, evaluation, and ranking. Taie, et al. [15] presents methods for classifying expertise, including domain-based classification (enterprise/organization and online community) and technique-based classification (machine learning and graph techniques). However, it is worth noting that combining content-based expertise indicators with social relationships does not completely resolve the issues related to expert identification and ranking [15]. Additionally, Singh [12] and Wang, et al. [16] highlight prominent expert finding methods, such as unstructured data mining, social networking sites, contact management systems, and self-disclosure data from experts.

According to Husain, et al. [10], EFSs have found application across various domains, including academics, enterprises, medicine, online knowledge-sharing communities, online forums, and social networks. In this study, Husain, et al. [10] asserts that defining specific tasks for expert finding systems in certain domains can be challenging. Consequently, there is a research gap in understanding the tasks that expert search systems support for businesses, especially small and medium-sized enterprises (SMEs). This gap will be the focus of the current study.

Moreover, while numerous studies have addressed technical aspects of EFSs, only a limited number of research into the specific needs of Vietnamese SMEs in locating experts in their respective fields to fulfill their human resource requirements effectively have been identified.

Lin, et al. [17] and Husain, et al. [10] have critically examined existing research in the field, highlighting several noteworthy gaps that demand attention and resolution. First and foremost, they emphasize that most studies in the field of EFSs have only focused on the academic domain, and very little is known about EFSs in other domains where expert knowledge is critical. Also, these studies bring up data-related problems that have not been properly dealt with yet, like security issues, data inconsistencies (like having multiple names for the same person or names that sound similar for different people), and the issues surrounding the completeness of expert information. Addressing these issues calls for the development of complex algorithms capable of seamlessly integrating data from diverse sources and tailoring expert-finding models to specific tasks and domains, a task that remains largely unmet. Moreover, Lin, et al. [17] and Husain, et al. [10] stress the imperative of fostering diversity in system development by creating combined datasets from multiple sources, promoting more versatile and robust solutions. Lastly, the identification of expert groups to solve interdisciplinary problems is highlighted as an essential requirement across various applications, underscoring the significance of collaborative and multidisciplinary approaches in expertise seeking. These identified gaps serve as critical pointers for future research, shedding light on the areas in need of further exploration and innovation within the realm of expert finding.

The expert finding task involves five key procedural aspects [10]:

- Expertise evidence selection: This step focuses on extracting data and information relevant to a person's expertise, which is crucial for determining their status as an expert in a particular field.
- Expert representation: EFS aim to provide users with information that aids in not only locating experts but also in selecting the most relevant ones. This requires identifying valuable information for decision-making, considering both documented evidence and contextual factors.
- Model building: Model building encompasses pre-processing, indexing, and modeling. Pre-processing involves handling diverse data sources, recognizing candidate expert identifiers (e.g., names, emails), and addressing challenges like named entity recognition and disambiguation. Modeling and retrieval involve creating models that associate candidate experts with user queries and rank them based on these associations, utilizing various methods such as probabilistic, network-based, and voting models.
- Model evaluation: Evaluating the efficiency of EFS is typically done using test collections (datasets) to assess their performance in retrieving relevant experts in response to user queries.
- Interaction design: Presenting expert search results to users is a critical practical concern. It involves displaying not only ranked lists of experts but also related documents, conferences, journals, and contact details to aid users in assessing the relevance of experts. Additional information like photos, affiliations, publications, and projects can help users gauge an expert's seniority and expertise alignment.

From an in-depth review of relevant EFS literature, we are dedicated to developing a tailored EFS for Vietnamese SMEs. This study will address the five key issues identified by Husain, et al. [10] and overcome the limitations mentioned by Lin, et al. [17]. The proposed EFS will incorporate all essential features from Singh [12] study, including robust data processing, advanced modeling, efficient retrieval, and a user-friendly interface. Our objective is to not only meet the specific requirements of Vietnamese SMEs but also set a global standard in EFS, adhering to best practices in the academic literature. Through this effort, we aim to enhance the expertise-seeking process for Vietnamese businesses, contributing to their growth and success in a dynamic marketplace.

III. METHODOLOGY

A. Research Design

The research process is structured into two distinct stages, each aligned with a research question.

For the first question, firstly, we conducted a review of EFSs to gain an understanding of the research problem and identify gaps in previous studies. Next, primary data was collected from businesses to gain a deeper understanding of the challenges they face when finding and using experts to support their activities. The following steps were taken:

- Determine research goals and questions
- Plan data collection
- Select some survey business
- Conduct interviews
- Analyze the interview results, focusing on identifying the problems that businesses are facing in the process of finding and using experts to support business activities.

For the second question, reliance is placed on the five key issues mentioned by Husain, et al. [10] with proposed methods for handling these issues:

- Identify details for each issue: Gather specific information about each of the 5 key issues highlighted by Husain, et al. [10].
- Collect relevant data: Gather data that is relevant to these issues.
- Develop a system: Create a system or framework to address each of the five key issues.
- Check solution evaluation: Evaluate the effectiveness of the proposed solutions for each of the five key issues. This can be done through data analysis, expert feedback, or user testing.

By following these steps, we can effectively provide practical solutions to the challenges faced in the process of finding experts.

B. Participants

The authors conducted in-depth interviews with 20 representatives of SMEs operating in various fields, including logistics, construction and architecture, information technology, and services (see Table I). Most of these enterprises are concentrated in Hanoi, with a few also located in Ho Chi Minh City or having branches in different areas. The number of permanent employees in each enterprise ranges from 10 to more than 200. The interviews focused on surveying the needs for general human resources and expert human resources in today's businesses. Additionally, the authors surveyed the need for information systems to support searching and linking with customers' human resources in different positions and locations. The interviews were mainly conducted using audio or video calls between December 2021 and January 2022. Most of the interview participants held important positions in the enterprises, such as General Director/Director, Head of department, or Executive Director. The data obtained from the interviews will be coded and synthesized according to groups of indicators, thereby synthesizing into a number of criteria to evaluate the current state of human resource needs in SMEs today. The survey data from the interviews related to how businesses seek sources of experts was used by the research team to propose solutions for building a system that meets the human resource needs of businesses. The system will provide expert information sources for businesses and create an information channel connecting businesses and experts in each field.

TABLE I. INTERVIEW CANDIDATES

#	Industry	Number of employees	Number of enterprises	Participants
1	Logistics	50-200	2	Delivery Director, Branch Head Manager
2	Information Technology	22-210	4	Director
3	Construction	30-600	7	Director, Deputy Director, Head of Department
4	Service	10-150	3	Director
5	Manufacture	23-120	2	Director
6	Architecture	10-30	2	Director

C. System Design

The system is built on a robust foundation that encompasses data collection from diverse sources, data integration, entity resolution, and indexing to ensure the accuracy and accessibility of expert information. The use of NoSQL databases for storing expert data is a practical choice, offering flexibility, scalability, and rapid performance, all essential for accommodating the growing volume of expert data over time. The model building process is systematic, involving input, pre-processing, entity creation, modeling and retrieval, and output generation (see Fig. 1), all aimed at providing users with a seamless experience in finding and connecting with experts. The emphasis on expert ranking is notable, as it helps users efficiently identify experts with substantial expertise and influence in their respective domains. The integration of a learning-to-rank algorithm for expert ranking is a forward-looking approach that promises to improve the quality of expert suggestions.

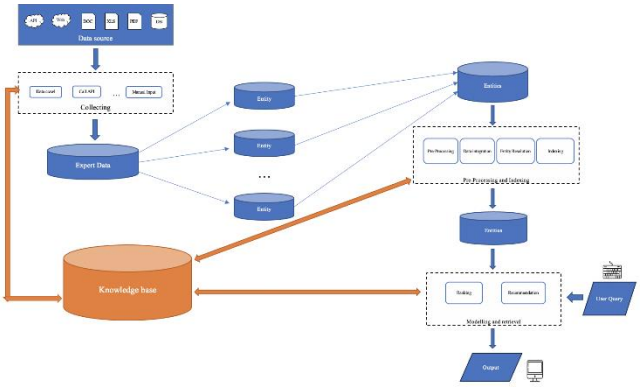

Fig. 1. System architecture model.

IV. RESULTS AND DISCUSSION

A. Understanding the Expert Resource Needs of Vietnamese SMEs

The interview results revealed several issues related to the needs and challenges businesses face when looking for experts, as follows:

1) Concerning the enterprise's available human resources: Assessing the organization's current human resources is the first step in determining the need for additional human resources. Does this human resource meet the business's work requirements during its operations?

According to the results of the interviews, the majority of businesses continue to lack significant human resources in numerous departments. Many positions, including senior managers, middle managers, department heads, team leaders, and employees, require additional personnel. In it, a respondent remarked:

"Positions that we often lack and need to recruit are middle managers and team leaders. However, finding the ideal candidate is not simple."

Most interview participants said that adding human resources is often done depending on the expansion needs of the business.

Typically, the missing human resources consist of both skilled and unskilled labor. All businesses reported a shortage of qualified personnel. One director of business explained:

"It is easier to supplement unskilled labor than highly skilled one. Finding and securing an agreement to collaborate with experts is time-consuming and difficult."

This result was also mentioned in the research of Thang and Nguyen [18], which noted the significant shortage of skilled and qualified human resources within Vietnamese businesses.

Therefore, it is clear that most businesses lack an adequate permanent workforce and must, therefore, consider expanding their human resources, particularly by adding expert personnel, to support their activities.

2) Regarding the importance of finding expert personnel: The majority of interviewees indicated that their organizations need external expert resources. However, companies have shown that the need to search depends on their operational requirements. These needs frequently arise when:

"The enterprise has a new project and requires experts to advise and support phases of the project or fulfill the requirements of fixed, recurring jobs."

Moreover, if a company wishes to expand its operations to a new international market, it will find Vietnamese experts residing in that country. A respondent listed the following as activities for which businesses seek assistance from specialists:

"Marketing, transportation, production, sales, and financial management" as well as "information and communication technology, legal, and risk management" are a few activities that need additional external human resources.

Besides, the European Commission [19] also points out that "*a virtual organization consists of a small core of fulltime employees and outside specialists temporarily hired as needed to work on projects.*" So, acquiring human resources with specialized knowledge from external sources, including foreign experts, is necessary.

3) Regarding the need for consulting and cooperation with experts: All interviewees indicated that they are willing to reach out to experts in the business's area of interest if they require expert advice or consulting services. These individuals also indicated that they had reached out to experts to request collaboration. This demonstrates that businesses desire assistance from individuals who have an in-depth understanding of the problems they are facing and need to solve.

In addition, quite a few instances have occurred when asking in greater detail about the outcomes of contacts with experts. Only a small portion of these got to collaborate. The majority of the remaining suggestions have been rejected to varying degrees.

"When I contact outside experts, they politely decline for a variety of personal reasons. Typically, this is due to an abundance of current work."

This is a significant obstacle for businesses when they want to collaborate with experts.

Thus, beyond the difficulties businesses encounter in finding and reaching out to experts, are there also impediments associated with collaborating with them? Several primary causes are listed, including:

"Not understanding the challenges faced by businesses"

"Unclear understanding of the business operating procedure."

"Unable to agree on conditions for cooperation"

Thus, it can be seen that another challenge businesses face when they want to collaborate with external human resources is how to help them understand the business's operating processes so they can provide the most effective and efficient support.

When interviewees were asked to choose between training existing workers themselves to meet the needs of the business and inviting experts to collaborate in each stage or project, more than half of the responses selected *"Use their employees"* rather than *"Invite experts to cooperate according to needs"* due to the many difficulties mentioned. An analysis of these processes reveals that, in addition to a fixed salary and other benefits, the implementation of the training workers will take a significant amount of time. Otherwise, if enterprises choose to work with experts who are available, they will only have to compensate based on the volume and effectiveness of their work.

Despite understanding the importance of locating and collaborating with experts, it is evident from the results of the interviews that there are numerous difficulties in the search process or contact with them.

4) Regarding the methods and tools used to find experts: According to interviewees, some methods and tools that businesses frequently use to find or contact experts are also critical issues (see Table II). So, they must be carefully considered and evaluated.

Surprisingly, all of the responding managers mentioned the method of finding personnel *"through relationships"* while the other methods were not used much. This leads to the conclusion that the current tools for supporting human resource search activities do not meet the needs of businesses adequately.

TABLE II. METHODS AND TOOLS THAT BUSINESSES FREQUENTLY USE TO FIND EXPERTS

Number of Participant	Methods/tools	Comments
5	Search engines	"Not very efficient. Finding suitable human resources remains a difficult challenge." "Low quality."
8	Job search websites	"At present, there are numerous human resources recruitment channels, but they frequently do not meet the appropriate needs or the quality is inconsistent, slow, or non-responsive." "It is time-consuming."
2	Expert finding systems	"Finding human resources that meet expectations is quite difficult." "The system is quite quick, but its effectiveness cannot be fully evaluated until a face-to-face interview is conducted. However, this is a preliminary initial step."
20	Interpersonal relationships	"This method is quite flexible, high efficiency but waste time and difficult to find number of experts at the same time ."

5) Concerning for finding experts in the field of interest: In light of the current situation that SMEs are facing in the process of searching for experts from outside, the authors have proposed to build an EFS that stores databases in the form of "metadata" about expert profiles for businesses to meet the needs of external personnel search and cooperation. A system with a large quantity of data about human resources who have in-depth knowledge in a variety of business-relevant areas. This system will be developed at no cost to establish a channel of communication between businesses and experts in various fields, and it can also introduce businesses to suitable experts from others if the system does not contain any relevant information.

To implement this idea, the authors conducted interviews with participants regarding system-related issues. The majority of interviewees stated that a specialized expert finding system for SMEs is essential. And the ideal system must provide the following essential features (see Table III):

Businesses have concerned the finding expert, with all of them expressing readiness to evaluate and offer feedback on this system once it's finalized.

D. Addressing Key Issues and Enhancing Efficiency of EFS for Vietnamese SMEs

Based on the insights gathered from the interviews, our objective is to develop an EFS that caters to the demands of locating proficient human resources for Vietnamese businesses. The system's database will be a substantial repository of big data integrated with the Knowledge Base System. The application of data processing techniques extends beyond facilitating information retrieval; it also delves into deeper data comprehension, uncovering interrelationships between data entities, and proffering actionable insights. This serves to motivate and support users in making informed decisions.

TABLE III. SEVERAL FEATURES REQUIRED IN EFS SYSTEMS DESIGNED FOR BUSINESS

#	Features	Requirements
1	Find an expert	Find the expert who most closely aligns with the user's query
2	Booking an Expert	Users submit a request for a specific job. The system will respond a list of potential experts suitable for the job position.
3	Connect or collaborate with experts	Submit a request for an appointment or propose collaboration with a particular expert
4	Introduce/Suggest experts	An expert can suggest another expert they are acquainted with for a customer's requirements.
5	Expert Q&A	Customers ask questions, experts answer.

Throughout the system development process, we gained valuable insights into the global landscape of Expertise Finding System implementations, with a particular emphasis on extensive research articles about EFS. Notably, a study conducted by Husain, et al. [10] has identified challenges within EFS systems that require resolution, including expertise evidence selection, expert representation, model development, model evaluation, and interaction design. These findings serve as a foundational framework for our endeavor to propose methods and techniques to address the aforementioned issues within our EFS system.

1) Expertise evidence selection: Expert information can be collected either manually or automatically, but it can only work against a pre-existing knowledge base (see Fig. 2). The knowlege base consists of a list of titles and positions, jobs by industry or field, high-ranking universities, and companies where many professionals work, certificates. The knowledge data comes from various sources drawn from predefined categories, such as the Yellow Pages directory, the research journals directory, the top-ranked universities directory, or the large-cap companies directory [20]. This dataset will be updated regularly during data analysis and processing.

Moreover, the Knowledge Base also facilitates the handling of Vietnamese data, including information pertaining to 3,000 career types in both Vietnamese and English languages, with synonym support. Additionally, it encompasses the names of nearly 200 countries, complete with geographical coordinates and names in Vietnamese as well as various other languages, along with phone numbers, to accommodate international customers utilizing global phone numbers. The Knowledge Base further includes 200 common Vietnamese names or surnames (unigrams) and almost 10,000 common Vietnamese surname combinations (bigrams) to aid in the identification of Vietnamese names. We have developed a Natural Language Processing (NLP) algorithm specifically designed for detecting Vietnamese names.

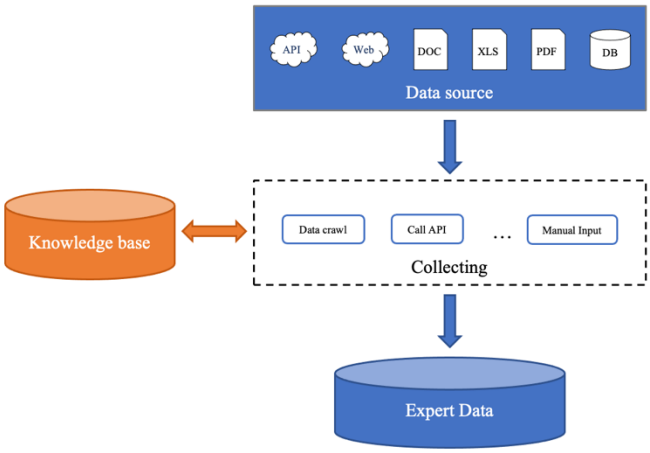

Fig. 2. Expertise selection.

The acquisition of data involves sourcing information from a diverse array of outlets, including the web, textual sources, social networks, APIs, and more. This process of gathering data is executed through a combination of manual and automated techniques. A proficient team will oversee the manual data collection aspect, while an automated data collection program will be deployed across multiple search servers. This automated system scans for pertinent information, extracts the requisite data, and deposits it into an unstructured database to facilitate subsequent analysis. In the context of data collection, the primary objective is to ascertain whether an individual possesses expertise in a specific field. To accomplish this, it is imperative to amass pertinent information pertaining to the individual.

Expert representation: Expert information needs to be effectively organized and stored, making it readily accessible and useful for various applications, such as expert ranking, collaboration, or expertise matching [21]. This information can be divided into the following collections:

a) Expert's Personal information

ID (Primary Key): An auto-incrementing unique identifier for each expert.

Name: The full name of the expert.

Title/Position: The expert's job title or position.

Contact Information:

Email: The expert's email address.

Phone: The expert's phone number.

Education: Details about the expert's educational background. This field can be more complex and structured, with subfields like:

Degree: The type of degree (e.g., Bachelor's, Master's, Ph.D.).

Institution: The name of the educational institution.

Year: The year of graduation.

Skills: A field to list the skills and areas of expertise possessed by the expert. This can be a text field or a list of keywords.

Areas of Expertise: A field to specify the main areas or subjects in which the expert has expertise. This can also be a text field or a list of keywords.

Awards and Honors: Any awards or honors received by the expert, with subfields like:

Award Name: The name of the award.

Year: The year the award was received.

Goal Vision: The expert's goal and vision.

Work Experience: Information about the expert's work history. This field can also be structured, with subfields like:

Position: The job title.

Company: The name of the company.

Start Date: The start date of the job.

End Date: The end date of the job.

Projects: Information about projects that were joined by expert.

Publications: A list of publications authored by the expert. This field can be structured with subfields like:

Title: The title of the publication.

Publication Date: The date the publication was released.

Books/Book Chapters: A list of books or book chapters authored by the expert.

Patents/Inventions: A list of patents or inventions authored by the expert.

b) Relationships

Collaboration, Association and Mentorship: The name of the organization, company or country the expert is affiliated with.

c) Presence

Social Media Profiles: Links or handles to the expert's social media profiles, if applicable.

Personal Website: Links to the expert's personal website.

d) Data Source

A list of data sources where expert information is collected.

Experts can be stored in a data schema that presents in the Fig. 3.

NoSQL databases stand out as an excellent choice for the storage of expert information, thanks to their versatility, scalability, and rapid performance [22]. NoSQL databases, including those employing key-value pairs and document-oriented structures, offer the flexibility to store expert information in a manner that is both adaptable and hierarchical. This facilitates effortless access and updates. Furthermore, these databases are engineered to handle substantial volumes of data and traffic without compromising on performance, rendering them well-suited for the enduring storage of expanding expert data over time. Notably, NoSQL databases excel in accommodating "one-to-many" relationships between entities, such as experts and their publications. As a result, all of an expert's details can be conveniently encapsulated within a single document, simplifying the retrieval and maintenance process.

Fig. 3. Data schema.

2) Model building: An expert finding system's model building process involves 2 steps [10] (see Fig. 4):

a) Pre-processing and Indexing: Cleaning, formatting, and transforming the raw expert data to make it consistent and suitable for analysis. This includes removing duplicates and irrelevant entries, standardizing data formats, handling missing data, tokenizing and normalizing text data, and creating indexes on specific fields or attributes to optimize query performance. Based on the Knowledge Base, the data will be classified, extracted into information fields, and concatenated to form experts.

b) Modelling and Retrieval: Developing a model that can analyze and rank the experts with support from the knowledge base. This model may use various techniques, such as machine learning, natural language processing, or weighted scoring, to evaluate and rank experts based on specific criteria. It takes user queries or criteria as input and searches the knowledge base for relevant experts. The retrieval system uses the model to score and rank experts based on how well they match the query, returning a list of suggested experts that meet the user's requirements.

This process enables users to efficiently discover and engage with experts in a given field or domain, and its effectiveness depends on the quality of data input, the accuracy of the model, and the efficiency of the retrieval mechanism.

Data cleaning and preprocessing are essential for ensuring accurate and reliable expert data. This involves standardizing

data formats, eliminating duplicates, handling outliers, and processing text data by removing special characters, tokenizing, eliminating stop words, and performing stemming/lemmatization. Encoding categorical data, scaling, and normalization are crucial. Finally, data splitting into training, validation, and test sets is necessary for building machine learning models. Data integration for expert information involves consolidating data from various sources to create a comprehensive dataset. This can be achieved through methods like data warehousing, ETL processes, data replication, data virtualization, and data federation. It ensures accessibility and accuracy in expert data for various applications. Entity resolution is vital for ensuring data accuracy in expert information. It involves identifying and consolidating records representing the same entity across diverse sources with variations in attributes. Preprocessing is essential to mitigate these variations. Indexing is used to improve search efficiency by adding indexes to relevant fields, allowing faster data access and reduced search times. It's especially useful in expert information systems for storing expert descriptions, background information, and relationships between experts. Multiple keywords and Boolean operators can be used to refine searches.

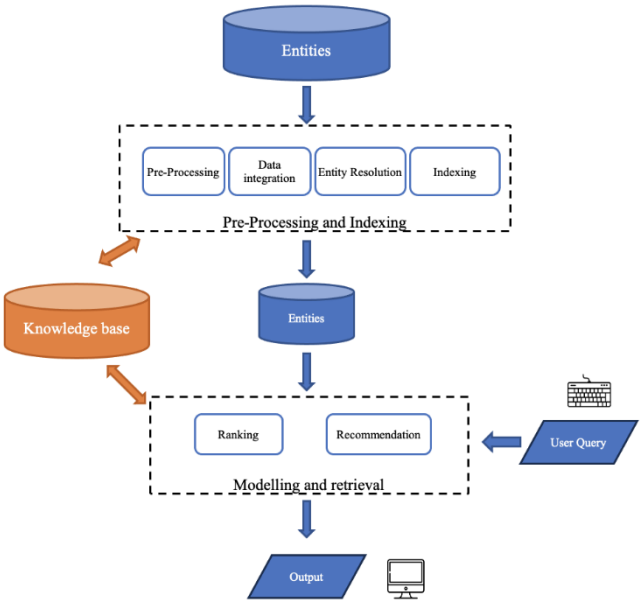

Fig. 4. An expert finding system's model building process.

Managing expert information involves understanding user queries, modeling them, retrieving relevant data, and providing accurate responses. This process begins with interpreting user intent through natural language understanding, query deconstruction, preprocessing, and semantic analysis. The technology also offers recommendation, reducing the need for users to enter complete queries by providing prompt suggestions related to service types, specialties, expert locations, company names, and individual names. The query is then modeled to create a structured representation, and information retrieval is performed, ranking and scoring results. We used Learning-to-rank algorithms to experiment with ranking experts, providing a list of suggested experts for various positions, saving time in the selection process.

3) Model evaluation: Various evaluation methods can be employed, depending on the specific function. For example:

a) Information retrieval: Precision, Recall, F1-Score, Mean Average Precision are used to evaluate the relevance and ranking of search results [23].

b) Recommendation: Precision at K (P@K), Mean Reciprocal Rank (MRR), or click-through rates are used to assess the quality of suggested queries [24].

c) Entity resolution: Measures like Precision, Recall, and F1-Score are used to evaluate the accuracy of entity resolution [25].

d) Ranking: Precision, recall, F1-Score, MAP, NDCG, or other relevant metrics are used to judge the quality of the ordered search results [26].

Moreover, domain experts with expertise in the system's relevant field offer subjective evaluations of its performance, assessing factors like the quality and relevance of search results, the precision of auto-suggestions, the efficiency of entity resolution, and the overall user experience.

4) Interaction design: Interaction design for the system, along with a booking feature, is a pivotal element in delivering a user-friendly and efficient experience. To start, the search functionality should be intuitive and easily accessible, empowering users to input their queries and apply filters to refine their results. The system should efficiently display a list of expert profiles after a search, offering a comprehensive summary of each expert's qualifications and availability (see Fig. 5). A clear and organized layout is essential to help users quickly identify the expert who best matches their needs.

Fig. 5. Advance expert search.

Upon selecting an expert profile, users should gain access to a detailed view of the expert's background, credentials, and reviews from previous clients. Additionally, the interaction design should incorporate easy-to-use booking features (see Fig. 6). Users should be able to select available time slots, input booking details, and confirm appointments with minimal effort. To prevent scheduling conflicts, real-time availability updates are crucial, ensuring a seamless and frustration-free booking process.

Our proposed system's information presentation on a world map offers users an extensive and user-friendly data visualization tool (see Fig. 7). Users have the flexibility to zoom in and out of the map to access statistical data across various geographic scales, from continents to individual towns. This feature not only empowers users to explore data in-depth but also provides a global perspective on the Vietnamese community's reach and activities. The automatic aggregation and real-time display of statistics on the map ensure that users have access to the most up-to-date and comprehensive information. This functionality enhances the system's usability and enables users to make informed decisions or gain a better understanding of the Vietnamese community's global presence.

V. Conclusion and Future Work

In conclusion, the purpose of the current study was to explore the EFSs customized for business applications, with a particular emphasis on SMEs operating in the Vietnamese context. By conducting in-depth interviews with Vietnamese SMEs, the study provides requirements and challenges these enterprises face when seeking expert resources. Subsequently, the research proposed an architectural model for an EFS for Vietnamese SMEs. This EFS automatically collect data from a multi sources to identify Vietnamese experts. Morover, this study is founded on a well-established framework that addresses five critical issues derived from Husain's seminal work, providing a roadmap for the development of an efficient and tailored EFS. Through the exploration of these key issues, the insights gained from this study may be of assistance to the creation of a specialized EFS capable of meeting the distinct needs of Vietnamese SMEs as they embark on their quest to locate and collaborate with experts in pursuit of business growth and innovation.

Further experimental investigations are needed to develop and refine the proposed EFS system. This should encompass the comprehensive design, construction, and testing of the system to ensure its seamless integration into the operations of Vietnamese SMEs. Continuous data collection and analysis must remain at the core, allowing the system's knowledge base to evolve in real-time and provide the most up-to-date expert information. Enhancement of the EFS model using advanced technologies such as machine learning and natural language processing will significantly improve the accuracy and efficiency of expert recommendations, catering to the unique requirements of Vietnamese SMEs. User feedback and extensive testing will fine-tune the system, making it even more user-friendly and effective for SMEs. In addition, an emphasis should be placed on security measures, scalability, and the potential expansion of the system to serve a broader range of industries and regions. Moreover, it is crucial to conduct long-term assessments to assess the lasting impact of the EFS on Vietnamese SMEs, tracking factors like increased efficiency, cost savings, and tangible business growth.

A Zero-Trust Model for Intrusion Detection in Drone Networks

Said OUIAZZANE, Malika ADDOU, Fatimazahra BARRAMOU
ASYR RT, LaGeS Laboratory, Hassania School of Public Works, Morocco

***Abstract*—Today's worldwide introduction of drone fleets in a range of industrial applications has led to numerous network security issues, opening drones up to cyberthreats. In response to these challenges, an innovative approach has been proposed to protect drone fleet networks against potentially dangerous cyberattacks. Indeed, drones are considered as flying computers, and the proposed approach takes into account their complex network structure and communication protocols. The proposed system is designed around a multi-agent architecture, with a hybrid zero-trust detection mechanism against known and emerging cyberthreats. The CICIDS2017 dataset was exploited after performing some essential pre-processing tasks including data cleaning, balancing, binarization and dimension reduction. The proposed approach guaranteed high levels of accuracy and scalability, enabling an effective response to potentially dangerous cyber threat scenarios threatening drone fleets. To evaluate the effectiveness of the proposed system, a test portion of CICIDS2017 was used. The accuracy in recognizing benign network traffic reached 99.99% with a very low false alarm rate, ensuring the system's effectiveness against known and unknown cyber threats. Extensive experimental testing has been carried out on never-before-seen data, highlighting the system's remarkable ability to rapidly recognize cyber threats in real time, thereby enhancing the overall security of drone networks. The contribution of the proposed approach is significant for drone network security, as it introduces a comprehensive model designed to meet the specific security requirements of drone fleets. Finally, the proposed approach offers practical prospects for improving the security of drone applications.**

Keywords*—*Fleet of drones; security; zero trust; intrusions; cybersecurity; zero day; Multi-Agent

I. INTRODUCTION

Over the past few years, the use of drones has grown dramatically, as the Federal Aviation Administration estimates that there are between 2 and 7 million consumer drones in use by 2020 [1]. This major growth in drone usage is reflected in the projected trajectory of the drone industry, which is expected to reach an impressive $30 billion by 2036 [2]. The widespread accessibility and affordability of consumer drones has facilitated their adoption by hobbyists and enthusiasts alike. Consequently, airspace has seen a surge in unmanned aerial vehicles, leading to radical changes in aviation practices and raising important questions about security, privacy and regulatory measures [3].

Drones and drone fleets have become priceless assets for critical and sensitive situation management in a variety of fields. For example, their role in border surveillance is vital for strengthening security and control through the detection of illicit activities [4]. And when it comes to critical infrastructure, drones carry out inspections to identify vulnerabilities in assets such as power lines, bridges and pipelines, thus promoting early detection and preventive maintenance [5]. As for police forces, they use drones to monitor crowds at public events and investigate crime scenes, keeping officers safe. In addition, drones can also contribute to damage assessment, survivor location and rescue operations by providing real-time aerial data during disasters. For environmental monitoring, drones investigate sensitive areas and nature reserves to combat illegal activities, while studying the behavior of flora and fauna [6]. Finally, drones can contribute to healthcare by rapidly delivering medical supplies to inaccessible regions [7].

So, as mentioned, drones are therefore used to deal with more critical situations, as any bypassing of the drone network security can result in material and human damage, and even endanger human lives [8]. Nevertheless, the scientific community focused on communication protocols, battery autonomy and drone network use cases, and ignored the security aspect of this widely used technology [9].

As a result, addressing the security aspect is a crucial point to be taken very seriously by the scientific community, in order to protect drone networks against emerging cyber-attacks. The present work aims to propose a new intrusion detection approach based on a multi-agent architecture with a hybrid detection mechanism respecting the zero-trust principle.

The remainder of this paper is structured as follows: In Section II, we describe the background to the study, defining some concepts relevant to our study. Section II examines the current state of the art regarding the security of UAV networks and several proposed approaches to deal with intrusion detection in UAV networks. Section III presents an in-depth exploration of the proposed IDS architecture, detailing its components and its operational principle. Section IV describes the simulation and testing methodology of the proposed system. Section V delves into results and discussion and Section VI concludes the paper.

A. Drone

A "drone" is any unmanned aircraft, commonly known as an unmanned aerial vehicle (UAV), unmanned aerial system (UAS) or unmanned combat aerial vehicle (UCAV) [10]. For the purposes of this discussion, we focus on consumer/recreational UAVs, as illustrated in Fig. 1.

Fig. 1. Examples of consumer drones.

B. Fleet of Drones

1) Definition of a fleet of drones: A drone fleet is a coordinated and synchronized set of drones that cooperate to accomplish a given mission [11]. UAVs can be configured with various functionalities to satisfy a wide range of user needs. Managing a fleet of drones can involve complex operations, such as centralized control, mission planning, inter-drone communication and real-time data collection [12]. There are a wide variety of possible deployments for drone fleets, from surveillance and inspection to precision farming, logistics and delivery, and disaster relief. [13]

2) Communication modes of a fleet of drones: A drone fleet can be designed based on four possible communication architectures: centralized communication architecture, cellular communication architecture, satellite communication architecture and adhoc communication architecture [14] [15].

a) Satellite communication architecture: This architecture involves establishing communications between drones via satellite connections as shown in Fig. 2. Such links offer global coverage and are therefore particularly well suited to applications requiring wide coverage in remote or extensive areas. [16]

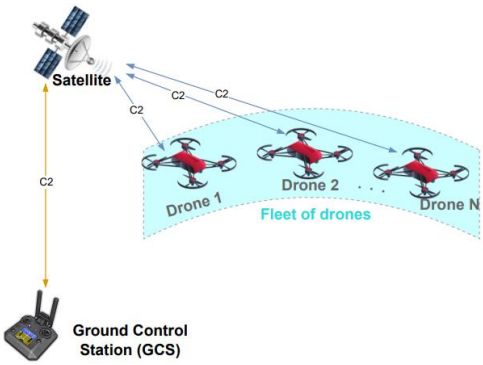

Fig. 2. Satellite communication architecture.

b) Ad hoc communication architecture: This type of communication is based on cooperation between drones in a dynamic, autonomous network, with no dependence on a static infrastructure, as shown in Fig. 3. Nearby drones interconnect autonomously, contributing to decentralized communications and collaborative data exchange, especially in scenarios where there is no conventional infrastructure. [17]

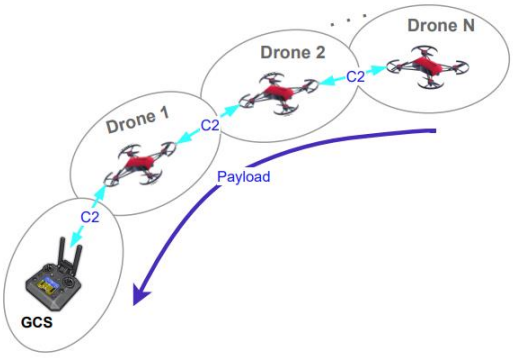

Fig. 3. Ad-hoc communication architecture.

c) Cellular communication architecture: A cellular architecture exploits existing cellular networks to ensure interaction between drones and ground stations as demonstrated by Fig. 4. Acting as roving nodes in the cellular network, drones ensure stable communication over extended distances, especially in urban environments or densely populated areas with established cellular coverage [18].

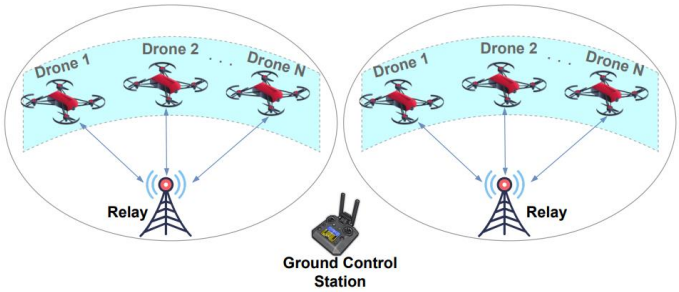

Fig. 4. Cellular communication architecture.

d) Centralized communications architecture: As shown in Fig. 5, this type of architecture relies primarily on a ground control station to manage communications. This configuration enables simplified coordination, efficient data processing and immediate decision-making, for scenarios requiring centralized control and supervision of drone fleets. [19]

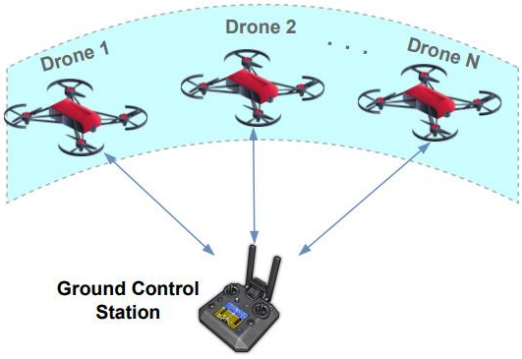

Fig. 5. Centralized communication architecture.

II. State of the Art

A. An Overview of Dangerous Tactics Targeting Drone Networks

Drone networks are vulnerable to a wide range of cyber-attacks. These attacks are all based on well-thought-out strategies, enabling hackers to achieve their malicious objectives, sometimes with life-threatening consequences. These attacks include:

- Communications jamming: The aim of communications jamming attacks is to disrupt or interfere with communications between UAVs and their control stations. Attackers can thus disrupt communication signals and cause loss of control, with serious consequences for ongoing operations. [20]
- DoS and DDoS attacks: This kind of attacks floods the UAV network with a large number of malicious requests, making it unavailable for legitimate communications. These attacks may lead to the interruption of critical business operations or even paralyze the network. [21]
- Data interception: Interception attacks capture sensitive data exchanged between drones and their associated control stations. This can lead to the exposure of confidential data and compromise mission confidentiality. [22]
- Usurpation of control: Spoofing is a serious threat that allows hackers to take control of a drone remotely, bypassing the legitimate control system. This can lead to malicious use of the drone for illegal or dangerous purposes. [23]

B. Attack Surface and Compromising Risk of a Drone Network

Drone networks are designed to cover large geographical areas and rely mainly on WiFi and radio waves as their communications medium [24]. Indeed, various types of communication can be involved in a network of drone fleets (see Fig. 6), including ad-hoc exchanges between drones, interactions with the control station and satellite links for GPS. Consequently, the attack surface of a drone network is considerable, exposing these networks to potential cybersecurity risks [25]. Given that anyone in the vicinity with a WiFi antenna/packet sniffer can potentially attempt to compromise the security principles of drone networks.

Drone manufacturers and researchers have mainly focused on developing communication protocols and improving battery life, while often ignoring the security aspect of drone networks. If the security of a drone network is compromised, numerous security risks can arise [9]. For example, a hacker could take control of the drone and gain access to its payload and the sensitive information it carries [21]. The hacker could also bring down the drone, resulting in property damage and the loss of the aircraft. In addition, the hacker could take control of the drone for malicious purposes, or integrate his own drone into the fleet, thus disrupting delivery and causing a denial-of-service issue [26].

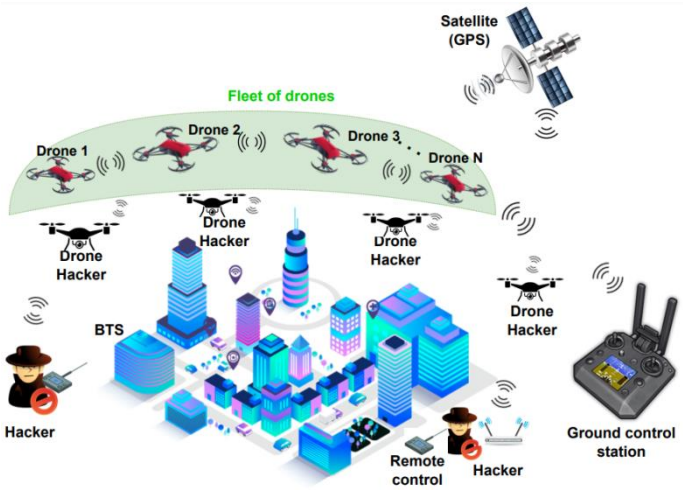

Fig. 6. Overview of a drone network and its attack surface.

C. Related Work

Recent research efforts in the field of intrusion detection systems for UAV fleets have seen the emergence of new, innovative approaches, each addressing distinct security issues and employing diversified methodologies. Fotohi, Abdan and Ghasemi (2022) [27] presented SID-UAV, an innovative system designed to counter the security risks associated with malicious drones, particularly in the context of drone-to-drone communication. In addition, Shrestha et al (2021) [28] proposed a UAV- and satellite-based 5G-network security model that can harness machine learning to effectively detect vulnerabilities and cyberattacks within a drone network. The proposed approach was suitable for both drone and satellite connections. Ouiazzane et al. (2022) [9] proposed a multi-agent intrusion detection system primarily designed according to a multi-agent architecture to counter denial-of-service (DoS) attacks targeting drone networks. The authors demonstrated remarkable accuracy in detecting DoS attacks while minimizing false alarms, underlining the system's effectiveness in protecting drone networks against a spectrum of known and unknown threats. Ihekoronye et al. (2022) [29] introduced a hierarchical intrusion detection system based on anomaly detection, suggesting an effective strategy for securing military UAV networks. They employed random cross-validation and finely tuned hyperparameters, guaranteeing resilience to network delays. The system considers payload constraints, battery limitations and the high mobility that characterizes Internet of Drones (IoD) networks. In a deep learning context, Abu Al-Haija and Al Badawi (2022) [30] proposed an autonomous intrusion detection approach adapted to drone networks. Such an approach makes use of deep convolutional neural networks to discern malicious activities within drone networks, efficiently processing encrypted Wi-Fi data records from commonly used drone brands such as Parrot, DBPower and DJI Spark drones.

Finally, Ouiazzane et al. took up the challenge of intrusion detection in UAV fleet networks in their 2020 study [14], focusing on ad hoc communication architectures. Their multi-agent system, enriched with detection mechanisms based on machine learning, underlines the importance of adaptable, intelligent security measures in the constantly evolving context

of drone fleet networks. These studies have made a significant contribution to the advancement of intrusion detection systems designed to meet the specific security challenges inherent in drone networks.

D. Discussion of Related Work Limitations

The state-of-the-art study carried out on drone security aims to understand the literature surrounding the topic. The security of a drone fleet is rarely addressed, even though these fleets represent the future trend in the use of drones for civilian missions. Most of the work cited in the state of the art has focused on routing protocols, autonomy optimization, and communication architectures while ignoring the security aspect, to which particular attention must be paid given the disastrous damage likely to occur whenever fleet security principles are successfully circumvented.

Little research has been carried out on the problem of intrusion detection in drone fleet networks. In fact, the approaches proposed by the community only address an aspect of the architecture or intrusion detection mechanism, and no complete work tackles all the aspects in question. Furthermore, there are no effective datasets for dealing with the problem of intrusion detection in drone fleets. In addition, even work based on machine learning sometimes uses polluted or obsolete datasets that fail to represent the real network traffic of a drone fleet. These factors lead to more attractive research avenues to further strengthen the security of drone fleet networks.

A drone, like a computer, is made up of a set of fundamental components. Among these, the central processing unit (CPU) and random-access memory (RAM) provide the computing power needed to execute the drone's tasks and missions. In addition, for communication with ground controllers and other aircraft, drones use diverse transmission methods, including WIFI and radio waves. Drones are also equipped with cameras to capture images and record video in their environment. Data storage is essential for drones to retain essential operating systems and files. Furthermore, drones are equipped with built-in sensors, such as GPS, that provide essential information on position and orientation. In the same way that computers depend on power sources, drones rely on batteries for their energy needs. Finally, drones integrate specialized aeronautical hardware enabling them to navigate in the air, while computers employ control peripherals for hands-on operations. To sum up, the analogy between drones and computers underlines the similarity of their components, asserting that the drone is a veritable flying computer.

Cyber security is becoming a major concern for drones and drone fleets [31]. Given their vast attack surface and their reliance on wifi networks and radio waves, these devices are vulnerable to a whole range of cyberattacks.

Like computer networks, drone networks are exposed to potential cybersecurity risks that can jeopardize the security of this widely used technology, essential for carrying out vital missions. In our approach, we see drones as flying computers, and therefore we address their security issues in a similar way to traditional computer network security practices.

III. Proposed Approach

A. Architecture of the Proposed ZT-NIDS System

In this research project, ZT-NIDS (Zero Trust-based Network Intrusion Detection System), a new network intrusion detection system, is introduced. The proposed system is designed with a multi-agent architecture consisting of a set of independent and cooperative agents working together to efficiently detect intrusions in drone. Fig. 7 illustrates the overall architecture of the proposed ZT-NIDS system.

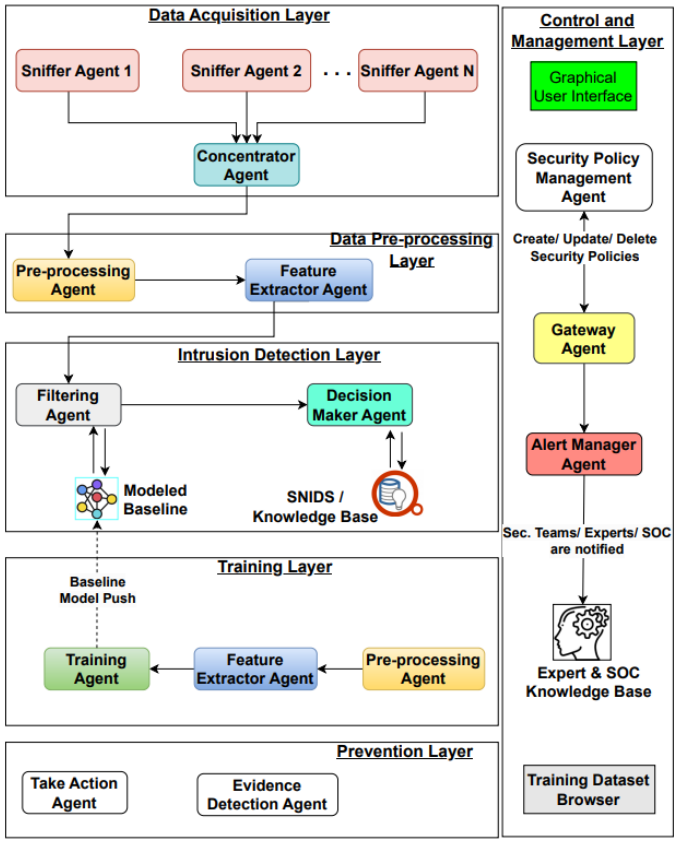

Fig. 7. The architecture of the proposed HNID&PS system.

B. Components of the Proposed Model

The ZT-NIDS system is designed according to a multi-agent architecture and consists of six layers, each with a set of agents.

1) Data Acquisition Layer – DAL: This layer is the input interface to the system, capturing and aggregating traffic from UAV fleet networks. It is made up of two types of agents:

- Sniffer agent: This agent captures drone network traffic in real time. Each sniffer can be positioned to cover a segment of the drone network.
- Concentrator agent: it aggregates all network events originating from all sniffers and timestamps all network events.

2) Data Pre-processing Layer – DPL: The DPL layer pre-processes captured network traffic to clean and process it. In this layer, we consider two types of agents:

- Pre-processing Agent: It cleans, normalizes, and correlates network traffic originating from the concentrator agent to eliminate missing and infinite values.
- Feature Extraction Agent: Its aim is to extract relevant features and reduce the dimensionality of network traffic, while retaining a maximum amount of information for recognizing network packets. To do this, it removes correlated, constant and quasi-constant attributes and passes the extracted features on to the adjacent layer.

3) Intrusion Detection Layer – IDL: The IDL layer receives the extracted attributes and compares them with the baseline and the signature database. It includes a set of two agents:

- Filtering Agent: It receives network packet attributes and checks the match values first against the baseline to recognize normal network traffic, then against the signature database to identify known attacks.
- Decision Making Agent: This agent is responsible for making decisions about the detected intrusions and their severity; it intervenes in accordance with the security policy governing the detection of abnormal activities on drone networks; it generates alerts and sends them to the Alert Manager Agent; it sends orders to the prevention layer, for example, to quarantine network equipment/systems contaminated by the intrusion.

4) Training Layer – TL: The TL layer is responsible for regularly training our system's detection mechanism. It includes three types of agents, the first two already presented: the Pre-processing Agent and the Feature Extraction Agent, plus a third, the Training Agent, described as follows:

- Training Agent: This agent is responsible for receiving pre-processed data sets as input; modeling the network baseline to recognize normal network behavior; generating and updating the modeled baseline module of the intrusion detection layer.

5) Prevention Layer – PL: The PL layer acts in the case of an intrusive attack through a set of two agents:

- Action agent: It is responsible for isolating and eliminating detected intrusions, e.g. by quarantining infected equipment; taking security measures, e.g. revoking access, blocking ports, suspending accounts, etc.
- Evidence Detection Agent: This agent is tasked with identifying the root cause of the security incident based on detailed information about the intrusion; it keeps a history of security incidents and all related documentation.

6) Control and Management Layer – CML: The CML layer enables IT security managers of UAV networks to define security policies and undertake configuration actions using three types of agents:

- Security Policy Management Agent: Managing and controlling the intrusion security policies; Updating machine learning models; Optimizing whitelists and blacklists with information on hacking sources; Managing threshold levels
- Gateway Agent: This agent is responsible for promoting communication and coordination between the various agents; managing data exchanges and communication protocols; coordinating response actions between agents in case of network intrusion; synchronizing agent activities for consistent system functioning.
- Alert Manager Agent: This agent is tasked with correlating alerts generated by the system, so that only relevant alarms are triggered; reducing the false positive rate; notifying security administrators in real time, so that they can anticipate and intervene in case of network intrusion.

C. ZT-NIDS Detection Mechanism / Zero-trust Principle

Since a drone is a sort of flying computer, the network configurations of drone fleets are comparable to those of modern computer networks. Consequently, the proposed intrusion detection system is well suited to overcoming the challenges inherent in cyber threats that could compromise the security of flying aircraft.

The diagram in Fig. 8 illustrates the deployment mode of the proposed system in a drone fleet network. The idea behind it is to monitor the flow of data between the various actors in a fleet of drones, then analyze it to identify known and unknown attacks. The system consists of a group of autonomous entities that work together to successfully accomplish the tasks involved in identifying intrusions into a drone network.

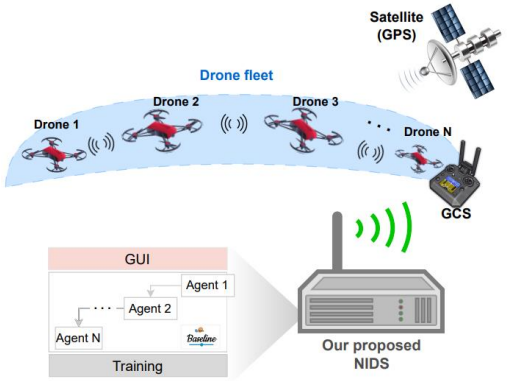

Fig. 8. Deployment mode of the proposed system.

A key element of the proposed system is its adherence to the "zero-trust" principle, which means that the detection mechanism works by considering a minimal level of trust in the processing of network traffic originating from drone fleets networks. To be more precise, the adopted detection mechanism is based on a network baseline as a reference, enabling us to identify any deviation from normal behavior. The diagram in Fig. 9 provides an overview of the system's detection mechanism. Its aim is to detect any attack attempts against drone networks, no matter whether they are already registered or not.

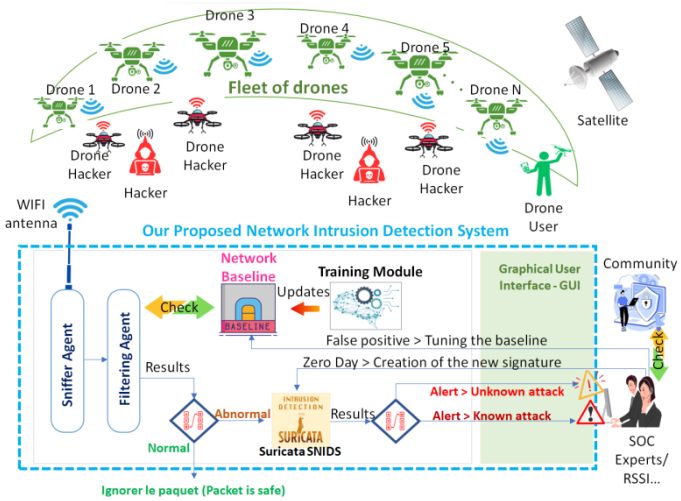

Fig. 9. Zero trust based intrusion detection mechanism.

For this purpose, the system is equipped with a baseline of normal behavior patterns, enabling it to distinguish legitimate transactions on the network. Any deviation from this basic pattern is interpreted as suspicious activity, triggering a notification to security managers. At the same time, the system has a standard signature database containing listed attack patterns. This signature database is continually updated as new attacks are identified through the process of comparing them with the network's reference baseline.

IV. Experimentation

A. Technical Architecture of the Lab used for Simulation

1) Lab environment: The entire laboratory is hosted by VMware on a workstation, whose characteristics are illustrated in Fig. 10.

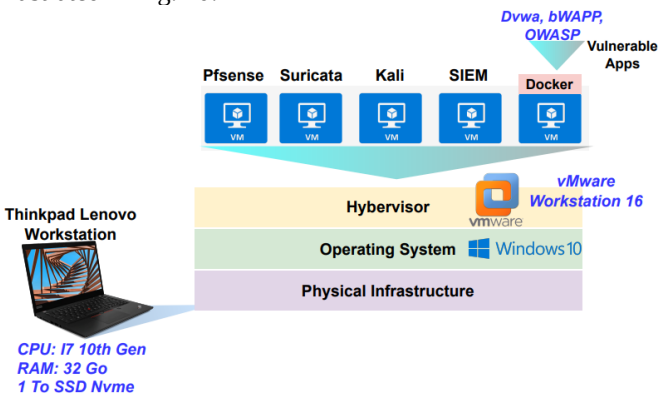

Fig. 10. Technical infrastructure hosting the ZT-NIDS experimental lab.

2) Applicative architecture of the Lab used for simulation: This laboratory aims to demonstrate the practical implementation of the ZT-NIDS system introduced in this research project. Fig. 11 gives a visual presentation of the laboratory's application architecture, highlighting the inputs and outputs of the platform designed to simulate the ZT-NIDS system.

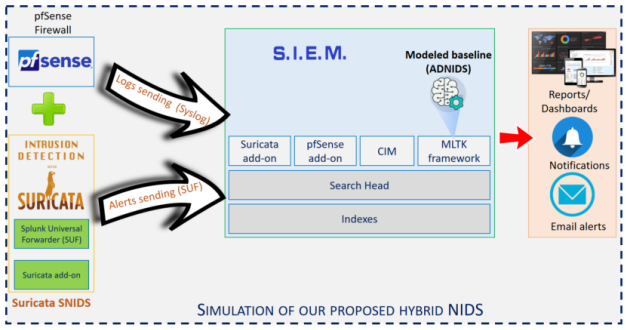

Fig. 11. Applicative architecture of the lab simulating the ZT-NIDS model.

The architecture diagram above shows two modules on the left-hand side: pfSense and Suricata. Both modules play a crucial role in intercepting, collecting and aggregating real-time events originating from drone networks. Suricata functions as a signature-based network intrusion detection system, and is either connected to a SPAN port on the switch, or to a network card operating in Promiscuous mode, enabling it to capture a copy of all ongoing network traffic in real time. The modules Splunk Universal Forwarder (SUF) and Suricata-Add-Ons have been deployed on the Suricata host to facilitate the extraction and recognition of the intercepted network events.

The network events collected are then directed to Splunk's SIEM (Security Information and Event Management) for processing, thanks to a number of additional modules. In particular, the Suricata-Addon, pfsense-Add-On and CIM modules integrated into the SIEM facilitate the normalization, indexing and storage of actionable network events, making it easier to extract attributes describing network packet behaviors.

In the SIEM, we have incorporated the MLTK framework to establish the baseline model for normal network operation. This enables the SIEM to recognize deviations from typical network behavior. With this configuration, Suricata excels at recognizing known attacks, while the Baseline module is specially designed to identify anomalies and previously unidentified zero-day attacks.

The SIEM is configurable to trigger alerts when real attacks are detected, and provides managers with comprehensive security indicators for in-depth analysis. In addition, it provides routine reports to administrators, giving them an overview of the security posture of the monitored networks.

B. Laboratory Components for Simulating the Proposed System

The practical simulation of our ZT-NIDS system relies on the set-up of a laboratory environment, as described in the previous section. This laboratory includes several components and software tools used to emulate the ZT-NIDS model proposed as part of our research. Table I below gives an overview of the components that make up our model and the simulation tools used.

C. Data Collection

Given that a drone is essentially a flying computer, and considering the similarity between traditional computer networks and those used by drones, the CICIDS2017 dataset

was deliberately chosen to evaluate the effectiveness of the system. The main focus was on the benign traffic portion of the data, with the aim of creating a representative baseline of normal network operation. CICIDS2017 was chosen for its consistency and relevance to modern network behavior, which differentiates it from conventional data sets that are often more theoretical than practical.

TABLE I. THE PROPOSED MODEL COMPONENTS VS. SIMULATION TOOLS

Our ZT-NIDS model components	*Simulation tools (Lab)*
Sniffer Agent	Pfsense
Concentrator Agent	Pfsense
Preprocessing Agent	Splunk Universal Forwarder
	Splunk TA for Suricata
	Splunk Common Information Model
	TA-Pfsense
Feature Extraction Agent	Machine Learning ToolKit (MLTK)/ Python/ Splunk Add-ons
Filtering Agent	Splunk Search Head
Decision Maker Agent	Splunk SIEM
Training Agent	Python & Machine Learning ToolKit
Take Action Agent	Ansible
Security Policy Management Agent	Splunk Administration Interface
Gateway Agent	Splunk SIEM
Evidence Detection Agent	Splunk Search App
Alert Manager Agent	Splunk SIEM
Signature-based NIDS	Suricata NIDS
Graphical User Interface	Splunk Dashboard
Benign traffic/ Baseline	CICIDS2017/ benign traffic

1) CICIDS2017 dataset used for evaluating the proposed system: The Canadian Cybersecurity Institute has released the CICIDS2017 dataset to help researchers tackle the challenges of intrusion detection [33]. The CICIDS2017 dataset is available in two distinct formats: CSV files for learning purposes, and PCAP files to enable rigorous evaluation of detection mechanisms proposed by the community.

In this study, we exploited the CICIDS2017 dataset in CSV format to train the ZT-NIDS system in recognizing normal behaviors using machine learning algorithms. This process has created the Baseline module integrated into the architecture of the ZT-NIDS system.

To test the system under real-life conditions, the PCAP format was adopted. Several packets were replayed using tools such as tcpdump, Wireshark and Snort. These tools enable the system to intercept generated network traffic and automatically identify records corresponding to possible signs of attack.

The different data structures used in this case study are shown in Fig. 12. On the one hand, CSV format data sets are used to feed the learning module, enabling the network baseline to be established. On the other hand, PCAP files are used to simulate real network traffic, in order to test the system in a practical, authentic environment.

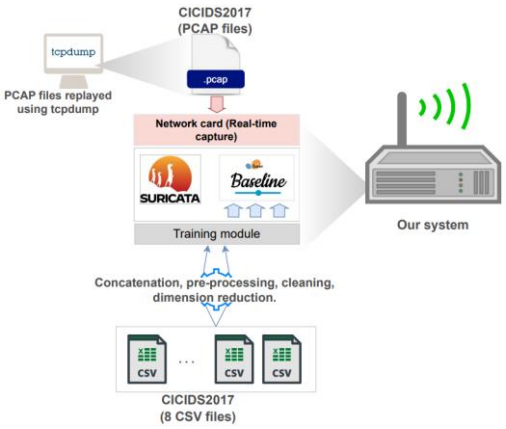

Fig. 12. Dataset used to train and to test the proposed system.

2) CICIDS2017 dataset preprocessing

a) Composition of the intial CICIDS2017 dataset: The CICIDS2017 dataset has been chosen to model the network baseline, as it is reliable, up-to-date and can represent the modern real network traffic [33]. However, it poses certain cleaning, scaling and conversion problems for the use by machine learning algorithms [34]. Accordingly, pre-processing operations need to be undertaken before using the benign class to model the network baseline.

The CICIDS2017 dataset is multi-class in nature, including a "Benign" category reflecting regular network traffic. Additional categories are also included, representing distinct types of known attacks, as shown in Fig. 13.

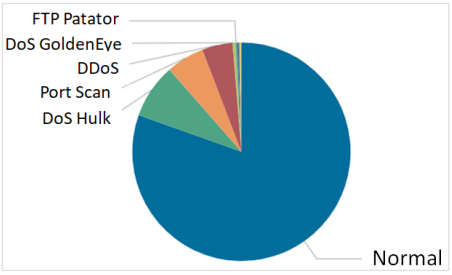

Fig. 13. Traffic classes contained in the intial CICIDS2017 dataset.

b) Cleaning up the CICIDS2017 dataset: The CICIDS2017 dataset suffers from problems of sanitisation, essentially due to the presence of infinite, null or sometimes missing records. Such problems can generally lead to falsified classification results during the machine learning process.

Some transformation processes can produce errors associated with undefined, infinite and oversized values. That's why we used certain Pandas methods like "drop()" to clean up the CICIDS2017 dataset of null, missing and infinite values.

c) Balancing of the CICIDS2017 dataset: The CICIDS2017 dataset is unbalanced regarding normal and abnormal records, as shown in Table II. Indeed, the class labeled "Normal" dominates over that labeled "Abnormal". The abnormal class refers to all the attack classes mentioned in Table I. As a result, over-fitting and under-fitting problems can be generated during the learning phase [35].

TABLE II. COMPOSITION OF THE DATASET BEFORE BALANCING

Class	Records Count	%
NORMAL	1818477	80 %
DoS Hulk	184858	8 %
Port Scan	127144	5.6 %
DDoS	102421	5.02 %
DoS GoldenEye	8234	0.36 %
FTP-Patator	6350	0.28 %
SSH-Patator	4718	0.2 %
DoS slowloris	4637	0.2 %
DoS Slowhttptest	4399	0.19 %
Bot	1573	0.07 %
Web Attack Brute Force	1206	0.05 %
Web Attack XSS	522	0.028 %
Infiltration	29	0.001 %
Web Attack Sql Injection	17	0.0007 %
Heartbleed	9	0.0003 %

In order to overcome the problems of overfitting and underfitting, the dataset has been balanced to ensure a balanced presence of the different classes. We used the SMOTE Python technique to increase the percentage of minority classes. On the other hand, the randomUnderSampler Python technique was used to decrease the number of normal records in order to avoid the performance problems that the laboratory environment might envisage. Accordingly, Table III highlights the dataset composition after its balancing using the two aforementioned python techniques.

TABLE III. COMPOSITION OF THE DATASET AFTER BALANCING

Class	Records Count	%
NORMAL	618000	50.2 %
DoS Hulk	240000	19.49 %
Port Scan	160000	12.99 %
DDoS	150000	12.18 %
DoS GoldenEye	12000	0.97 %
FTP-Patator	7000	0.56 %
DoS Slowhttptest	7000	0.56 %
DoS slowloris	7000	0.56 %
SSH-Patator	5000	0.4 %
Bot	5000	0.4 %
Web Attack Brute Force	5000	0.4 %
Web Attack XSS	5000	0.4 %
Infiltration	5000	0.4 %
Web Attack Sql Injection	5000	0.4 %
Heartbleed	5000	0.4 %

d) CICIDS2017 dataset binarization: The modeling of the network baseline is based on the class tagged "Normal/Benign" in the CICIDS2017 dataset. Therefore, the balanced dataset was transformed into another binary dataset including two main classes of network traffic: Normal and Abnormal.

Python libraries were used and the binary pre-processed dataset comprises 618000 normal traffic records and 618000 abnormal records. Consequently, both classes are present with an equal percentage of 50% each, as shown in Fig. 14.

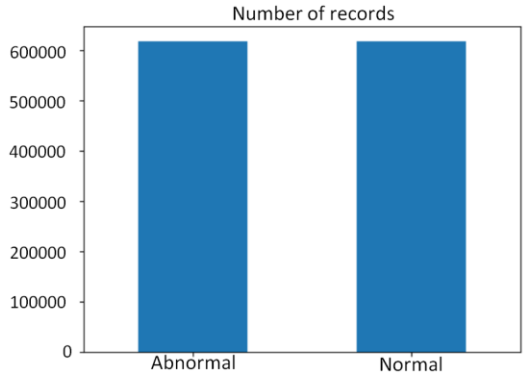

Fig. 14. Proportion distribution after balancing the binarized dataset.

e) Dimension reduction of the training dataset: The binarized balanced CICIDS2017 dataset contains a large number of attributes that are not necessarily relevant (79 attributes). This large number of attributes could cause enormous processing delays and could lead to falsified results when modeling the baseline. It makes more sense to eliminate unnecessary attributes and keep only the most relevant ones.

The StandardScaler imported from the sklearn.preprocessing library was used to downscale the features within the Pandas dataframe before applying the PCA transformation for dimension reduction. 30 principal components with zero cumulative variance were thus retained using the PCA technique, as shown in Fig. 15. This represents a considerable dimension reduction from 79 to 30 components that can describe 99.9% of the information within the standardized dataset.

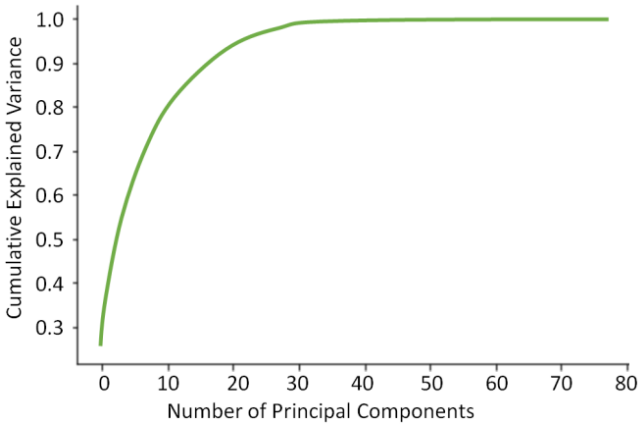

Fig. 15. PCA components used to represent the CICIDS2017 dataset.

D. Baseline Modelling and its Performance Evaluation

1) Network baseline modelling: After preprocessing the CICIDS2017 dataset, we used the "fit()" function in Splunk's MLTK framework to train the system on normal network traffic and generate the baseline model as output.

The MLTK framework is based on the Scikit Learn python library to train machine learning models [36]. This framework is very powerful, fast and reliable, as it copies the events to be processed into memory before launching the pre-processing and training operations.

The sequence of actions undertaken by the "fit()" function is illustrated in Fig. 16 below, in order to generate a model capable of recognizing the network baseline.

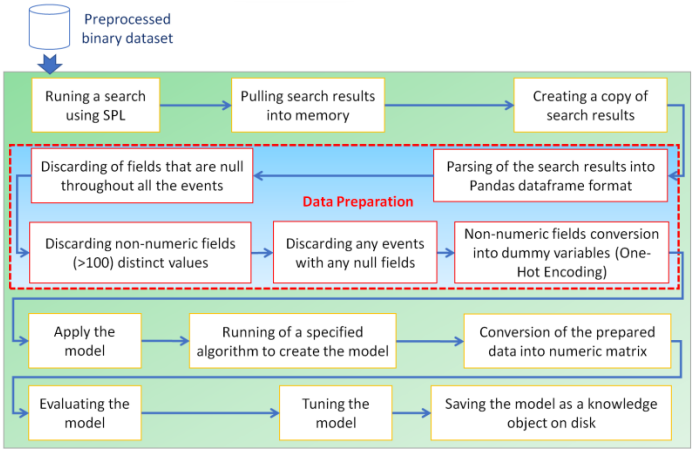

Fig. 16. Workflow of the training process using MLTK Framework applied on the optimized binary CICIDS2017 dataset.

2) Machine learning algorithms used to train the baseline

a) Machine learning algorithms and data sampling: After pre-processing and binarization of the CICIDS2017 dataset, a number of machine learning algorithms were used to build up a model capable of characterizing the network baseline. We used algorithms encompassing a variety of approaches, including Random Forest, Decision Tree, Naïve Bayes and Multi-Layer Perceptron. The key objective was to determine the most efficient and accurate machine learning algorithm that can differentiate between normal and abnormal drone's network traffic.

Having been pre-processed and binarized, the CICIDS2017 dataset was randomly separated into two sets: one for training (comprising 80% of the data) and the other for testing (comprising 20% of the data). In addition, PCAP files were used to evaluate system performance against real-time computer network data. These PCAP files were replayed using the tcpdump utility.

b) Performance evaluation metrics: The evaluation process incorporated key performance measures, such as Accuracy, Precision, Recall, F Score and Confusion Matrix. Importantly, cross-validation was applied with a k-fold value set at 10, guaranteeing a robust and reliable evaluation procedure.

Accuracy measures the number of correct predictions (both true positives and true negatives) that a model makes out of all predictions. It quantifies the overall accuracy of the model's predictions.

Precision measures the exactness of the positive predictions made by a model. It estimates the percentage of true positive predictions out of all positive predictions, and thus the model's ability to avoid false positives.

Recall, also known as sensitivity or true positive rate, measures the model's ability to identify all true positive instances. It refers to the proportion of true-positive predictions to all true-positive cases.

F1 score is the harmonic mean of precision and recall. It is a balanced measure that combines both precision and recall. It is particularly useful in unbalanced data sets where one class clearly outnumbers another.

The confusion matrix is a powerful tool for evaluating the performance of machine learning algorithms. According to [32] and as shown in Fig. 17, the confusion matrix is generally composed of four basic elements:

- True positives (TP): These are cases for which the model was able to correctly predict the positive class.
- True negatives (TN): These are cases for which the model was able to correctly predict the negative class.
- False positives (FP): These are Type I errors, in which the model has incorrectly predicted the positive class when it should have been negative.
- False negatives (FN): Also known as Type II errors, these correspond to cases where the model has incorrectly predicted the negative class when it should have been positive.

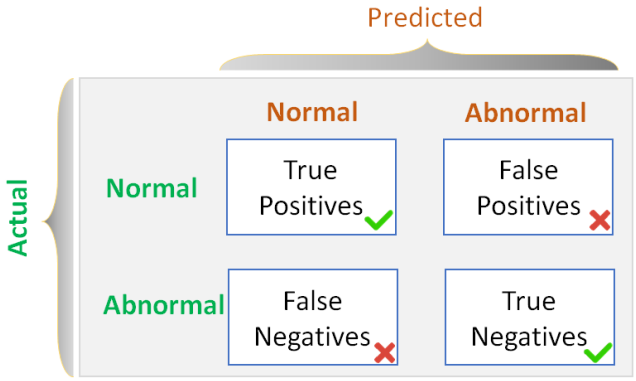

Fig. 17. Components of a confusion matrix (the normal class is our target).

3) Evaluation of the generated network baseline: To develop a highly efficient baseline network model, we tested a number of machine learning algorithms on the pre-processed and binarized CICIDS2017 dataset. In particular, we applied Random Forest, Decision Tree, Naïve Bayes and Multi-Layer Perceptron models.

a) Random Forest – RF: The Random Forest classifier was used to model the baseline of drone network traffic (regular operation of UAV networks). The test confusion matrix is shown in Table IV. The results obtained showed that the model generated was able to accurately recognize benign traffic with an accuracy, F1 score, precision and recall that all reached the exceptional level of 99.99%.

TABLE IV. RANDOM FOREST – TESTING CONFUSION MATRIX

	Predicted NORMAL	Predicted ABNORMAL
NORMAL	247194	6
ABNORMAL	10	247190

b) Decision Tree – DT: The decision tree was tested for modeling the network baseline (benign traffic modeling) and the confusion matrix for the tests carried out is presented in Table V. The generated model was capable of accurately recognizing benign traffic. The measures of accuracy, F1 score, precision and recall all reached the exceptional level of 99.99%.

TABLE V. DECISION TREE – TESTING CONFUSION MATRIX

	Predicted NORMAL	Predicted ABNORMAL
NORMAL	247192	8
ABNORMAL	12	247188

c) Naïve Bayes – NB: Table VI shows the confusion matrix results derived from the evaluation of the Naïve Bayes algorithm. This algorithm was employed to model the network baseline, with the pre-processed and binarized CICIDS2017 dataset. The performance measures obtained include 99.85% in accuracy, 99.84% in F1 score, 99.87% in precision and 99.83% in recall.

TABLE VI. NAÏVE BAYES – TESTING CONFUSION MATRIX

	Predicted NORMAL	Predicted ABNORMAL
NORMAL	246899	301
ABNORMAL	405	246795

d) Multi-Layer Perceptron – MLP: Table VII shows the testing confusion matrix following the use of the Multi-Layer Perceptron algorithm to model the network baseline, focusing on the classification of benign network traffic. The results reveal a precision rate of 99.93%, with F1 score and recall both reaching 99.92%. In addition, the precision measure achieved a high accuracy level of 99.94%.

TABLE VII. MULTI-LAYER PERCEPTRON – TESTING CONFUSION MATRIX

	Predicted NORMAL	Predicted ABNORMAL
NORMAL	247070	130
ABNORMAL	195	247005

4) Baseline modeling – Discussion: The classification results of benign traffic using a set of machine learning algorithms on the CICIDS2017 dataset are extremely promising. For the most part, the algorithms demonstrated an exceptional capacity to recognize normal network traffic with high performance and accuracy. As a result, the model generated can be integrated into the ZT-NIDS system to ensure the detection of deviations from regular network traffic. The positive results obtained are mainly attributable to the pre-processing, balancing, binarization and dimension reduction actions carried out on the CICIDS2017 dataset prior to its use.

In this laboratory, the Decision Tree algorithm was used to model the benign network traffic. This model was then integrated into the ZT-NIDS system, founded on the zero-trust principle, meaning that no network packet should be assumed to be trustworthy. The aim is to distinguish what is considered normal, and any deviation from this basis is automatically considered suspicious.

E. Signature-based Module

As mentioned earlier, the ZT-NIDS mechanism integrates both signature-based and anomaly-based modules enabling it to identify known and unknown cyber threats. Concerning the anomaly-based module, a baseline of benign network traffic has been created. The next focus is on the signature-based module, responsible for recognizing known intrusions.

We have already used Suricata as a signature-based module to detect known intrusions in one of our previous research works [34], and it has demonstrated excellent performance. We highlighted some of its advantages over Snort, such as its multithreading capability and its efficiency in handling known attacks. Consequently, for the ZT-NIDS mechanism, we used Suricata as a SNIDS (Signature-Based Network Intrusion Detection System) module to guarantee detection of known intrusions that deviate from the network baseline.

F. Preparing Attack Scenarios – Going Into Production

To evaluate the effectiveness of detection and simulate network attacks, we used tcpdump to replay pcap records from the CICIDS2017 dataset. Replaying a PCAP portion of CICIDS2017 that was never seen by the system allowed us to measure the performance and accuracy of the proposed approach. The illustration in Fig. 18 gives an overview of the lab architecture and attack scenarios.

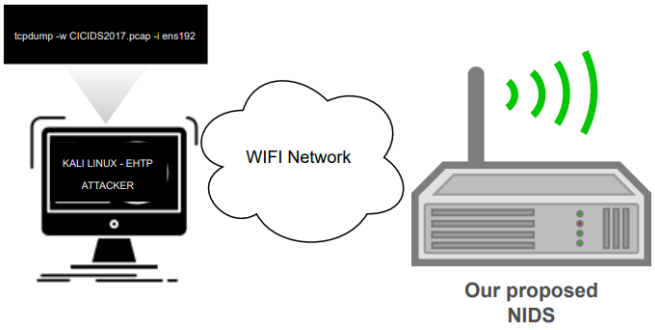

Fig. 18. An overview of the architecture used to reproduce the attack scenarios.

G. Testing the Baseline Model on New, Never-before-seen Data

This section outlines the methodology adopted to evaluate the real-time functioning of the proposed ZT-NIDS system with particular emphasis on its components. Fig. 19 shows the sequential steps involved in testing the system with new network events. Notably, the step "Transform search results using data preparation" reproduces the procedures detailed in the training phase diagram (indicated by a red strikethrough outline in Fig. 16).

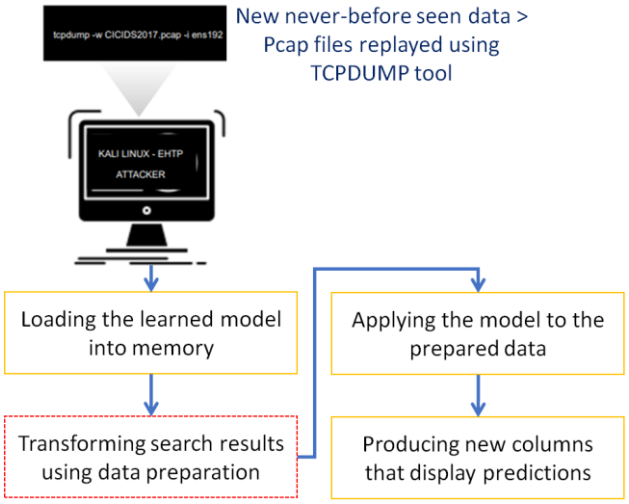

Fig. 19. Worfkow of testing process of ZT-NIDS on never-before-seen network events.

In order to evaluate the modeled baseline in a real network, we used an intact part of the CICIDS2017 dataset in PCAP format, which had not been used during the ZT-NIDS model training phase. The TCPDUMP tool, running under Kali Linux, was used to replay the CICIDS2017 pcap files. These network events were then transmitted to the SIEM system, where they were compared with the baseline and Suricata.

The SIEM then extracts the characteristics of the network events received and compares them to the baseline models, which had previously been stored in memory, and to Suricata's SNIDS. A new column is then generated to store the predicted values generated after application of the base model, as shown in Fig. 20. Further comparisons are made between the values predicted by the model and the actual values, enabling the calculation of performance metrics that serve as evidence of the model's effectiveness.

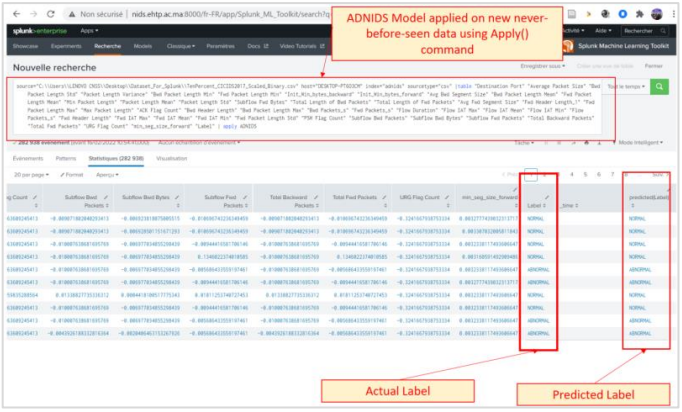

Fig. 20. The baseline model applied on never-before-seen network events.

V. Results and Discussion

A. Results

The following section summarizes all the results obtained after testing different machine learning algorithms on the pre-processed, balanced and binarized CICIDS2017 dataset. In particular, we focused on the recognition of benign traffic, i.e. the creation of the baseline. Consequently, Table VIII presents all the results obtained.

TABLE VIII. Summary of Results

Algorithms	Recall	Precision	Accuracy	F1
Random Forest	0,9999	0.9999	0.9999	0.9999
Decision Tree	0,9999	0.9999	0.9999	0.9999
Naïve Bayes	0,9983	0,9987	0,9985	0,9984
Multi-Layer Perceptron	0,9992	0,9994	0.9993	0,9992

B. Discussion of the Obtained Results

As we have previously noted, there has been limited research addressing the specific challenge of intrusion detection within drone fleet networks. Most existing studies have focused on aspects such as routing protocols, battery autonomy, and other functionalities, often overlooking security concerns. However, given the increasing importance of drone technologies and their modern applications, the security of these networks has become critically significant.

The analysis of drone networks has led us to the conclusion that drones can be regarded as flying computers, and their networks share similarities with modern computer networks. Building upon this insight, we have introduced a model named ZT-NDIS, designed with a multi-agent architecture to implement a detection mechanism in line with the zero-trust principle.

The multi-agent architecture has proven well-suited to the challenge of intrusion detection in drone networks due to its characteristics of distribution, autonomy, and cooperation among the various agents. The detection mechanism comprises two complementary modules: a signature-based detection module and an anomaly detection module.

To materialize the proposed model, we conducted a comprehensive simulation of all components of the ZT-NIDS architecture using a real-world laboratory setup. Initially, we preprocessed, balanced, and reduced the dimensionality of the CICIDS2017 dataset. We then assessed a range of machine learning algorithms to model the baseline of benign network traffic. Cross-validation techniques were employed to ensure classification performance. While all tested algorithms yielded promising results, we ultimately selected the "Decision Tree" model.

Subsequently, we constructed the baseline model using the MLTK framework based on Scikit Learn, implementing the Decision Tree algorithm. To complement the proposed detection mechanism, Suricata was integrated for recognizing attacks with known signatures.

Finally, a real-world testing was conducted by networking the system and replaying CICIDS2017 PCAP files. The results were highly satisfactory, and the system was able to effectively identify both normal and abnormal network.

This proposed system represents a significant contribution and marks the initial step toward enhancing the security of civilian drone networks, which continue to gain popularity in various applications.

VI. Conclusion and Perspectives

We introduced in this work a network intrusion detection system called ZT-NDIS, designed with a multi-agent architecture and a zero-trust detection mechanism adapted to drone networks. The multi-agent architecture is suitable to drone networks given their distributed, autonomous and cooperative characteristics. The zero-trust principle enabled us to detect various types of cyberattack, including zero-day threats, through continuous comparison of network traffic against the modelled baseline of benign traffic.

Thanks to the pre-processing of the CICIDS2017 dataset, we were able to create an effective network baseline model with almost 100% accuracy. The inclusion of Suricata has further enhanced the system's performance, particularly against known attacks.

To evaluate the system's effectiveness, we carried out real laboratory tests. This enabled us to assess its ability to detect emerging cyber threats that could target drone networks.

The proposed system represents an important step towards improving the security of drone networks and gaining a better understanding of their security posture. Future work will focus on developing the various agents, generating real network traffic from drone networks and testing the system in a production environment.

***Abstract*—Flooding, caused by the overflow of water bodies beyond their natural boundaries, has severe environmental and socioeconomic consequences. To effectively predict and mitigate flood events, accurate and reliable flood modeling techniques are essential. This study provides a comprehensive review of the latest modeling techniques used in flood prediction, classifying them into two main categories: hydrologic models and machine learning models based on artificial intelligence. By objectively assessing the advantages and disadvantages of each model type, we aim to synthesize a systematic analysis of the various flood modeling approaches in the current literature. Additionally, we explore the potential of hybrid strategies that combine both modeling methods' best characteristics to develop more effective flood control measures. Our findings provide valuable insights for researchers and practitioners in the field of flood modeling, and our recommendations can contribute to the development of more efficient and accurate flood prediction systems.**

***Keywords*—Flood prediction; hydrologic model; machine learning; systematic review**

I. Introduction

Floods are one of the most destructive and widespread natural disasters, inflicting severe environmental and socio-economic impacts worldwide [1]. In recent years, the frequency and intensity of floods have increased, underscoring the urgent need for accurate flood modeling to guide effective disaster response and management. Devastating floods have resulted in massive property damage, loss of human and animal lives, destruction of crops, and the propagation of waterborne diseases [2].

Understanding the intricacies of floods and accurately predicting their occurrence and severity is critical in developing strategies for flood management and mitigating potential damages. In the field of flood modeling, two primary approaches have been widely utilized: hydrologic models and data-driven prediction models. Hydrologic models aim to simulate the complex physical processes and interactions within the hydrological system, relying on high-quality data and hydrological expertise. However, these models face challenges in accurately evaluating uncertainty propagation and predicting real-time flood depths [3]. Conversely, data-driven prediction models, leveraging machine learning techniques, have shown superior accuracy and broad applicability in flood forecasting [3]. Nevertheless, a promising avenue for advancement lies in the hybridization of both approaches, harnessing the strengths of each to overcome the limitations.

The primary objective of this study is to explore and compare different modeling approaches employed in flood modeling, specifically categorizing them into hydrologic models and data-driven machine-learning-based models. The research aims to address the existing knowledge gaps in flood modeling and shed light on the diverse methodologies used in simulating and understanding flood events.

To achieve this objective, the study presents an analysis of the strengths and limitations of both model types. Furthermore, it highlights the potential benefits of integrating these approaches to create more robust and accurate hybrid models. The study analyzes a comprehensive range of sources, including case studies, real-world data, and academic research, to provide a well-rounded evaluation of flood modeling techniques. The article introduces and compares one-dimensional (1D), two-dimensional (2D), and three-dimensional (3D) hydrologic models, with a focus on their capabilities, limitations, and applications in flood hazard simulation and prediction. Additionally, the study delves into the advantages of hybrid models, demonstrating how their integration can contribute to more effective flood management strategies.

Contribution: This article's main contribution is to provide valuable insight into flood modeling, and advancement in the field, and ultimately aid in better understanding and managing flood events. By combining a thorough exploration of modeling approaches with a critical assessment of their performances, this study aims to lay the foundation for more resilient flood management practices in the face of escalating climate challenges. The article is structured as follows:

Section II provides the systematic approach adopted to gather related work and literature review along with bibliometric analysis. Sections III and IV provide introductions to various subdomains in Hydrologic modeling and Machine-learning-based modeling, respectively. Sections V and VI analyze the literature review on Hydrologic modeling and Machine-learning-based modeling, respectively. Section VII provides the analysis and discussion, while Section VIII provides the conclusions.

II. Bibliometric Analysis of Hydrologic Modeling and Machine Learning in Predicting Flood

The study focused on examining the trends and patterns in research publications in the field of flood prediction using machine learning-based modeling and hydrologic modeling. Two widely used databases, Web of Science (WoS) and Scopus, were utilized to gather relevant research papers. Additionally, the Dimension database was included to ensure comprehensive coverage of the literature. To visualize and analyze the data, VOSviewer software [4] was employed, along with traditional methods of data representation.

Using information from the Scopus and WoS databases, the bibliometric analysis produced the two instructive visualizations shown in Fig. 1 and Fig. 2. The size of the circles in Fig. 1 represents the number of citations each document in the hydrologic modeling and flood prediction domain has received. Greater circles indicate more citations, which reflects the importance and influence of the corresponding works on this topic. Similar to Fig. 1, but with a focus on machine learning modeling, Fig. 2 shows the citation distribution for the same domain.

Similarly, Fig. 2 and Fig. 3 show the number of citations in the context of machine learning and Hydrologic Modeling in flood prediction. Bibliometric analysis software VOSviewer was used to create both visualizations. A better knowledge of the current trends and contributions in hydrologic modeling and machine learning applied to flood prediction research is made possible by these numbers, which provide insightful information about the research environment by highlighting the most important and cited articles in both fields.

Table I lists how many articles have been written about using hydrologic modeling and machine learning techniques to anticipate flooding. The article counts or publication records for each type of study are shown in the table, indicating the volume of research done in the field of hydrologic modeling and machine learning for flood prediction across the various databases.

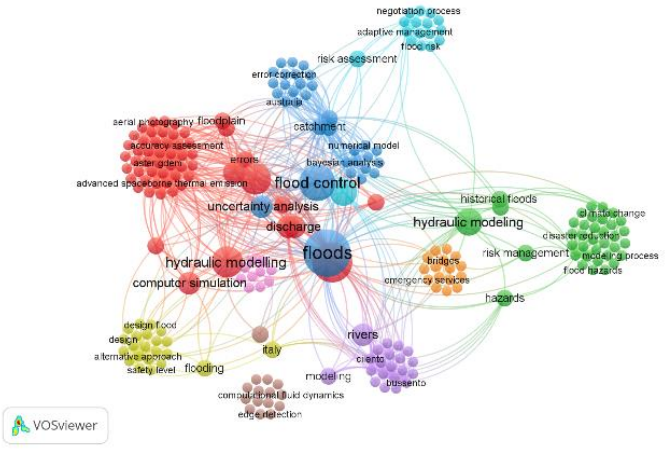

Fig. 1. Map the hydrologic modeling and "Flood prediction" network – Scopus.

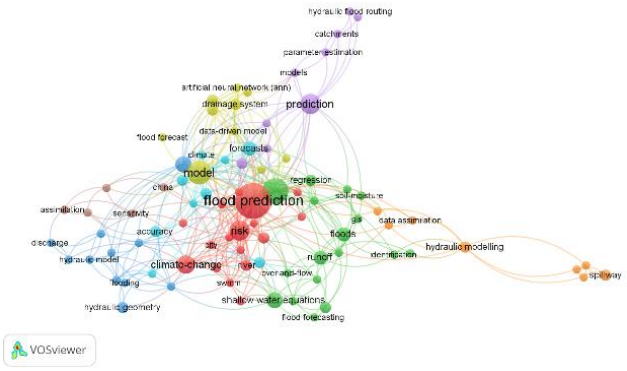

Fig. 2. Map the hydrologic modeling and "Flood prediction" network- WoS.

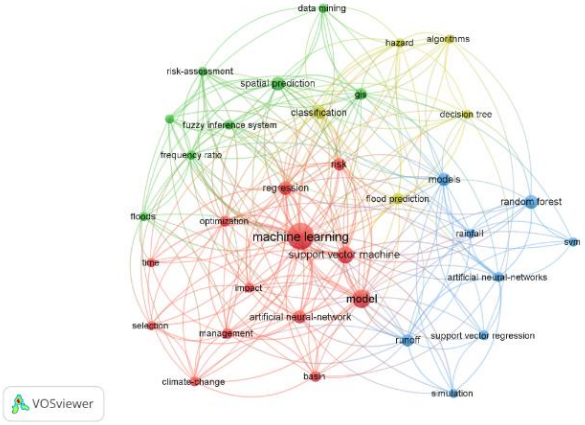

Fig. 3. Map machine learning and "Flood prediction" network WoS.

TABLE I. The Number of Articles Related to the Use of Hydrologic and Machine Learning in Flooding Prediction

Topic \ Database	*WoS*	*Scopus*	*Dimension*
Hydrologic	1493	1249	1255
Machine learning	3,027	2280	3,730

A. Bibliometric Analysis

The bibliometric analysis revealed an interesting trend in the distribution of research papers. It became evident that there is a significantly higher number of research papers dedicated to machine learning compared to those published in the field of hydrologic modeling (see Fig. 4, 5, 6, and 7). This indicates a greater emphasis on the utilization of machine learning techniques in flood forecasting research.

The higher number of research papers on machine learning suggests that it has gained significant attention and interest in the field of flood forecasting. Machine learning techniques offer the potential to improve the accuracy and efficiency of flood prediction models by leveraging large datasets and complex algorithms. On the other hand, the relatively lower number of research papers on hydrologic modeling may indicate a need for further exploration and development in this area. The findings of this study provide valuable insights for researchers and practitioners interested in the field of hydrologic modeling, machine learning, and flood forecasting.

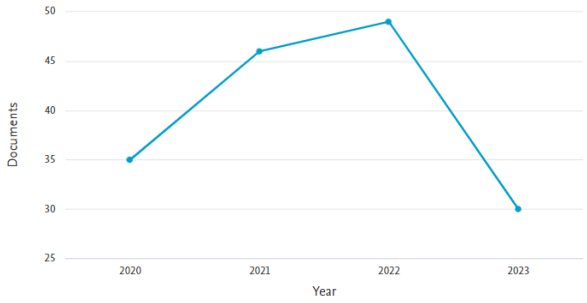

Fig. 5. Publications over time: Machine Learning and "Flood Prediction" Scopus.

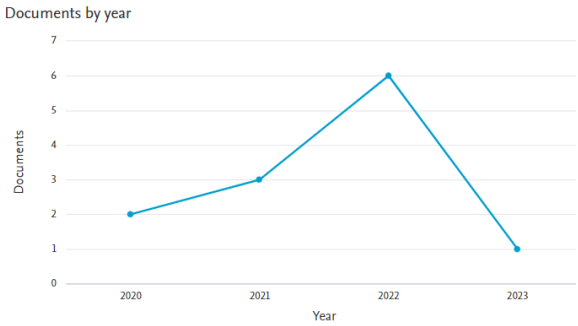

Fig. 6. Publications over time: Hydrologic Modeling and "Flood Prediction" Scopus.

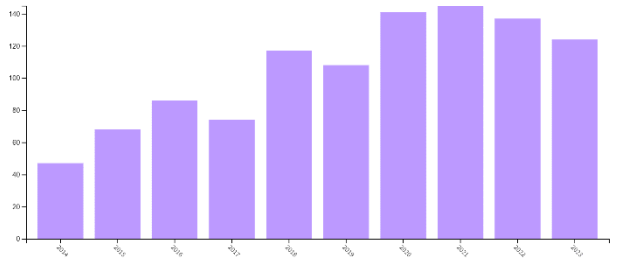

Fig. 7. Publications over time: Hydrologic modeling and "Flood prediction" WoS.

III. Hydrologic Modeling

Hydrologic modeling plays a crucial role in simulating and predicting flood hazards, enabling a deeper understanding of the complex dynamics associated with floods. This modeling approach encompasses various techniques, including one-dimensional (1D), two-dimensional (2D), and three-dimensional (3D) models, each offering unique advantages and limitations. This study delves into these different modeling approaches, exploring their applications, capabilities, and challenges in simulating flood events. By examining the strengths and limitations of each modeling method, the study aims to enhance the understanding of hydrologic modeling and its significance in effectively managing and mitigating the impacts of floods.

Fig. 8 shows the hydrologic model configured for 1D, 2D, and coupled 1D/2D simulations (a, b, and c) [5]. The 1D simulation in panel (a) shows a condensed version of the hydrologic system that works well in settings with linear flow patterns. The 2D simulation, which considers two-dimensional flow characteristics, illustrates the hydrologic processes in more detail in Panel (b). The coupled 1D/2D simulation, which combines both methods in panel (c), enables a more precise and in-depth portrayal of complicated flow interactions in situations when both 1D and 2D models are required. This figure helps academics and practitioners choose the best strategy based on particular modeling requirements and objectives by providing a useful visual reference for understanding the various modeling setups and their applications in hydrologic simulations [5].

A. One-Dimension Hydrologic Modeling

Various authors have discussed the effectiveness of hydrologic modeling methods in simulating and predicting flood hazards. For example, a study conducted by Ambiental Environ-mental Assessment [6] demonstrates that the 1D model effectively captures the interconnected network of a river by linking multiple cross-sections that traverse both the land and the river. Through this model, the water level is simulated and allowed to flow in a single direction along the channel. Additionally, the model accommodates the possibility of reverse water flow, such as in cases where the presence of structures obstructs the passage of water. Pinos et al. [7] highlight that river flood events are among the most frequent and economically burdensome natural disasters. Despite floods being a natural component of the hydrological cycle, they have far-reaching environmental consequences and can cause significant human and financial losses. Consequently, the utilization of modeling techniques becomes essential in simulating and predicting these occurrences.

Pinos et al. [7] conducted a study on the performance of the hydrologic 1D model approach in approximating flood levels for a mountain river. The study utilized HEC-RAS, Mike 11, and Floor Modeler as modeling tools. In the case of HEC-RAS, high-resolution cross-section surveys were conducted at intervals of 25 meters along the river line. The validation of the model was based on historical flood regions with return periods ranging from 2 to 10 years. The findings of research [7] served as reference models for different return periods and were compared to other models. The 1D model is considered an acceptable approximation as long as the water remains within the roadway profile. However, when the flow in the streets exceeds the curbs, there is a potential for the flow direction to shift, making the 2D model more suitable at that point [8]. It is important to note that using the 1D hydrologic modeling

approach has certain limitations. One major limitation is the assumption that the floodplain between the various cross-sections of the river is similar. Additionally, there is a need to determine the specific number and spacing of cross-sections to accurately represent the river channel and neighboring topography, and the guidelines for establishing these parameters are limited [10].

B. Two-dimensional Hydrologic Modeling

2D flood modeling is an approach used to analyze and interpret the two-dimensional flow of water during anticipated flood events. It relies on digital terrain modeling and the bathymetry of water channels to establish the depth of water and depth-averaged velocity on a mesh or grid [11]. One of the advantages of this modeling technique is that it does not require predefined flow routes, allowing for a more flexible representation of the flow dynamics.

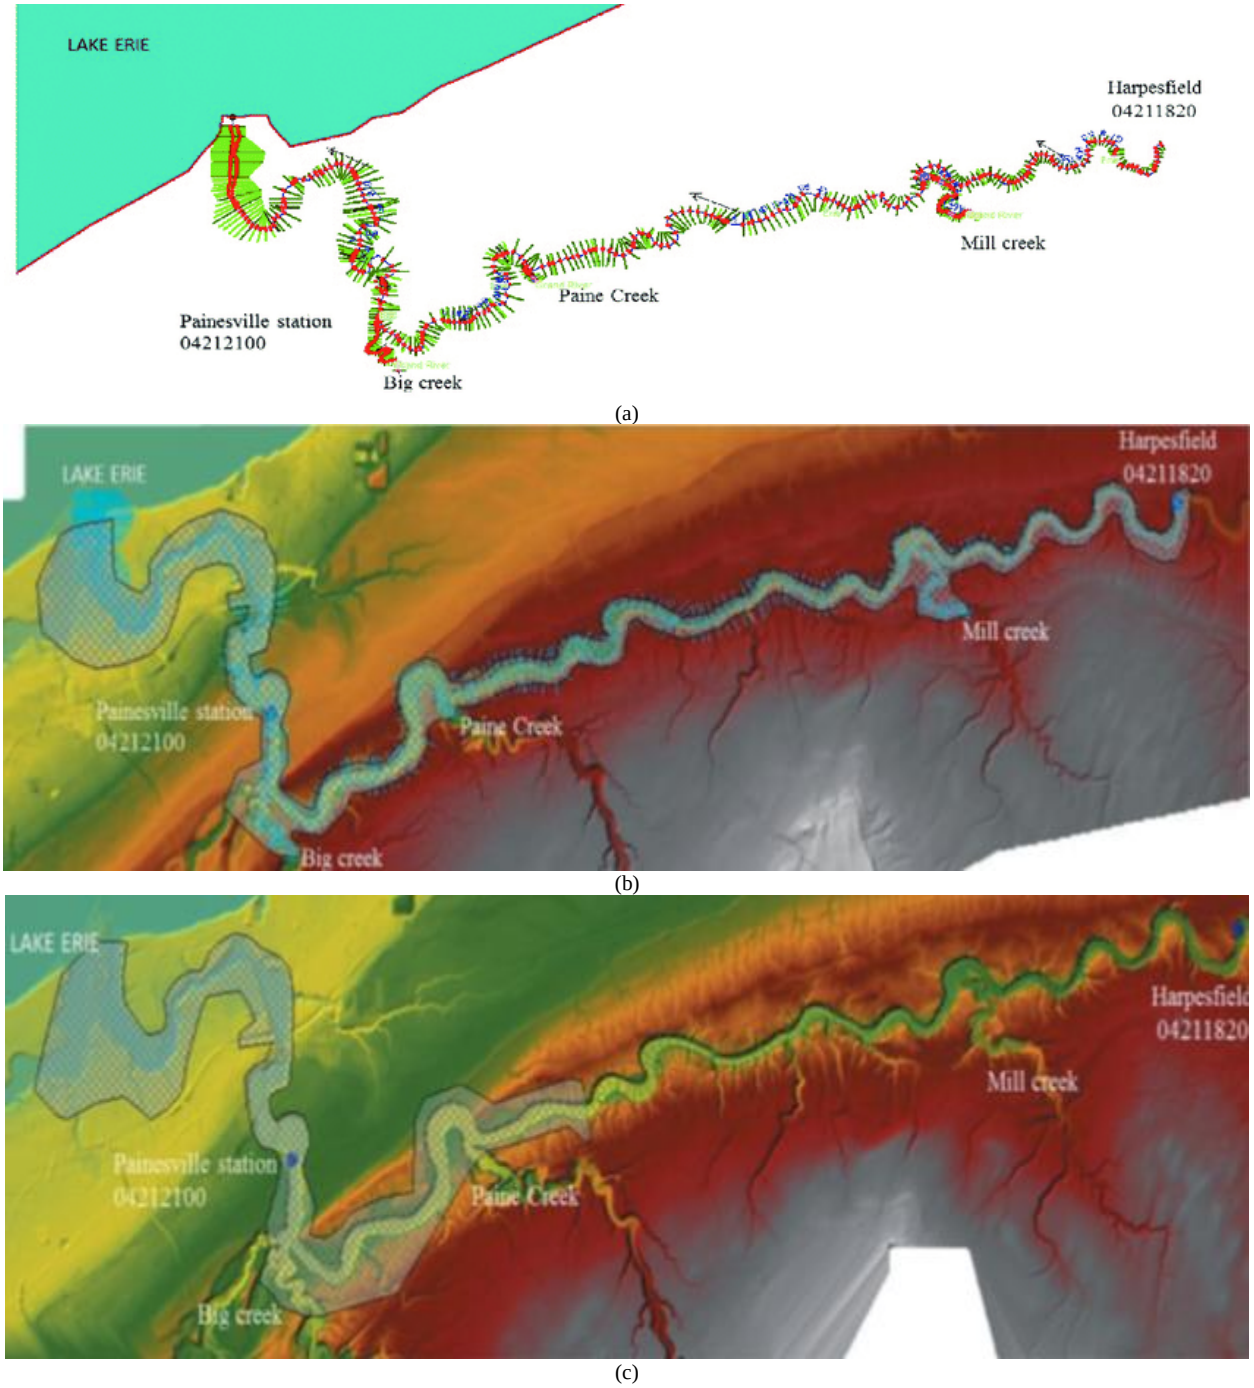

Fig. 8. Hydrologic model set up of (a) 1-D simulation, (b) 2-D simulation, and (c) coupled 1-D/2-D simulation [5].

An example of the application of 2D flood modeling can be seen in the assessment of the Medjerda River conducted by Gharbi et al. [12]. The researchers utilized 2D hydrologic modeling to understand the behavior of the river and accurately estimate the extent of flood zones. Their findings demonstrated that 2D analysis provides a more precise depiction of the flooded region compared to the one-dimensional (1D) unsteady flow study. The visual representation of flood extent through 2D model maps is superior to the traditional water-depth curves used in 1D models [9].

However, it is important to acknowledge the limitations of the 2D modeling approach. Firstly, the complexity of the 2D model makes it more computationally costly compared to 1D models. The computational time required for a complete run of a 2D model is significantly longer, often taking hours as opposed to minutes for a 1D model [8]. This can pose challenges for inexperienced hydrologists who may struggle with the complexity of the model and the efficient transfer of information to relevant departments.

Furthermore, the application of 2D modeling may be hindered by the availability of quality data. High-quality data, obtained through on-site sensors and Internet of Things (IoT) devices, is crucial for achieving accurate results [12]. Additionally, when analyzing flood risk within large cities and complex structures, relying solely on 2D geographical data may not be effective. In such cases, the integration of 3D city model-based GIS solutions becomes necessary to provide decision-makers with comprehensive information [13].

C. Three-dimensional Hydrologic Modeling

3D modeling involves the mathematical representation of surfaces in three dimensions, utilizing specialized software to manipulate vertices, edges, and polygons in a simulated 3D space [14]. When it comes to simulating and predicting flood hazards, 3D models have proven to be computationally expensive but crucial for accurately representing the three-dimensional flow around urban areas and interactions between flood waves and constructed buildings [15].

In the context of flood simulation and its impact on utilities, Adda et al. [16] emphasize that 3D modeling offers robust visual depictions that enable decision-makers to assess the safety of buildings located in flood zones. Their research explores the use of LiDAR (Light Detection and Ranging) data and 3D modeling to analyze flood risk on government utilities and buildings. LiDAR data is highlighted as an inexpensive and comprehensive method for multidimensional 3D mapping [16].

Data collection for 3D modeling often involves ground-controlled points obtained through GPS methods. Adda et al. found that their 3D approach revealed regions that were potentially situated on low-lying terrain prone to flooding. This information is vital for emergency decision-making and prioritization. The use of 3D hydrologic modeling enables rapid reaction, alert, and warning systems, mitigation strategies, and effective planning and management of complex geographic issues.

By utilizing 3D geospatial data, planning challenges can be better addressed, and conditions that may increase the risk of flooding can be identified. This aids in understanding and evaluating the nature of dangers and facilitates the development of clear management strategies for rescue operations. Additionally, one significant advantage of 3D hydrologic modeling is the ability to test infrastructure projects before implementing them on the ground, minimizing potential risks [17].

However, it is important to acknowledge the limitations of the 3D modeling approach. While it offers valuable insights, it is more suitable for localized hydrologic issues and may require substantial details, resulting in longer simulation times [17], [18].

D. Discussions

The evaluation and discussion of 1D, 2D, and 3D modeling methodologies for flood simulation and prediction emphasize the advantages and disadvantages of each methodology as well as some of the field's practical uses.

A common technique for simulating flow in a single direction along a channel is 1D hydrologic modeling. As long as the water stays inside the roadway profile, it offers a simplified portrayal of flood threats and is supposed to be acceptable. The primary benefit of 1D modeling is that it is straightforward and computationally efficient, making it appropriate for use in large-scale applications. A drawback of this method is that it necessitates particular rules for setting cross-section spacing and assumes uniform floodplain features between cross-sections.

On the other hand, 2D hydrologic modeling, which considers the two-dimensional flow of water and incorporates digital terrain modeling and bathymetry, provides a more in-depth simulation of flood events. It enables the depiction of flood inundation patterns and offers a more precise estimation of flood extent. The use of 2D models is particularly valuable when the flow exceeds the curbs and shifts direction, such as in urban areas with complex topography and structures. However, 2D modeling is computationally more expensive and requires high-quality data, including LiDAR data, to achieve accurate results [19].

It may also pose challenges for inexperienced users and information transfer to relevant departments. Additionally, it might make it difficult for new users to transmit information to the appropriate departments.

The study also emphasizes the value of 3D modeling in assessing flood risks, particularly when it comes to examining three-dimensional flow patterns around built-up areas and their interactions. 3D models enable precise simulation of flood impacts on utilities and infrastructure and offer a more thorough understanding of flood wave behavior. They give decision-makers useful information that enables them to evaluate the security of structures in flood-prone locations and prioritize emergency responses. By offering visualization tools, assessing hazards, and testing infrastructure projects before execution, 3D modeling also helps with planning and management. 3D modeling, on the other hand, necessitates specialist tools and comprehensive data and is more difficult and computationally expensive. It may take longer to simulate problems and is best suited for limited hydrologic problems.

IV. Machine Learning Algorithms in Flood Prediction

The destructive nature of floods has necessitated the advancement of flood prediction as a basis for risk reduction, policy suggestions, and minimizing property damage and loss of life. These requirements have led to the development of machine learning algorithms that mimic the mathematical expressions utilized in examining the physical processes of floods over the past two decades. In their study, Mosavi et al. [20] acknowledged that machine learning methods have improved prediction accuracy and provided cost-effective solutions, which has contributed to their increased popularity among hydrologists. Fig. 9 shows the fundamental steps in creating an ML-based model.

A systematic review revealed that several critical factors guide the selection of machine learning methods, including robustness, speed, computation cost, and generalization capability. Lawal et al. [21] discovered that the popularity of machine learning in predicting flood alerts and reducing the impact of floods arises from its low computational requirements, as it relies on observational data. However, a comparative study conducted by Lawal et al. [21], which evaluated logistic regression, support vector classification, and decision tree algorithms, highlighted the importance of considering performance accuracy, recall, and receiver operating characteristics when choosing machine learning algorithms for flood prediction.

Machine learning has made it possible to monitor the changing patterns of river water levels, which helps mitigate the socioeconomic implications caused by floods. According to Mosavi et al. [20], popular machine-learning methods for flood prediction include ANNs, SVM, SVR, ANFIS, WNN, and DTs. However, hybridization through various methods is also common. The study also found that the data decomposition technique is preferred to improve dataset quality and prediction accuracy, while ensemble methods facilitate generalization and reduce prediction uncertainty.

In addition, Mosavi et al. [20] identified that applying add-on optimizer algorithms improves prediction quality by tuning ANNs to optimal neuronal architectures. In a study on the detection of flooding from river water levels, Zehra [22] observed that non-linear (NARX) and support vector machines (SVM) are viable machine learning methods. The study revealed that NARX and SVM utilize hydrological resource variables such as precipitation amount, seasonal flow, peak gust, and river inflow, which are regressed into flood and non-flood classes.

Accurate prediction of floods and other hydrological events is crucial for water resource management techniques, policy development, and evacuation models. Improving prediction systems for short- and long-term flood events is significant in minimizing damage. It is important to note that machine learning (ML) approaches for flood prediction can vary significantly depending on the specific application, dataset, and type of prediction required.

For instance, ML approaches for predicting short-term water levels may differ greatly from those used for predicting long-term stream flows. When building an ML model, all the available data undergoes training, validation, verification, and testing processes [23]. These steps ensure that the model is trained effectively and performs accurately when applied to new data.

Overall, the development and utilization of ML models in flood prediction play a crucial role in improving the accuracy and effectiveness of water resource management, policy ideas, and analyses, as well as evacuation planning.

When accurate data are available, machine learning approaches can be a powerful tool in risk analysis. However, the findings obtained from these approaches may not be as sophisticated or predictable as those from model-driven studies, such as hydrodynamic models [24]. The use of a data-driven approach with machine learning for predictive studies can be relatively straightforward, particularly in the presence of uncertainty related to climate change.

One of the key advantages of using machine learning prediction models is their ability to capture flood nonlinearity based solely on historical data, without requiring an understanding of the underlying physical processes. Data-driven prediction models based on machine learning hold promise as they are easier to construct and require fewer inputs. Over the past two decades, the continuous improvement of machine learning algorithms has demonstrated their usefulness in flood forecasting, often surpassing conventional approaches in terms of performance and accuracy [25]. The distinguishing factor of machine learning technology in flood prediction is its ability to extract crucial information solely from input data without the need for specialized knowledge [26].

It is important to consider certain aspects of machine learning algorithms. Firstly, their performance is only as good as the quality of their training, which involves the system learning the intended task from previous data. Therefore, ensuring robust data enrichment is crucial in machine learning algorithms. Secondly, the competence of a machine learning algorithm varies depending on the specific task, which is commonly known as the "generalization problem." It refers to how effectively a trained system can forecast situations for which it was not specifically trained [20].

Fig. 9. The fundamental steps for creating a machine learning (ML) model.

Wagenaar et al. [27] discovered that the field of flood risk analysis, focusing primarily on rare extreme events, often faces challenges in data collection during such events, resulting in a lack of data for machine learning applications in flood risk and impact modeling, particularly for effective model training. However, advancements have been made in utilizing machine learning for descriptive hazard assessment using data from social media. Machine learning algorithms are effective optimization approaches rather than black box models, offering efficiency, reliability, and quick convergence at low computational costs.

The following are some commonly used ML algorithms in flood prediction:

A. ANNs: Artificial Neural Networks

The most often used algorithms for modeling flood prediction are ANNs. ANNs interpret historical data rather than the physical qualities of a catchment. As a result, ANNs are regarded as trustworthy data-driven tools for building sophisticated and nonlinear black-box models of the links between rainfall and flood. Despite their benefits, ANNs have several disadvantages, including network architecture, data management, and the inability to physically perceive the modeled system. The comparatively low precision while employing ANN is a significant disadvantage [20].

B. MLP: Multilayer Perceptron

The MLP is a class of FFNN that trains its network of interconnected nodes with multiple layers using supervised learning from BP. The MLP is characterized by simplicity, nonlinear activation, and a large number of layers. These qualities led to the model's widespread application in complicated hydrogeological models and flood prediction. MLP models were shown to be more effective and more generalizable in a review of ANN classes used in flood simulation. However, it is typically discovered that the MLP is more challenging to optimize [28].

C. SVM: Support Vector Machine

SVM, a supervised learning machine that operates on the statistical learning theory and the structural risk minimization (SRM) rule, is very well-liked in flood modeling. To reduce the predicted error and overfitting concerns of a learning machine, the SRM principle operates as a tradeoff between the quality and multidimensional character of the approximation function [29]. The SVM's training method creates new, non-probabilistic binary linear classifiers that maximize the geometric margin through inverse problem-solving and minimize the empirical classification error. Hydrologists use SVM extensively for flood prediction [20]. SVM, which is based on the structural risk reduction concept, is a reliable and efficient method for equation fitting, data analysis, hydrological forecasting, and other applications. Furthermore, SVM is used to handle small sample, non-linear, and high-dimensional pattern recognition problems and has unique benefits. SVM may be applied to classification as well as regression issues [30].

SVM applications are widely used in hydrological modeling and flood predictions. SVM's enhanced form as a regression tool supports vector regression (SVR) is a developed and efficient alternative procedure for dealing with regression difficulties during the last two decades by giving alternative loss functions. SVR is based on mapping and solving the original data into a high-dimensional feature space using linear and/or nonlinear regression classification. SVR formulation is based on SRM rather than ERM, which minimizes an upper bound of the generalization error rather than the prediction error on the training set [29].

SVM and other data-driven ML models rely on the quality and amount of training data as well as model optimization parameters. If the data is insufficient and inadequate to cover the differences, their learning falls short and, as a result, they cannot achieve reasonable accuracy. The disadvantages of SVM-type ML models for dealing with the "generalization problem" might be mitigated by a strong and complete understanding of ML techniques, as well as user-specified practical solutions [29].

SVM is essentially a linear machine and can be thought of as a statistical tool that solves issues using an approach akin to Artificial Neural Networks (ANN). Its approximate use of the Structural Risk Minimization (SRM) concept aids in its ability to generalize effectively to new data. While it has all the advantages of ANN, it also addresses some of the fundamental flaws that were observed in the ANN application. [31]. ANNs employ empirical risk minimization, but SVMs use structural risk minimization to handle the overfitting problem by balancing the model's complexity against its success in fitting the training data. [35].

The reason why the SVM algorithm is more popular in flood prediction than other algorithms is SVM may automatically choose the critical vectors in the training process as support vectors and delete the nonsupport vectors from the model. As a result, the model performs effectively in noisy environments. Furthermore, with certain crucial real training vectors encoded in the models as support vectors, SVM can trace back historical occurrences to enhance future forecasts with lessons learned from the past. Because the input vectors of SVM are fairly versatile, it is quite simple to integrate other relevant elements into the model (such as temperature, evaporation, date, etc.). Because SVM parameter optimization is a convex issue, there is only one optimal point, unlike ANN which has more than one optimal [33].

D. DT: Decision Tree

Because DTs are rapid algorithms, ensemble models to simulate and predict floods have become increasingly popular. The classification and regression tree (CART) is a common DT type used in machine learning. The decision tree is very useful for determining the level of risk of flooding [34].

E. GA: Genetic Algorithm

A genetic algorithm had been created by Holland. The survival of the fittest is the foundation of the idea. It uses chromosomes, which have several genes on each one. Every gene represents a choice variable (or model parameter), and every chromosome represents a potential best-case scenario [35].

F. ACO: Ant Colony Optimization

Dorigo developed the ACO after becoming curious about how ants choose the quickest route between their colony and a food source. It was discovered that although ants cannot see, they can communicate with one another via a chemical called a pheromone. Each spreads a scent along its course. Ants are therefore likely to select the route with the highest concentration of pheromone. According to this, ants will finally take the shortest way if there are both lengthy and short routes leading from the nest to the food source [35].

V. Analysis of Hydrologic Modeling Techniques

When it comes to hydrologic modeling, deciding between a steady-state and a non-steady-state flow is significantly easier. Although 2D modeling can yield better results in some cases, there are also scenarios where 1D modeling can produce outcomes equally as good as or better than 2D models, with less work and computing resources. Many situations are complex, and it is possible to include both the positive and bad aspects of each approach depending on the context.

A few instances of scenarios in which it is believed that 2D modeling is preferable to 1D modeling are as follows:

Water may flow in several directions if a levee is broken or overtopped in a model region located behind a levee system. Before it reaches the lowest point and begins to pool and maybe overtop or breach the levee on its lower end, water can flow overland in the protected region in several different ways thanks to the slopes present there. When the protected area is relatively small, and the entire area eventually fills to the level of a pool, a 1D model may accurately predict the ultimate water surface and the extent to which the region will be inundated.

Tides, river flows, and other water sources entering an estuary or bay can cause the water to flow in various directions—a place or occurrence where the water's flow path is not entirely clear. It is challenging to forecast flood occurrences due to the episodic character of flow evolutions on alluvial fans. This is because the channels' whole direction may shift while the event takes place, making it impossible to generate accurate predictions.

It is best to avoid making sharp bends when there is a good chance that considerable super elevation may occur. Because flood plains are expansive and level, the water that leaves the overbank zone may go in various directions. Measurements of precise velocities are required to correctly analyze the hydrology of flow around an item.

Because of the complexity of urban terrain, flows on the urban surface are often substantially different from flows in channels. In recent years, several examples have been explored and applied to coupled 1D/2D techniques, in which the urban surface is represented using two-dimensional (2D) flow approaches and combined with a 1D pipe network model. Roads, buildings, barriers, and other elements of metropolitan surfaces abound [30]. These structures, particularly buildings, will alter the direction and velocity of the flood water, resulting in a variety of complicated flow pathways. The information on the buildings may be distorted or lost if the grid resolution is too coarse. Models with finer grid resolutions may offer more precision and a more accurate depiction of physical processes.

Constructing an entirely 3D model is more complex, but once it has been constructed, changes to the design may be made methodically and straightforwardly. Applying design changes in a 2D model is more challenging than in 3D.

There are three types of instruments for predicting hydrological variables: conceptual, physically based, and "black-box" models. The underlying physics of the first two categories, which may be represented by either simplified relations or partial differential equations in one or two dimensions, must be understood. Furthermore, using these models to forecast rainfall/runoff processes and/or river routing also calls for a significant amount of topographic, land-use, and other information that might not be accessible. Additionally, the lengthy calculation requirements associated with this method, particularly when two-dimensional models are required, sometimes limit real-time forecasting derived from physically based models [36].

VI. Analysis of Machine Learning Techniques for Flood Prediction

This study on hydrologic modeling and machine learning in flood hazard assessment gives a thorough examination of machine learning techniques for flood prediction in this section. This analysis's goal is to assess the usefulness and applicability of several machine-learning strategies for anticipating flood dangers.

A. Evaluation Standards for Prediction

Establishing evaluation standards that cover accuracy, dependability, robustness, consistency, generalization, and timeliness is essential for creating accurate flood prediction models. These standards act as the basic rules for evaluating the efficacy of flood prediction models and guaranteeing their dependability in practical implementations.

B. Metrics for Performance Evaluation

Root-mean-square error (RMSE), mean error (ME), mean squared error (MSE), Nash coefficients (E), and correlation coefficient (CC or R^2) are some of the performance evaluation metrics for flood prediction models that are frequently utilized. These measures allow for a quantitative evaluation of the model's prediction skills and make it easier to compare various strategies.

C. Analysis of Various ML Algorithms in Flood Prediction

The study identifies the advantages of ANNs, such as enabling working with huge datasets, and the benefits and drawbacks of particular ANNs, such as Backpropagation Neural Networks (BPNN), functional networks, and the NARX network. The study also investigates how the inclusion of autoregressive models can improve the precision of flood forecasts.

The performance of the MLP and various DT models, such as the ADT model, the Rotation Forest (RF), and the M5 model tree (MT), is specifically examined. The study draws attention to their strength and effectiveness, particularly in cases with lengthy lead times.

SVM's excellent generalization capacity, promising hourly flood prediction results, and uncertainty evaluation for potentially dangerous flood quantiles are identified.

D. Hybrid Designs

The study investigates the effectiveness of hybrid models like the Adaptive Neuro-Fuzzy Inference System (ANFIS) and Wavelet Neural Network (WNN) for longer-term flood predictions that last longer than two hours. ANFIS's excellent capacity to predict flash floods in real-time, as well as its high accuracy and dependability is also identified. The study also looks at the advantages of sophisticated ANFIS hybrid models calibrated by Support Vector Regression (SVR) for nonlinear and real-time flood prediction, highlighting their enhanced prediction accuracy and cost-effectiveness.

E. Ensemble Methods

Finally, the study looks into cutting-edge hybrid models and ensemble techniques that combine statistical, soft computing, and machine learning techniques to improve flood prediction models. It examines Ensemble Prediction System (EPS) techniques, such as ANN, MLP, SVM, and RF ensembles, which show promise in enhancing prediction precision, and robustness, and lowering model uncertainty.

Table II lists the machine-learning techniques that have been applied to flood modeling. Although data-driven technologies, artificial neural networks (ANNs) have limits when it comes to understanding systems. The Multilayer Perceptron (MLP) is straightforward but difficult to optimize. Small sample sizes are effectively handled by a Support Vector Machine (SVM), but it requires high-quality data. Although Decision Tree (DT) is rapid and appropriate for flood modeling, more study is required. The Genetic Algorithm (GA) seeks the best options, but it depends on accurate encoding. For hydrogeological modeling and flood prediction, these methods have advantages and factors to consider.

An accurate forecast should be judged by its accuracy, dependability; robustness; consistency; generalization; and timeliness [37]. Durable and simple models are the best way to ensure that projects are completed on schedule. Using various root-mean-square errors (RMSE) can also evaluate the accuracy of forecasting models, mean error (ME), mean squared error (MES), and R^2 correlation coefficients, as well as the mean and squared errors for each model tested (CC). *RMSE* and R^2 values close to one indicate that flood forecasting models are generally reliable (Calculated using Eq. (1) and Eq. (2) respectively).

The flood forecasting models' reliability can be determined by examining their *RMSE* and R^2 values, where values close to one indicate higher reliability (calculated using Eq. (1) and Eq. (2) respectively). By referencing [20] and reviewing approximately 45 references, the study extracted and presented the results in Fig. 10 and Fig. 11. Evaluations of this study considered various factors, including the dataset, processing cost, and specific application. The study also assessed the method's generalizability, speed, installation cost, ease of use, and maintenance expenses. Standard deviation (RMSE) was measured using a single unit for accurate representation, and thorough confirmation ensured the absence of errors. R^2 and *RMSE* were utilized to assess the performance of single and hybrid ML approaches for short-term flood forecasting, as depicted in Fig. 10 and Fig. 11, based on Mousavi's research [20].

$$R^2 = \frac{\sum_{i=1}^{N}(x_i-\bar{x})(y_i-\bar{y})}{\sqrt{(\sum_{i=1}^{N}(x_i-\bar{x})^2)}*(\sum_{i=1}^{N}(y_i-\bar{y})^2)} \quad (1)$$

$$RMSE = \sqrt{\frac{(\sum_{i=1}^{N}(x_{obs,i}-x_{model,i})^2)}{n}} \quad (2)$$

where, the values are defined as follows:

x_i, y_i	The values that were observed and forecasted, along with the residue correspond to the i[th] data point.
$\bar{x}$ & $\bar{y}$	The arithmetic means of those values
X_{obs}	Observed value
X_{model}	The forecasted values for the specific year i

An ANN is a short-term forecasting technology that is widely viewed as promising. Improved methods for greater effectiveness Although ANNs performed severely in some early research, especially in the generalization component, they showed improved results when dealing with massive datasets. In this case, BPNNs and functional networks should be avoided. The models can handle noisy datasets accurately, efficiently, and quickly. In contrast, the NARX network outperformed the BPNN network. Even so, incorporating autoregressive models could improve accuracy.

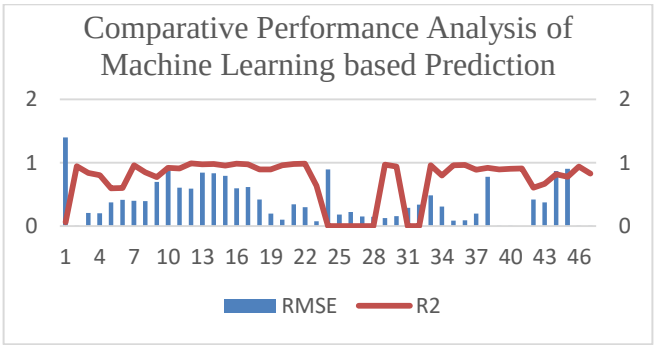

Fig. 10. Comparison of machine learning technologies in flood prediction based on R^2 and *RMSE* [20].

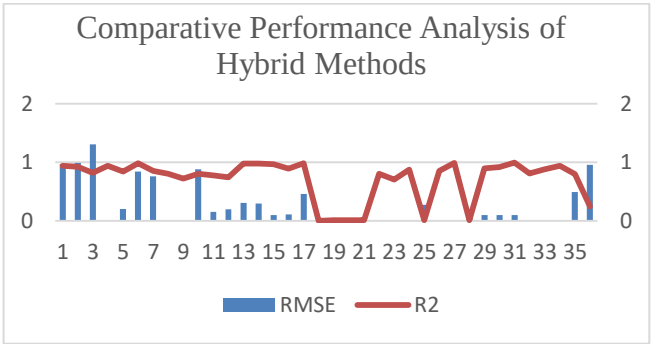

Fig. 11. R^2 and *RMSE* comparison of ML technologies in flood prediction [20].

TABLE II. A COMPARATIVE ANALYSIS OF MACHINE LEARNING ALGORITHMS FOR FLOOD MODELING

Algorithm	*Description*	*Advantages*	*Disadvantages*	*References*
ANNs (Artificial Neural Networks)	Interpret historical data, build sophisticated and nonlinear models	Trustworthy data-driven tools	Network architecture limitations, inability to perceive the modeled system	[30]
MLP (Multilayer Perceptron)	FFNN with multiple layers, widely used in hydrogeological models	Simplicity, nonlinear activation, effectiveness	Challenging to optimize	[39]
SVM (Support Vector Machine)	Supervised learning machine based on structural risk minimization	Reliable and efficient, handles small sample and nonlinear problems	Dependence on training data quality, challenges in generalization	[29], [30], [31][32], [43] [8]
DT (Decision Tree)	The rapid algorithm, increasingly popular in ensemble models	Speed, suitability for flood modeling	Further research is needed for flood prediction	[30]
GA (Genetic Algorithm)	The survival of the fittest concept uses chromosomes and genes	Ability to search for optimal solutions	Dependent on suitable chromosome encoding	[47]

TABLE III. A SYSTEMATIC REVIEW OF KEY RESEARCH PAPERS FOCUSED ON FLOOD MODELING AND PREDICTION

Location	*Methodology*	*Results*	*Key Factors*	*Implications*	*Reference*
Kalvan watershed, Iran	Tested five ML algorithms (ERT, RRF, PRF, RF, BRT) with 15 climatic and geo-environmental variables	ERT yielded the highest AUC (0.82)	Topographical and hydrological parameters	Aid in flood mitigation planning	[43]
Various urban settings	Reviewed prevailing flood modeling approaches	Overview of methods for pluvial flood modeling	-	Guide urban flood managers in selecting appropriate methods	[44]
Quannan area, China	Compared NBTree, ADTree, and RF methods using 13 flood explanatory factors	RF demonstrated high accuracy for flood susceptibility assessment	Multiple environmental factors	Support flood prediction in the study area	[45]
Khiyav-Chai watershed, Iran	Employed MDA, CART, SVM, and ensemble modeling with various factors	MDA had the highest predictive accuracy (89%)	Slope, drainage density, distance from river	Identify flood-prone areas for prevention	[46]
Various urban areas	Summarized calculation methods for urban flood numerical simulation	Identified trends for improving model accuracy and computational efficiency	1D-2D coupling, finite volume method, unstructured meshing	Guide hydrologists in model selection	[47]
Damansara River catchment, Malaysia	Combined FR approach with SVM using 13 flood conditioning parameters	Effective for flood risk management along an expressway	Environmental parameters	Replicable in other areas for flood risk assessment	[48]
Various locations in Thailand	Used MIKE-11 hydrologic model and ML techniques to improve runoff forecasting	Enhanced flood prediction accuracy	Hydrological data	Real-time flood prediction for better management	[49]
Jakarta, Indonesia	Utilized environmental factors and satellite imagery	Supported flood susceptibility prediction for flood risk management	Environmental conditions	Effective flood risk assessment	[50]
Indian monsoon forecasting	Employed neural networks for ISMR prediction	Demonstrated superior accuracy over existing models	Indian monsoon data	Improved ISMR forecasting	[51]
Various locations	Utilized various ML models for flood prediction	Compared models to improve prediction accuracy	Environmental and hydrological data	Enhanced flood prediction for management	[52]

Overall, the single prediction models examined could produce reasonably accurate short-term forecasts. However, hybrid models such as ANFIS and WNN scored better for forecasts lasting more than two hours. Non-linear and actual flood predictions were made more accessible and accurate with SVR-tuned advanced ANFIS hybrid models.

The capacity of (ML) models to capture the intricate (potentially unknown) nonlinear interactions between predictor (input) and predict and (output) variables sets them apart from other hydrologic modeling techniques, which solely base their predictions on previously observed data. Another benefit of these flexible models is their relatively high computational efficiency, which has increased their appeal over the past 20 years because of the continuing advancements in computing power [20].

Table III provides a comprehensive overview of various studies that have employed these approaches, encompassing a diverse range of locations and methodologies. The studies demonstrate the effectiveness of ML algorithms in improving flood prediction accuracy, emphasizing the importance of

environmental and hydrological factors in flood susceptibility assessment. Furthermore, the table highlights the development of various modeling techniques for urban flood modeling and the potential of integrated approaches combining ML and traditional methods for enhanced flood risk management. These findings underscore the transformative role of ML and other advanced techniques in addressing flood-related challenges, paving the way for more effective flood preparedness and mitigation strategies.

VII. Analytical Discussion

This systematic review offers valuable insights into the state of the art in flood modeling and prediction, providing a foundation for informed decision-making in flood risk management and urban planning. It underscores the potential of machine learning techniques in enhancing the ability to predict and mitigate the impacts of flash floods and pluvial flooding in urban areas. The study also highlights the strengths and weaknesses of both hydrologic models and data-driven machine learning models, paving the way for potential hybrid modeling approaches that can provide more accurate and efficient flood management strategies.

Additionally, the review identifies trends in research focus and geographic areas, which can guide future research directions and flood management efforts. Overall, this comprehensive analysis contributes to the ongoing efforts to develop effective flood control measures and adapt to the increasing challenges posed by climate change and urbanization.

Regarding computed water surface elevations and flow/stage hydrographs, 1D modeling can be just as accurate as 2D and 3D modeling while requiring less computational time and effort. The following are some examples of where this might be possible:

Rivers and floodplains where the predominant flow and force directions and paths follow the overall river flow. For most river systems, this is believed to be true, despite debates about the influence of lateral and vertical velocity on predicted water surface heights as well as the flood inundation boundary.

Gravity-driven streams with sloping beds tend to have very little overbank area. According to the river's dams, levees, pumping stations, and bridges, the river's predicted level and flow are affected by these gated projects.

The hydrologic flow characteristics present in many of the river systems are something that no 2D model has been able to represent adequately. It is a case where 1D models are much ahead of 2D models in terms of technological sophistication. These characteristics can be implemented in 2D models, but a popular 2D model with such a comprehensive collection of features is yet to be developed.

Medium to big rivers are considered when modeling a significant portion of the river system (100 or more miles) (i.e., 2-week to 6-month forecasts). Even with multi-processor computing and GPU (Graphics Processing Units) computation, 2D models have substantial geographical and simulation time restrictions regarding real-time forecasting. This is going to change over time. There is no evidence to justify using a 2D model in these situations. Many of the benefits of a 2D model will be thwarted by inaccurate topographical data due to a lack of information in the overbank and channel bathymetry.

As a result, the correctness of a 1D or 2D modeling approach for a given application is frequently in question. It is not as simple as choosing whether to solve the Saint Venant equations in one or two dimensions. There are other variables to consider. It was concluded that there are knowledge and tool gaps when determining whether to employ 1D, 2D, or 3D. It is necessary to use 1D and 2D models in the modeling efforts, and Hydrologic modeling software must be improved in this area.

Le et al. [38] [39] proposed many ANNs for seasonal flood forecasting and compared the outcomes. Data from 1970–1985 was employed as a training tool, while the 1986–1987 dataset was used to verify the results. The ANNs were able to identify whether the dataset was incomplete accurately. According to [20], employing ANNs to speed up data analysis could lower analytical expenses. ANNs have also been used to create precipitation forecast models, as seen in the [40]. An ANN model was used for a historical dataset spanning the years 1900–2001 to evaluate prediction accuracy. For this dataset, more than 100 floodstream localities were examined. The ANN, on the other hand, had issues with generalization. Despite this, water management found the ANN to be helpful in this instance.

Prediction models for heavy rain and flooding were developed by [37] using a variety of BPNNs. This dataset covered 1871–2010, and it did so every month. It was discovered that BPNN models using virtual networks were ideal for nonlinear flood forecasting since they were both fast and resilient. The following source may be long-term flood projections: BPNN and LLR-based models were used by Shamim et al. [41] to explain nonlinear floods better. An estimated two decades' worth of rainfall, evaporation, and water level statistics stretches back to 1988 in this dataset. According to their findings, LLR outperformed the BFGSNN neural network model in terms of efficiency and durability. In contrast to the other approaches, BPNN performed well.

According to [20], the most reliable ANN for long-term flood prediction is the BPNN model. For the long-term forecasting of flood discharge, ANNs performed better than BPNNs and MLPs in reference. There were promising outcomes while employing MLP. There was, however, the problem of generality. Mulualem and Liou [40] used an SVM model to forecast streamflow and reservoir inflow long-term. For comparison, they used neural networks and ARMA. Monthly river-flow flows from 1974–1998 were used to train the models, and data from 1999–2003 was used to evaluate them. According to a comparison of model performance, SVM outperformed the ANN when predicting long-term discharges.

ANNs are the most extensively utilized ML tool for dealing with complex flood features and incomplete data sets because of their accuracy, high fault tolerance, and parallel solid processing. ANN, on the other hand, has a problem with generalization. In [30], ANFIS, MLP, and SVM outperformed ANNs. As suitable data pre-processing, wavelet transformations may increase the performance of most machine

learning (ML) methods, which have been suggested. WANs, as opposed to traditional ANNs, have few benefits.

According to Hosseini et al. [42], short-term and long-term rainfall-runoff models' accuracy, precision, and performance were all improved by deconstructing ML algorithms (such as WNN). However, while WNNs have proven a success, long-term forecasts are limited. Hybrid WNN/autoregressive models WMRA and WARM were developed to improve the precision of one-year-ahead forecasts.

Through deconstruction, models performed far better in some circumstances, resulting in more accurate results. For example, wavelet–neuro-fuzzy models outperformed standalone ANFIS and ANNs in terms of accuracy and speed [42]. However, as the lead time lengthened, so did the degree of uncertainty in the predictions. Future research should take into account the accuracy of the model. An essential part of developing hybrid techniques was using data decomposition methodologies such as autoregressive, wavelet transformations (DWT), wavelet–autoregressive, IIS, and EMD.

Extrapolative prediction systems are another advancement in prediction accuracy and generalizability (EPS). Recent ensemble techniques have significantly changed speed, accuracy, and generality. Many non-traditional approaches to machine learning were used in developing ANN and WNN model training algorithms, such as BB sampling and genetic programming, in addition to typical ML techniques like the basic average and Bayesian inference. Conversely, ensembles outperformed models that did not include human decision-making as an input component. New decomposition–ensemble prediction models appropriate for monthly forecasts were the most significant hybrid models. Their accuracy and generalization improved significantly compared to SVM, ANFIS, and ANNs.

Predicting floods using machine learning models is still a developing field. An overview of machine learning models used in flood forecasting is presented in this study, along with the development of a classification strategy to examine the literature. More than 6,000 items were analyzed and investigated in the survey. Several original and significant studies compared the precision of at least two machine learning models. Models were classified into two groups depending on the lead time, with hybrid and single-method subgroups further subdividing.

Considering performance comparisons from previous literature helped in accessing and analyzing how these approaches perform. All approaches were examined using R^2 and RMSE, as well as a generalization, robustness, and computing costs/speeds. Despite the previous optimistic results, there was a lot of research and testing to enhance and develop the most popular machine learning algorithms like ANNs and SVM, SVR and ANFIS, WNN, and DTs. Four essential topics emerged from the research on improving prediction models' accuracy and general models.

The initial stage was to use both conventional and soft computing in conjunction with at least two different types of machine learning algorithms. Secondly, data segmentation methods were used to increase the dataset's quality, resulting in much higher accuracy in the predictions made from the data. Generalizability and predictive power were significantly improved and decreased by employing several approaches. Add-on optimizer algorithms, for example, can be used to increase the quality of neural network models.

Flood prediction is projected to improve significantly in the near and long term due to the development of these four leading technologies. Developing these new machine learning approaches relies heavily on applying soft computing principles in algorithm design. As a result, future hybrid machine-learning methods will rely heavily on soft computing techniques, as detailed in the study.

VIII. Conclusion

In conclusion, the study has underscored the critical impact of floods on the environment, emphasizing the need for effective prediction models to mitigate their adverse effects, such as loss of life, crop destruction, and increased waterborne ailments. The investigation has focused on the application of one-dimensional, two-dimensional, and three-dimensional hydrologic modeling for flood hazard forecasting, providing valuable insights for the development of preventive interventions. Notably, the study has revealed the growing superiority of machine learning (ML) techniques over traditional hydrologic models in predicting flood occurrences.

The findings indicate that ML, armed with sophisticated algorithms and extensive datasets, excels in its ability to provide accurate flood predictions. Notably, the study suggests that ML models can offer effective solutions by correctly estimating complex hydrological parameters, as exemplified in the accurate determination of water flow through structures like the hydrologic manifold P-10. This superiority of ML over hydrologic modeling systems is further supported by the bibliometric investigation, which revealed a burgeoning interest in utilizing machine learning for flood prediction.

Two key recommendations emerge from this study to further advance flood prediction accuracy. First, there is a discernible shift toward the use of machine learning techniques, and it is recommended to collect real-world data on flood events from Jeddah municipality. This data would serve as a valuable resource for training machine learning algorithms, enhancing their accuracy and applicability in the specific context of the study. Second, acknowledging the need for a comprehensive approach, the study recommends developing a hybrid model that combines time-series data for machine learning-based algorithms with the expertise of 1D/2D/3D hydrologic modeling. This hybrid approach aims to leverage the strengths of both methodologies for improved flood prediction, acknowledging the importance of evolving hydrologic modeling science while embracing the advancements offered by machine learning.

***Abstract*—Stereo matching techniques are a vital subject in computer vision. It focuses on finding accurate disparity maps that find its use in several applications namely reconstruction of a 3D scene, navigation of robot, augmented reality. It is a method of obtaining corresponding matching point in stereo images to get disparity map. With additional details, this disparity map could be converted into a depth of a scene. Obtaining an efficient disparity map in the texture less, occluded, and discontinuous areas is a difficult job. A matching cost using an improvised Census transform and an optimization framework is proposed to produce an initial disparity map. The classic Census transform focus on the value of pixel at the center. If this pixel is prone to noisy condition, then the census encoding may differ which leads to mismatches. To overcome this issue an improved census transform based on weighted sum values of the neighborhood pixels is proposed which suppresses the noise during stereo matching. Additionally, a deep learning based disparity refinement technique using the generative adversarial network to handle texture less, occluded, and discontinuous areas is proposed. The suggested method offers cutting-edge performance in terms of both qualitative and quantitative outcomes.**

***Keywords*—Census transform; deep learning; depth; generative adversarial network; occlusion; stereo matching**

I. INTRODUCTION

Stereo matching has gathered attraction recently because of its applications in fields like visual entertainment, 3D reconstruction, autonomous driving, object detection [1], outdoor mapping, navigation and 3DTV [2], [3]. It is a research area that tries to imitate vision systems in humans by using two or several 2D views of the same scene to get three-dimensional depth details of the scene. It intends to find the corresponding relationship between matching pixels. A stereo matching algorithm uses stereo images that are rectified as an input [4], [5]. The horizontal displacement between the matching pixels is called disparity. With additional details, a disparity map could be transformed to a depth of scene. Disparity map accuracy is very crucial as small inaccuracies may affect the result. Obtaining an efficient and precise disparity map is a tedious task because of the existence of noise, occlusions, low textures, ill-posed regions, and the lighting conditions. Hence, it is significant to create a good disparity map.

Stereo matching techniques are classified as conventional algorithms and deep learning methods. Conventional algorithms are grouped into local and global algorithms. In local approaches, disparity is computed by comparing small areas [6] [7]. The disparity calculation relies on intensity in a defined support area. In real time the stereo images collected may be prone to noise, lighting distortions which reduces the efficiency of these algorithms. To overcome these drawbacks, a census transform in stereo matching is proposed in [8] which can decrease the effect of amplitude distortion. It aims at mapping the pixels to a binary string and then calculates the similarity between the pixels by means of Hamming distance. But, this method relies mainly on the central pixel, leading to false matching in a noisy environment. To reduce this shortcomings, a three-state census is proposed in [9] which is tolerant to any noise and enhances the robustness of stereo matching. An algorithm is implemented in [10] to perform census transform that reduces the noise interference and amplitude distortions in the images. A star-census transform (SCT) is introduced [11] that initiates the neighborhood pixel sampling in a symmetrical order that excludes the central pixel in the matching window. An improvised AD-Census stereo matching using gradient fusion (ADSG) is introduced in [12]. The absolute difference is used along with census transform for cost calculation, the result is then combined with gradient cost. These methods focus only on the information locally and hence have a low complexity and execute in shorter time. But the results generated by these local methods in the areas of occlusion, texture less and discontinuities is not satisfying.

The semi global algorithm was proposed in [13]. The accuracy and computational efficiency of semi global algorithms lies in between that of local and global algorithms. A global method considers disparity computation as a global energy minimization method for all disparity values. The energy function has two terms namely data term which penalizes pixels with inconsistent values and smoothness term with enforces smoothing constraint by considering the neighboring pixels. Some of the commonly used global algorithms are graph cuts algorithm [14] and belief propagation technique [15]. A disparity estimation based on tree structure named Pyramid-tree is introduced in [16]. It performs cross regional smoothing that can handle low texture regions. Global methods can generate a good quality disparity map, but they are also quite expensive and time-consuming.

Deep stereo methods are popular these days. Zbontar et al. [17] used a network to get patch-wise details to compute matching cost. The proposed network is trained to find the similarity that exists between a pair of images. It is then processed using classic post processing. The GC-Net [18] is a network with a high performance. It applied 3D convolution kernel to the correspondence space and proposed disparity refinement. This provided improvement over the previous approach. A pyramid stereo matching network is proposed in [19]. It improved the feature extraction by means of multi scale feature extraction network [20]. A network namely cascaded residual learning [21] was introduced which uses a DispNet. This is made up of two sub parts called DispFullNet and a DispResNet. The first network computes the raw disparity map. The second network tries to optimize the raw disparity map by computing the multiscale residual information. Williem et al. [22] introduced a method known as self-guided cost aggregation that uses a convolution network for local stereo matching. The network is made up of emotional weight network and descent filtering network. In LEA Stereo [23] a search is performed to streamline matching pipeline. Shivam Duggal et al. [24] developed a trainable network. Many recent papers introduced refinement components steps to improvise the disparity map quality. The MSMD-Net [25] introduced multi scale technique in which the stereo images are processed using multi resolution pyramid network. The RAFT- stereo [26] consists of a network for stereo estimation along with refinement stage. The deep learning-based methods can produce depth map from a given stereo image pairs, but these stereo methods still find it difficult to find correct correspondences in texture less and the occluded regions.

Though several techniques have been proposed to improvise the matching accuracy, the low accuracy in the occluded and texture less regions has not been handled very well. A depth estimation technique using improvised census transform and disparity refinement using deep learning to enhance the results in occluded and texture less regions is proposed . The weighted sum of the center pixel and its four neighbors is used to calculate the center pixel value in the improvised census transform in order to reduce noise in initial disparity map. The occluded and texture less regions of initial disparity map are refined using Generative adversarial network (GAN) deep learning framework. The extensive experiments performed on Middlebury datasets shows the efficacy of our method. Our method improvises the efficiency of disparity map by a considerable amount. The suggested method is explained in Section II. The outcomes of the suggested method are shown in Section III. In Section IV, the paper's conclusions are discussed.

II. METHODOLOGY

The proposed method applies improved census transform is applied for the stereo images and a matching cost is obtained using Hamming distance. Then, a cost aggregation is carried using semi global method to compute an initial disparity map. Finally, a disparity refinement network using GAN is proposed to increase the efficiency of disparity map from which depth is estimated. An overview of the whole methodology is Fig. 1.

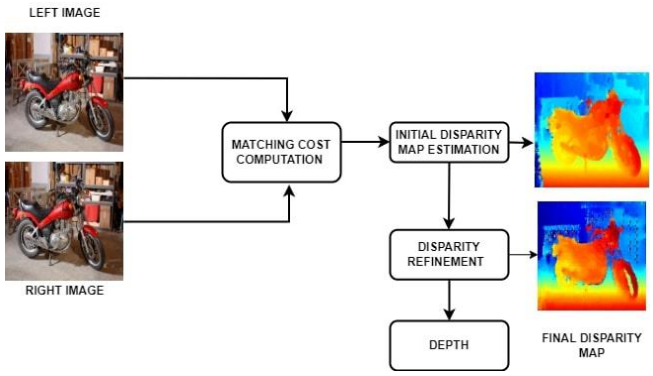

Fig. 1. Block diagram of the methodology.

A. Improves Census Transform

Methods for stereo matching based on intensity difference contain a lot of errors, especially for the outdoor images. To overcome these drawbacks Census transform (CT) method is used for computing matching cost. It is a local method that relies on relative ordering of pixels rather than intensity within a fixed window. Hence it can efficiently handle radiometric variations like lighting changes and illumination differences and discontinuities. The traditional CT is shown in Fig. 2. Census transform consider the center pixel value, compares with all the remaining pixels and assigns the 1 if the center pixel value is less than the compared pixel, otherwise 0 is assigned. It is then represented as a binary bit string.

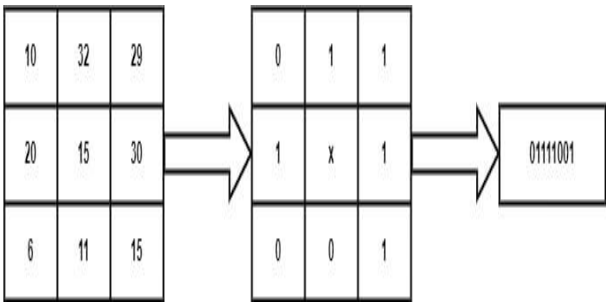

Fig. 2. Traditional census transform.

Census transform is represented by the following equation

$$T_{cen} = \otimes_{i \in w_p} \xi[I(p), I(m)] \quad (1)$$

$$\xi[I(p), I(m)] = \begin{cases} 1, & I(p) \le I(m) \\ 0, & otherwise \end{cases} \quad (2)$$

Here, $\otimes$ is a bitwise operation, w_p represent window with p as centre pixel, m is any point in w_p and $I(p), I(m)$ are pixel values of points p and m respectively.

The traditional CT can reduce the impact of distortions in amplitude, but it depends heavily on the middle pixel. It is prone to noise, as it measures the relative difference of the neighboring pixels based on middle pixel. When the center pixel is affected by noise, encoding from the census transform might vary drastically which may lead to mismatched pixels. Due to noise if the center pixel value changes from 15 to 35, the traditional CT transformation for a 3 X 3 patch of image is depicted in Fig. 3. Since the traditional CT depends on the

pixel at the center, the noisy center pixel value 35 is considered to compare with the remaining pixels in the image patch. The census code obtained is 00000000. Here there is a difference in 5 bits as compared to the initial code 01111001.

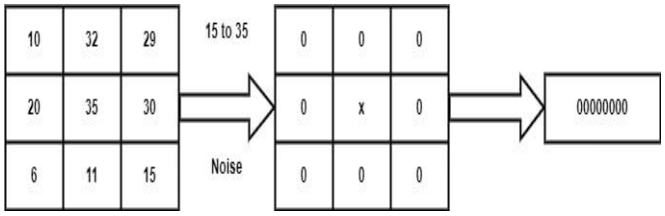

Fig. 3. Traditional census transform in noisy condition.

Aiming to overcome this drawback, an improvised census method is proposed in this paper where the weighted summation of pixel at the center and the four neighboring pixels is used to update the center pixel.

Let $I(m,n)$ be the center pixel. The weight distribution of pixel of the center and the four neighboring pixels are:

$$\mathrm{wt(m,n)} = 0.4 \quad (3)$$

$$\mathrm{wt(m+1,\ n)} = 0.15 \quad (4)$$

$$\mathrm{wt(x-1,\ y)} = 0.15 \quad (5)$$

$$\mathrm{wt(m,n+1)} = 0.15 \quad (6)$$

$$\mathrm{wt(m,\ n-1)} = 0.15 \quad (7)$$

The weights are assigned in such a manner that the weight of each pixel lies in between 0 and 1 and the total weighted sum of the pixel at the center and four neighboring pixel is 1.

The weighted sum of pixel centered at (x, y) is computed using the following equation.

$$I_{wt}(m,n) = I(m,n)wt(m,n) + I(m+1,n)wt(m+1,n) + I(m-1,n)wt(m-1,n) + I(m,n+1)wt(m,n+1) + I(m,n-1)wt(m,n-1) \quad (8)$$

The following equation is used to update the value of the center pixel.

$$I_{mid}(m,n) = \begin{cases} \{ I(m,n), & |I_{wt}(m,n) - I(m,n) \le T| \\ I_{wt}(m,n), & |I_{wt}(m,n) - I(m,n) > T| \end{cases} \quad (9)$$

If the variation between the weighted sum of center pixel and the original center pixel is more than the threshold $T = 6$, then the pixel value in the center is updated by the weighted sum otherwise the original is used.

The improvised technique for census transform proposed in the paper is depicted in Fig. 4.

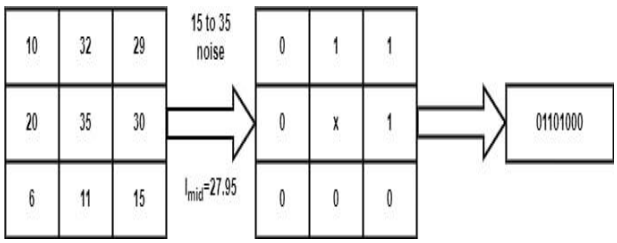

Fig. 4. Census transform of the proposed method in noisy condition.

Due to noise if center pixel value change from 15 to 35, the improvised method proposed in the paper updates the value of center pixel to 27.95 using the weighted sum as shown in Fig. 4 (i.e 35*0.4+11*0.15+32*0.15+30* 0.15+20*0.15). This value is compared with the remaining pixels in the patch to get the census code 01101000. The pixels differ only by 2 bit as compared to original code 01111001. This demonstrates how the approach is noise-resistant and improves matching performance.

B. Matching Cost Computation

To ascertain whether the values between two pixels indicate the matching point of a scene, a matching computation of cost is carried out. After the census transform the correspondence of pixels can be determined using Hamming distance [8]. The Hamming distance between matching points is found to estimate the correspondence between matching points. Let $S_{cenL}(p)$ be a binary bit array of pixel p in the left stereo image and $S_{cenR}(q)$ be the binary bit array of pixel q in right stereo image for disparity d. The following calculation uses the Hamming distance to compute the matching census cost between p and q.

$$C(p,d) = Hamming[S_{cenL}(p), S_{cenR}(q)] \quad (10)$$

The cost computation for the center pixel of $3\,X\,3$ image patch is depicted in Fig. 5.

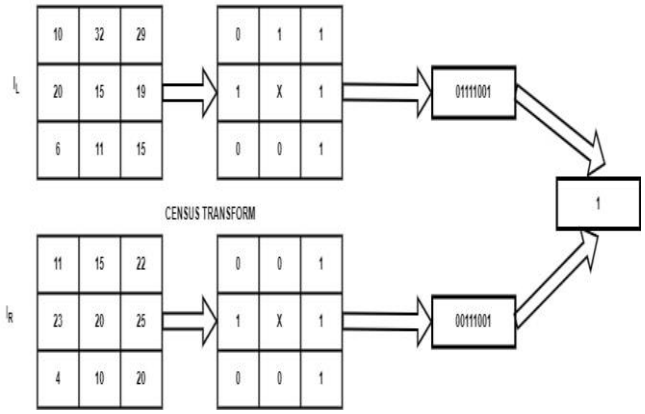

Fig. 5. Matching cost computation.

C. Initial Disparity Estimation

Due to noise, the pixel wise cost may produce ambiguous results. Hence additional constraint is included to get a smooth disparity by penalizing the changes in the neighboring pixels [27]. The smoothness constraint and pixel wise cost is represented by the energy function $E(D)$.

$$E(D) = \sum_P C(p, D_P) + \sum_{x \in N_p} P_1\, T\left[\left|D_p - D_x\right| = 1\right] + \sum_{x \in N_p} P_2\, T\left[\left|D_p - D_x\right| > 1\right] \quad (11)$$

$C(p, D_P)$ is the cost summation of all the pixel for disparity D. P_1 is the penalty applied to pixels x in N_P with low disparity difference. P_2 is the penalty for pixels in N_p with high disparity difference.

The stereo matching problem aims to minimize the energy function$E(D)$. Finding the minimum energy function $E(D)$ is computationally expensive. The energy function is

approximated by aggregating the matching cost from all directions $'r'$. The total number of directions r is 8. The cost at direction r is represented by,

$$S_r\ (p,d) = C(p,d) + min\big[S_r(p-r,d), S_r\ (p-r,d-1) + P_1, S_r(p-r,d+1), S_r(p-r,i) + P_2\big] \quad (12)$$

$C(p,d)$ is cost for pixel p and $S_r(p-r,d)$ is the pixel cost at direction r with disparity d, $S_r\ (p-r,d-1)$ is cost at direction $'r'$ and disparity $'d-1'$. $S_r(p-r,d+1)$ denotes cost for disparity $'d+1'$ and direction $'r'$. S_r is minimum pixel cost at direction r.

The following equation is then used to determine the initial disparity.

$$D(p) = argmin \sum S_r\ (p,d) \quad (13)$$

D. Disparity Refinement

The initial disparity calculated may contain wrongly matched disparities at the object boundaries, occluded areas and the texture less regions. Finding the correct disparities in these areas is a difficult task. Hence, an appropriate disparity refinement method is needed. A disparity refinement is performed based on deep learning-based technique using the generative adversarial network (GAN) to handle texture less, occluded, and discontinuous areas. The method proposed uses GAN network introduced by Good fellow [28] for disparity refinement. GAN includes two networks called generator and a discriminative network that are implemented based on neural networks. The generator takes initial disparity map as its input and focuses on generating a refined disparity map. The discriminator is fed with ground truth disparity along with disparity map produced by the generator. The discriminator aims to differentiate the ground truth disparity and generated refined disparity map. The feedback from the discriminator is given to the generator to fine tune the generated image. This procedure is repeated until the resulting disparity resembles the ground truth disparity. The disparity refinement network proposed in the paper is depicted in Fig. 6.

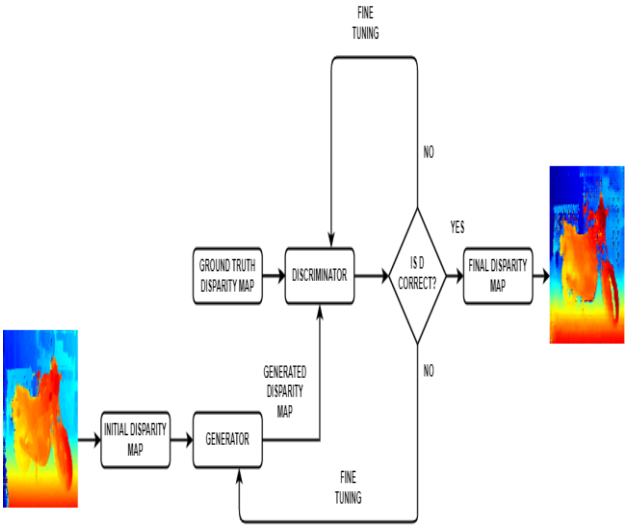

Fig. 6. Architecture of disparity refinement network.

A Pix2Pix GAN [29] is used to refine the disparity map. Pix2Pix GAN is an adversarial network. Pix2Pix GAN is known for the capacity of producing high quality images. The initial disparity is given as input to the generator. The generator generates the disparity map which is then fed to the discriminator. The various generator networks available are UNET 128, ResNet 6 and Resnet 9. The proposed disparity refinement network uses UNET128 as it can learn with few training images. The architecture of UNET 128 generator used in the proposed approach is depicted in Fig. 7.

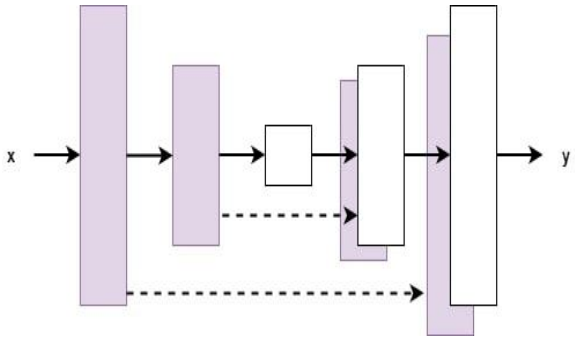

Fig. 7. Architecture of generator.

It uses a network consisting of several convolutional layer, batch normalization, dropout, and activation layers. It is trained using adversarial loss and then revised by means of L_1 loss. This loss drives the generator to generate image close to ground truth disparity. The generator is then updated using a sum of L_1 loss and a loss called as adversarial loss. A comparative study of UNet 128 with other networks such as ResNet 6 and ResNet 9 is given in Table I. ResNet 6 and Resnet 9 are the deep residual networks which include 6 residual blocks and nine residual blocks respectively. The information details are passed via a shortcut connection. Convolutional, batch-normalization, and corrected Liner Unit (ReLU) layers make up a traditional residual block. For evaluation, measurements like squared relative difference (SRD) and absolute relative distance (ARD) are used. Lower values of the above metrics indicate better performance. The efficiency of the generator architecture is shown in Table I. Results obtained for UNet 128 is better than the ResNet 6 and ResNet 9.

$$ARD = \frac{1}{N}\sum \frac{d_t\,(p,q) - d_g(p,q)}{d_t(p,q)} \quad (14)$$

$$SRD = \frac{1}{N}\sum \frac{\left|d_t(p,q) - d_g(p,q)\right|^2}{d_t(p,q)} \quad (15)$$

Here d_t is generated disparity map, d_g is ground truth disparity map. N is the total pixels.

TABLE I. COMPARATIVE STUDY OF GENERATOR ARCHITECTURE

	ResNet 6	ResNet 9	UNet 128	
ARD	0.058	0.051	0.037	Lower is better
SRD	0.409	0.413	0.403	

The discriminator is based on Patch GAN model. This PatchGAN model provides extremely high frequency information. The GAN's primary objective is described as,

$$L_{GAN}(G,D) = E_{p,q}\left[logD(p,q)\right] + E_{p,r}\left[log\left(1 - D\big(p,G(p,r)\big)\right)\right] \quad (16)$$

Here, p de represent the a ground truth disparity, q denote the generated disparity and r denotes the initial disparity map

The generator G attempts to decrease the objective as response to the discriminator D which attempts to increase it. The result is as follows:

$$G^* = argmin_g max_d L_{GAN}(G,D) \quad (17)$$

The aim of G is to decrease the objective and the generator updates itself using Loss L_1. It is computed as,

$$Loss_{L_1}(G) = E_{p,q,r}\left[\|\big(q - G(p,r)\big)\|_1\right] \quad (18)$$

The objective is updated as

$$G^* = argmin_g max_d L_{GAN}(G,D) + \lambda Loss_{L_1}(G) \quad (19)$$

The performance of training model is depicted in Fig. 8. Here the training loss decreases gradually as the number of epochs increases. Lower the loss, the more effective the model is.

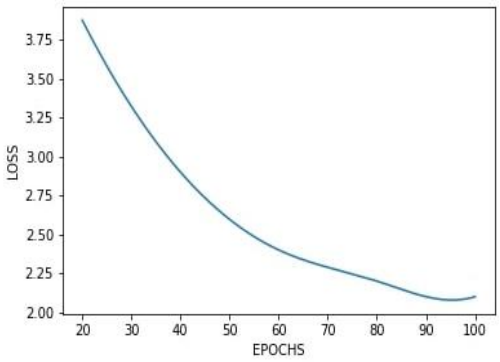

Fig. 8. Training loss versus epochs.

E. Depth

Once the disparity map is generated for the stereo images, the depth Z is estimated using the following formula:

$$Z = \frac{f\ X\ B}{D} \quad (20)$$

Fig. 9. Point cloud generated for motorcycle image.

Here f is focal length, B is stereo camera baseline. These values are obtained from the stereo calibration. Once the depth is estimated the exact coordinates of each pixel in the scene can be computed. These coordinates are made used to construct point clouds. The point cloud generated for Motorcycle image is shown in Fig. 9. The coordinates are stored in polygon format file. The output ply file is plotted using ply file plotters. The point cloud shown above was constructed using open3d.

III. Results and Discussion

The experiments were performed using Middlebury dataset [30], [31] images to analyze the performance. The refinement network is trained using the Pytorch framework on a personal machine. The computer hardware environment used is a Dual Intel-Xeon E5-2609V4 8C having 1.7 GHz 20M 6.4 GT/s and 128GB Memory. A Dual NVDIA Tesla server P100 GPU having 3584Cores and maximum of 18.7 TeraFLOPS is used. The datasets are downscaled to 256 pixels width and 256 pixels height for computational purposes. The Adam optimizer is used to optimize the discriminator. The learning rate is 0.0002. The GAN models does not converge, hence a balance has to be established between the generator and discriminator. The number of epochs is 100.

A. Middlebury Dataset

The Middlebury dataset includes rectified stereo images from indoor and outdoor surroundings utilizing a stereo vision concept. These images are complex, and it has images of different characteristics such as, different resolutions and low texture areas. Hence, the dataset consists of complex images for framework evaluation. Our stereo matching technique is robust to occluded and non-textured regions. The details of testing images like Cones, Teddy and Venus from Middlebury 2001 and 2003 are given in Table II. The details of higher resolution images from Middlebury 2014 are given in Table III.

TABLE II. Image of Middlebury 2001 and 2003

Images	Disparity level	Image resolutions
Cones	60	450 × 375

B. Noise Resistance Test

The traditional CT heavily depends on the center pixel. If this pixel is prone to noisy condition, then the census encoding may differ which leads to mismatches. To analyze the

efficiency of the proposed improved census transform in a noisy condition, salt and pepper noise of 2% and 5% noise is applied to Cones, Teddy and Venus images. The qualitative results for Teddy image when 2% salt and pepper noise is applied is represented in Fig. 10 and Table IV shows the percentage of bad matching pixels (PBMP) of the initial disparity map for the proposed improved census transform and traditional CT. The outcome conclude that results of the method proposed in the noisy condition is remarkably good than the traditional CT.

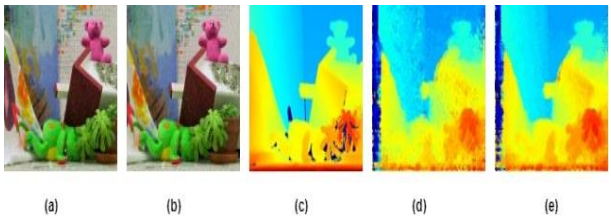

Fig. 10. Visual results for initial disparity map on noisy Teddy image (a) Left reference image (b) Right image (c) Ground Truth Disparity (d) Initial Disparity Map using traditional CT (e) Initial Disparity Map using proposed method.

TABLE IV. PBMP OF INITIAL DISPARITY MAP

	Salt & Pepper Noise (2%)		Salt & Pepper Noise (5%)	
	Traditional CT	**Proposed**	**Traditional CT**	**Proposed**
Cones	8.984	7.556	12.990	8.980
Teddy	13.492	9.715	19.492	12.103
Venus	3.229	1.370	6.062	2.740

C. Qualitative Results

The initial and improved disparity maps estimated by the suggested method are shown in Fig. 11. In the Fig. 11, the Fig. 11(a) is the left reference image. Fig. 11(b) is the right image. The ground truth disparity is given Fig. 11(c). The fourth column Fig. 11(d) represent initial disparity map. The refined disparity map is represented in Fig. 11(e). The red rectangular regions marked in Fig. 11(d) represent the occluded areas which are filled in the refined disparity map obtained by the suggested approach. The yellow circular region marked in the initial disparity of the Venus image shows the texture less region which is filled in the refined disparity map. It is discovered that the suggested method effectively creates high-quality disparity maps in noisy, textureless, and occluded regions.

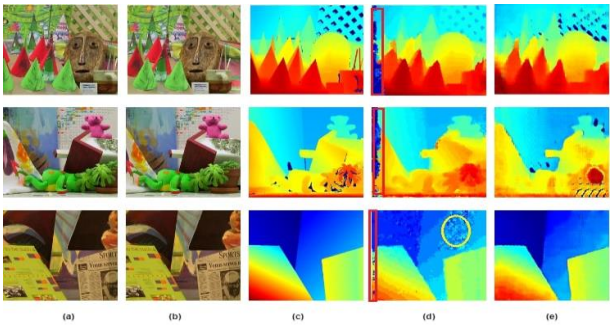

Fig. 11. Visual results on Cone, Teddy, and Venus images (a) Left image (b) Right image (c) Ground Truth Disparity (d) Initial Disparity Map (e) Refined disparity map.

The disparity maps generated for images such as Jade Plant, Adirondack, Motorcycle and Recycle are presented in first, second, third and fourth rows respectively in Fig. 12. The first row of the Fig. 12 shows a Jade Plant image from Middlebury dataset. This image is very challenging to match due to brightness difference. But, the proposed method has correctly discovered the disparities. The second and third rows of Fig. 12 shows Adirondack and Motorcycle images. The texture less surfaces in the initial disparity map of Adirondack image is highlighted by the yellow circular region. These regions are well recreated by the proposed approach. The fourth row of Fig. 12 shows Recycle image. The occluded areas in the initial disparity map is highlighted by the red rectangular region. The possibility of getting wrong matches in these regions are very high. These occluded areas are filled accurately in the estimated disparity map. We find that the proposed method produces efficient results in occluded and texture-less regions.

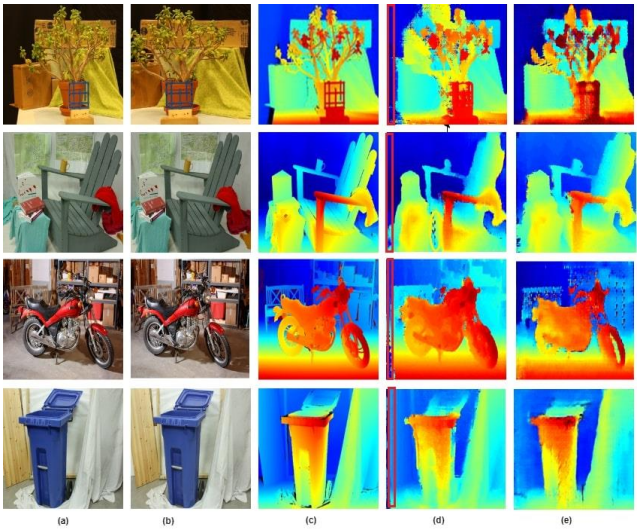

Fig. 12. Visual results on Jade Plant ,Adirondack, , Motorcycle and Recycle images (a) Left reference image (b) Right image (c) Ground Truth image (d) Initial Disparity Map (e) Refined disparity map.

D. Evaluation Metrics

The quantitative analysis is performed using the evaluation metrics namely root mean square error (RMSE) and PBMP. The efficiency increases when PBMP and RMSE values decrease. N be the number of pixels. d_t and d_g be the disparity map estimated and ground truth disparity maps respectively.

RMSE is calculated as:

$$RMSE = \left[\frac{1}{N}\sum\left|d_t(x,y) - d_g(x,y)\right|^2\right]^{\frac{1}{2}} \quad (21)$$

PBMP is calculated as follows:

$$PBMP = \left[\frac{1}{N}\sum\left|d_t(x,y) - d_g(x,y)\right| > T\right] * 100 \quad (22)$$

E. Comparison with Existing Methods

The proposed method is compared with ADSG [12] and Deep Pruner [24]. The results for the methods compared are obtained from Middlebury evaluation leader board. An improved AD-Census method using gradient fusion is used in

ADSG. The absolute difference and census transform is used for cost calculation, which is then combined with gradient cost. This method focus only on local information and hence do not give satisfying results in the areas of occlusion, texture-less and discontinuities. Deep Pruner uses a trainable network. It do not produce satisfactory results in the occluded regions. Tables V and VI demonstrate that the comparison of RMSE and PBMP results.

TABLE V. COMPARISON OF RMSE RESULTS

Images	ADSG	Deep Pruner	Proposed
Adirondack	19.5	6.18	5.14
ArtL	24.6	9.50	6.22
Jade plant	25.8	28.2	5.44
Motorcycle	79.6	10.3	6.52
Pipes	32.1	13.9	6.74
Playroom	35.2	8.91	7.85
Playtable	50.0	4.89	3.52
PlaytableP	19.9	4.74	3.54
Recycle	17.6	3.81	5.55
Shelves	21.9	4.28	5.66
Avg	32.62	9.471	5.618

TABLE VI. COMPARISON OF PBMP FOR THRESHOLD=1

Images	ADSG	Deep Pruner	Proposed
Adirondack	38.9	39.7	23.97
ArtL	35.5	41.8	42.36
Jade plant	49.8	62.8	44.50
Motorcycle	43.2	45.3	45.92
Pipes	41.5	53.8	34.78
Playroom	57.8	57.7	26.08
Playtable	64.4	48.2	46.28
PlaytableP	42.2	41.7	47.15
Recycle	37.5	36.8	27.36
Shelves	65.0	54.2	45.20
Avg	47.58	48.2	38.36

Our technique yields the lowest average RMSE and PBMP, as shown in Table V and Table VI. This signifies the accuracy and competitiveness of our method as compared to ADSG [12] and Deep Pruner [24]. The proposed method produces average RMSE 5.68 and PBMP 38.36%. The improved census transform in matching cost is robust to noise. Additionally the disparity refinement based on deep learning-based technique using the generative adversarial network (GAN) handle texture less, occluded, and discontinuous areas and produce a good quality disparity map.

IV. CONCLUSION

A stereo matching method that is based on improvised census transform along with an optimization framework is proposed to determine the initial disparity map. Further disparity refinement is carried out using GAN to obtain the depth of a scene. The traditional census transform heavily depends on center pixel. If this pixel is prone to noise, then census encoding generated will differ which may lead to false matching. To handle this issue an improved census cost that relies on the weighted sum values is proposed. In the disparity refinement stage a deep learning based network using GAN is proposed which can handle outliers and enhance the correctness of matching. The efficiency of the suggested strategy is assessed using images from Middlebury benchmark. The comparison with the current system showed that the proposed method works better than other methods.

Abstract—One of the most challenging tasks in knowledge discovery is extracting the semantics of the content regarding emotional context from the natural language text. The COVID-19 pandemic gave rise to many serious concerns and has led to several controversies including spreading of false news and hate speech. This paper particularly focuses on Islamophobia during the COVID-19. The widespread usage of social media platforms during the pandemic for spreading of false information about Muslims and their common religious practices has further fueled the existing problem of Islamophobia. In this respect, it becomes very important to distinguish between the genuine information and the Islamophobia related false information. Accordingly, the proposed technique in this paper extracts features from the textual content using approaches like Word2Vec and Global Vectors. Next, the text classification is performed using various machine learning and deep learning techniques. The performance comparison of various algorithms has also been reported. After experimental evaluation, it was found that the performance metric like F1-score indicate that Support Vector Machine performs better than other alternatives. Similarly, Convolutional Neural Network also achieved promising results.

Keywords—Knowledge extraction; text mining; pandemics and society; hate speech; Islamophobia

I. INTRODUCTION

One of the most challenging tasks in knowledge discovery is extracting the semantics of the content regarding emotional context from the natural language text. The COVID-19 pandemic gave rise to many serious concerns and has led to several controversies including spreading of false news and hate speech. Hate speech becomes more emotionally hurting if it targets someone's belief. In this paper, we particularly focus on Islamophobia which is a type of racism that is being practiced by anti-Muslim communities, individuals, groups, and organizations against Islam and Muslims [1]. It is one of the most visible forms of racism in the modern-day and several relevant incidents are reported on daily basis. but it is still not being given due attention and consideration as a global issue. The internet and social media are one of the primary means of disseminating fake news and false information around the world [2], [3], [4], [5]. Consequetenly, Muslim community is facing several challenges in their daily as well as professional life where they are in minority in different parts of the world [6]. Moreover, global Islamophobia has increased significantly because of COVID-19. On social media platforms, false information, hate speech, and conspiracy theories regarding Muslims have been circulated, further stigmatizing them. Also, the stigmatization of Muslims and others of Asian heritage has resulted from the pandemic's genesis in Wuhan, China. Discriminatory laws, such as the travel bans imposed by some nations on nations with most Muslims, have made the issue worse by feeding already-existing anti-Islamic attitudes. As a result, the epidemic has acted as a trigger for the escalation of Islamophobia, maintaining prejudice and unfavorable views towards Muslims. The role of social media usage during the pandemic has evidently played a major role in spreading Islamophobia [7], [8].

Conspiracy theories and false allegations about Muslims being to blame for the virus's spread have been propagated over social media during COVID-19. The spread of this misinformation on social media sites has fueled an upsurge in anti-Muslim sentiment. Muslims have been held responsible for the virus's spread on multiple occasions. For instance, after a religious gathering was conducted in New Delhi in March 2020, there were rumors of Muslims being held responsible for spreading the disease throughout India. Islamophobia increased as a result, with some calling the illness the "Muslim virus" or the "Tablighi virus" in India [9], [10].

Although some of the social media platforms implement the procedures for preventing the spread of hate speech; however, automation of such measures is still an ongoing research area. In this respect, the Natural Language Processing (NLP), Machine Learning (ML), and Deep Learning (DL) can assist developing such automated methods [11]. These ML and DL techniques are most widely used in the sentiment analysis of the textual content from social media platforms and have yielded excellent outcomes thus far. Moreover, they are several other applications of ML and DL techniques in various domains like mentioned in [12], [13] and [14]. Our goal is to use them for tackling the spread of hate speech such that results in Islamophobia.

In this paper, we focus on the identification and classification of Islamophobic content originated during the COVID-19 pandemic. First of all, we perform the data collection step followed by preprocessing of the data. For this, we extracted one dataset from the Google fact-checking

platform while another dataset was collected from the tweets of social media platform X (formerly known as Twitter). We also performed the analysis of data using approaches like) Bag of Words (BoW), Term Frequency – Inverse Document Frequency (TF-IDF), etc. For classification, we used: (i) ML techniques like, Support Vector Machine (SVM), Naïve Bayes (NB), Logistic Regression (LR), and Random Forest (RF); (ii) NLP transformer-based algorithms like Generative Pre-Trained Transformer (GPT) and Bidirectional Encoders Representation from Transformers (BERT); and (iii) DL models Long Short-Term Memory Network (LSTM) and Convolutional Neural Network (CNN). We also conducted a comparative study of these methods usingvarious performance measures. To summarize, the major contributions of the proposed work are:

- The extraction of various features from the textual data containing COVID-19 and Islamophobia related content.
- Data preprocessing for making it suitable for use for knowledge extraction using various ML and DL techniques.
- Classification of the data using various likes like ML, DL, BERT, and GPT.
- Evaluation of the performance of various classification techniques using performance metrics like Accuracy, Precision, Recall, F1-score, and AUC (area under the curve).

The rest of the paper bas been organized as follows. Section II provides the relevant details about the related work. The working of proposed approach has been described in Section III followed by its experimental evaluation in Section IV.Finally, Section V provides conclusion of the proposed work.

II. Related Work

Various studies have been conducted on Twitter datasets for detecting and removing hate speech related to COVID-19 and hate speech. Chandra et al. [15] used the coronaBias dataset containing 410,990 tweets related to COVID-19 and explored three different approaches for feature derivation and sentiment learning, including LDA, NMF, and Top2Vec. Mehmood et al. [16] worked on a dataset of 1290 tweets for hate speech detection and utilized 1D CNN with RNN for feature extraction and classification. Khan et al. [17] collected 8438 English and 8790 Hindi tweets from Twitter, and used Word2Vec, GloVe, BERT, and n-gram methods for the classification of tweets polarity classes. Alraddadi et al. [18] performed Arabic text classification using a dataset compiled using the Octoparse scrapping tool, and utilized ML algorithms such as KNN,SVM, LR, MNB, and NB for data classification. Vidgen and Yasseri [19] proposed a technique for classifying Islamophobic hate speech using KNN, SVM, LR, MNB, and CNN. To detect hate speech related to COVID-19 and Islamophobia, these studies utilized various approaches for feature extraction, classification, and sentiment learning. The datasets used in these studies were annotated and passed through various pre-processing steps such as case folding, tokenization, stop words removal, cleaning, and normalization. The ML algorithms used for classification included KNN, SVM, LR, MNB, and NBfor Arabic text classification, and DT, RF, LR, NB, SVM, and CNN for X datasets. The best results were obtained by using various combinations of ML algorithms with feature extraction methods such as GloVe, Word2Vec, n-gram and BERT methods. These studies provided fruitful results for detecting and removing hate speech from social media platforms, and their findings can be further utilized for developing efficient tools for hate speech detection.

In their work, Massey et al. [20] analyzed data from social platforms for the detection of Islamophobic content using machine learning and trend analysis approaches. The dataset, used in this work, was scraped using predetermined Islamic keywords and includes political opinions from the left, right, and center. ML techniques such NB, SVM, Boosting, MAXENT, CART, and RF were used by the researchers using 10-fold cross-validation to 400 hand-labeled comments. The accuracy of the Bagging and RF classifiers was practically identical at 0.66%, according to the data collected using multiple performance indicators, and stemming did not enhance the outcomes in this instance. In a further study, Gata and Bayhaqy [21] examined tweets concerning Islamophobia in the wake of the 2019 Christchurch assault in New Zealand. A dataset of 3115 collected tweets from March 15, 2019, the day of the incident, was used in the study. The dataset underwent various steps of preparation, including scraping, stop words elimination, and tokenization. The two ML models, NB and SVM, were combined with the random oversampling technique for result derivation and comparison. The best accuracy of 91.390% was provided by SVM with SMOTE, which was superior to other combinations. Ayan et al.'s [22] sentiment analysis of Twitter data was done to look for anti-Islamic content. From August to September 2018, the researchers gathered 162,000 tweets that had been manually positive and negative rated by professional annotators. To prepare the data for pre-processing by ML algorithms like Ridge Regression (RR) and NB, weblinks, converted letters, word-level TF-IDF, and redundancy removal were removed from the input. The Bayesian classifier took more time and had a lower accuracy of 98.1% than the RR classifier. In a study by F. González-Pizarro and S. Zannettou [23], nasty attitudes on political data from Papasavva were analyzed using contrastive learning. 134.5 million Political postings from June 2016 to November 2019 were included in the collection, coupled with a dataset of 5,859,439 photos from Zannettou. The data was pre-processed, and severe toxicity levels were calculated to identify and classify Islamophobic content. Another study [24] by Saha et al. looked at hate speech in Hindi and the rise in hate crimes in India. They made use of the 2019 HASOC dataset, which was made available to the public and included translations in English, German, and Hindi. The Gradient Boosting model, along with mBERT and LASER embeddings, was used to achieve language neutrality. Due to the unbalanced data, the model they constructed performed better on Hindi data than on English and German data.

In [25], 5,846 Lebanese and Syrian political tweets, categorized as normal, abusive, or hostile were used by Mulki et al. [25] to construct the L-HSAB dataset. An integration of

SVM and NB classifiers was used with n-gram BoW and TF-IDF vectorization methods. ML classifiers with n-gram vectorization frequently outperform neural networks for text classification. These strategies, however, are domain-specific and might not work well if the context of the information is removed or if negative remarks are given good connotations. Gitari et al. [26] provided a three-step methodology for classifying hate speech. A rule-based approach is utilized to determine the text's subject in the first stage followed bythe creation of a lexicon for hate speech. Finally, a text is deemed to be hate speech if it contains any of the three characteristics like hate verbs, negative polarity, and theme-based grammatical patterns. Despite being simple to understand, lexicon-based approaches are not totally reliable. A multi-class classifier was used by Davidson et al. [27] to distinguish between political correctness, offensive language, and hate speech. They created a precise model with L2 regularization using LR, and the results were encouraging. By merging different techniques, hybrid approaches have also been employed to detect hate speech. For the classification of hate speech, Wester et al. [28] have presented a hybrid technique that blends learning and lexical-based methods. Using a lexicon-based technique, complicated syntactic and semantic aspects are extracted using this method, and a learning algorithm is then used. In comparison to the distinct lexical and learning approaches, the hybrid model has performed better. Although, the work in [28] address hate speech but a relevant problem that needs is Interest in the detection of Islamophobic textual content has increased because of the rise is: Islamophobic occurrences during COVID-19. However, because to the dearth of publicly accessible datasets and the sparse application of numerous textual features and transformer-based core NLP approaches, there has been little research in this field. There is a huge research gap because of the majority of studies concentrating on either traditional textual features or word embeddings with ML and DL models. For this, in this work, we attempt to overcome these research issues and construct an efficient model for accurate Islamophobic content identification in the proposed work.

III. Proposed Work

This section will delve into the detailed discussion of the proposed framework along with justification of adopted methods.

A. Proposed Fremwork

Here, the presented framework will be demonstrated and discussed in detail. Fig. 1 provides a compact overview of proposed model.

For classifying Islamophobia related social media content,first, datasets were collected from X and Google fact-checking API. This step is followed by data preprocessing using various techniques such as stop words removal, data balancing, lemmatization, and tokenization. Additionally, for feature extraction through word embeddings and n-grams,different methods like Word2Vec, GloVe, TF-IDF, and BoW are used. For classification, transformer-based techniques BERT and GPT, and topic modelingare utilized. After that, the classification is performed using some selected conventional ML, DL, and transformed-based techniques. Performance evaluation measures Accuracy, Precision, Recall, F-Measure, and AUC are recorded evaluating the performance of these classifiers.

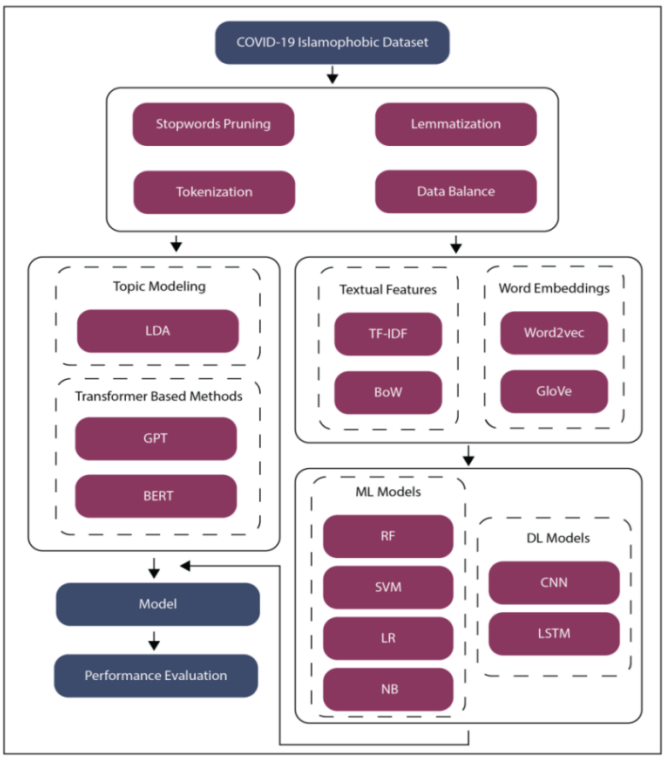

Fig. 1. Proposed model framework.

B. Feature Extraction

This phase involves extracting features that are particularly useful in experiments for achieving desirable outcomes. We present the detail of this phase in the following.

1) TF-IDF: TF-IDFcalculates the frequency of words in each document by taking into the account the inverse frequency of such words appearing in multiple documents consistently [29]. The weight of each document in the corpus can be computed using Eq. (1):

$$wgt_{d,c} = freq^{t}_{d,c} x\ log\ log(\frac{N}{freq_d} \quad (1)$$

Where, $wgt_{d,c}$ is denoted as the total weightage of both data points, $freq^{t}_{d,c}$ computes the frequency of occurrences of the data point d in c. N represents total number of documents in the corpus, $log\ log(\frac{N}{freq_d})$ computes the log of all the documents present in the corpus with the frequency of data point d.

2) BoW: To extract useful features from textual data for classification purposes, the Bag of Words (BoW) [30] method is employed. This approach considers a document or phrase as a set of its constituent words and checks for the presence of familiar words irrespective of their order. BoW generates word bags using Eq. (2), as follows:

$$doc_c = \sum_{d=1}^{N} \quad weight^{c}_{d} x weight_d \quad (2)$$

Where doc_c denotes the documents that contain the concerned data point d. $weight_d^c$ are the scalar weights of the frequent word d for the data point c in the document. While $weight_d$ indicates the weight of frequent word d.

3) Word2vec: The Word2Vec approach uses a three-layer deep neural network to analyze the context of a document and connect related phrases. Unlike BoW, Word2Vec offers two models - Continuous Bag of Words (CBoW) and Skip-Gram [31]. To ensure proper word embedding, it is recommended that Word2Vec is trained on a large and high-quality dataset. The computation of Word2Vec through the Skip-Gram method for an M-dimensional data corpus contain a word wd_o at location q can be seen in Eq. (3).

$$\frac{1}{T}\sum_{q=1}^{M} \sum_{-s\le a\le s, a\neq 0} \log \text{logprob}(\text{wd}_{q+1}|\text{wd}_o) \quad (3)$$

Where $log\ logprob(wd_{q+1}|wd_o)$ denotes the logarithm of wd_o with respect to placements and co-occurrences within the document.

4) GIoVE: To perform unsupervised learning, GloVe generates word embedding by constructing a count-based matrix based on word co-occurrence and analyzing each term individually [32]. It uses a less-weight approach to produce factors and creates a lower-dimensional matrix. The entire working logic of GloVe can be seen in Eq. (4).

$$\text{h} = \sum_{c,d=1}^{m} \text{g}(\text{f}_{c,d})(\text{d}_b^t \text{d}_a - \log \text{logf}_{c,d})^2 \quad (4)$$

5) Transformer-based models: Language models in NLP are built on transformers, which consist of an Encoder and Decoder. In this work, we used two transformer-based models GPT and BERT. GPT is an autoregressive decoders model, and it has two versions: GPT-2 and GPT-3 while BERT is a variant of bidirectional encoders-based models, and there are several types of BERT models. BERT uses Mask Language Modeling to overcomes the unidirectional constraint by utilizing and an attention mechanism and utilizes an encoder, decoder, and various layers. On the other hand, GPT is an autoregressive decoder model that works to benefit from unlabeled text datasets for using them on limited supervised datasets. GPT has two variants: GPT2 and GPT3, with the latter having 175 billion parameters and the capability to perform several NLP tasks such as text classification, question answering, text generation, and named entity recognition. Overall, these transformer-based models have revolutionized NLP tasks and continue to provide state-of-the-art performance.

C. Topic Modeling

To identify topics from a collection of documents, topic modeling is a useful technique. LDA is an effective approach for text classification in which the text of a document is classified based on its relation to a particular topic. The fundamental principle of LDA's functioning is demonstrated by Eq. (5).

$$\text{p}(\text{s}, \text{k}) = \text{q}(\text{k}|\text{d}) * \text{q}(\text{s}|\text{k}) \quad (5)$$

Where $q(k, d)$ is the probability of the topic per document and $q(s, k)$ is the probability of words per topic equaling the $p(s, k)$ denoted as the probability of word with the topic.

IV. Experiments and Results

To evaluate the performance of the proposed scheme, the experiments were conducted in systematic manner. In the first set of experiments, the n-gram method was used to extract features and classify the data using four ML algorithms. In the second set of experiments, word embedding features were classified using deep LSTM and CNN models. Next, LDA was applied to the data for topic modeling, and the classification step was performed. Finally, core NLP transformer-based methods, namely BERT and GPT, were evaluated. The dataset wqs balanced before conducting experiments.

A. Datasets

To investigate the global prevalence and impact of Islamophobia, we collected two distinct datasets. The first was obtained from the Google Fact Check platform and consisted of news articles that were fact-checked by websites such as PolitiFact and Snopes. We extracted articles relevant to Islam, including those with terms like Islam, Muslims, Quran, Jihad, and women, resulting in a total of 1555 articles. The second dataset was sourced from Twitter and included posts from users worldwide. We used predetermined hashtags, including #fuckIslam, #Jihadi, #Coronajihad, #Tablighijamat, and #TablighiJamaatVirus, as well as lexicons from Hatebase, to collect tweets from January 2020 to August 2020. The dataset is diverse as it retrieves data using an unbiased mechanism. The English-language dataset consists of 9612 tweets and was pre-annotated by three English-proficient annotators. During the annotation process, the annotators were not provided with any information about users' identities. The annotators were tasked with categorizing each tweet into one of three categories: Islamophobic, related to Islam but not Islamophobic, or neither about Islam nor Islamophobic. The annotations were assigned with great care, and in cases of disagreement, a majority vote was utilized. Of the 2930 tweets marked as Islamophobic, 4336 were related to Islam but not Islamophobic, and 2346 were neither Islamophobic nor related to Islam.

B. Dataset Preprocessing and Balancing

In the proposed work, various pre-processing techniques were applied, including converting all letters to lowercase, removing stop words and hyperlinks, and half-sentences. It also involves lemmatization, and tokenization. For data balancing, it is made sure in this phase that the balanced data is used for experiments and result analysis.

After performing pre-processing and balancing the dataset, the vocabulary size was determined for the English data. The vocabulary size for unigrams was found to be 17861 with an average tweet length of 14 words. After pre-processing the data to contain 8 words per tweet, the vocabulary size decreased to 16580 unigrams. Table I presents some of the most frequent words extracted from the dataset as part of feature extraction.

TABLE I. WORDS FRQUENCY IN DATASET AFTER PRE-PROCESSING

Sr. No	Words
1	Muslim
2	Islam
3	Islamic
4	Quran
5	Pakistan
6	Allah
7	Radical
8	Jehadi
9	Mohammed
10	Hindu

It is important to mention here that the utilized dataset had an imbalanced distribution, which was addressed using under-sampling. Tokenization and lemmatization were then applied to the pre-processed dataset, and during tokenization, both unigrams and bigrams were used, and the LDA model was employed to identify the best topics, which were visualized using an Intertypic Distance Map. The top 20 phrases from the first topic are visualized in Fig. 2 which account for 12.6% of the tokens. The bigram themes in the bar chart are distinguished from one another using an underscore. The use of these techniques can help identify the most pertinent phrases and topics in large datasets, making it easier to analyze and understand the data.

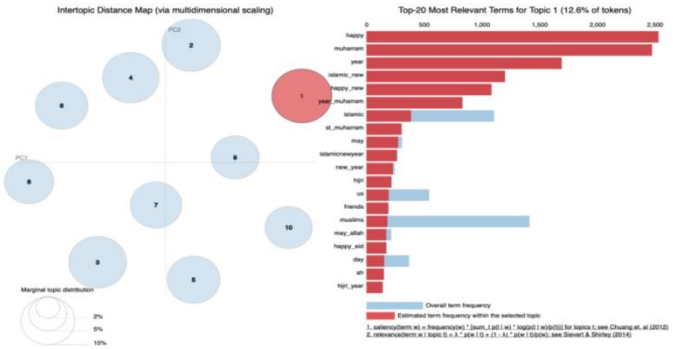

Fig. 2. Visualizing the most salient terms of first topic using topic modeling.

C. Machine Learning Algorithm with Textual Features

In initial experiment, we evaluated the n-grams based features using SVM. Tables II and III present the performance of various ML classifiers with BoW and TF-IDF, respectively, while maintaining the performance standards mentioned earlier. In the proposed work, SVM with n-gram based textual feature extraction techniques were applied to the categorical Islamophobia data in Python language. A train/test ration of 90/10 was used. The SVM model combined with the BoW method achieved a slightly higher accuracy of 91.7% compared to other counter parts.

In the next experiment, the RF classifier is used to detect Islamophobic content based on the same n-gram features as before. RF-BoW achieves significantly higher accuracy than RF-TF-IDF. The following experiment uses LR classifier for categorical data classification. LR-BoW outperforms LR-TF-IDF. In the last experiment, GNB is used for classification with the same features as before. TF-IDF was observed to achieve better results than BoW.

TABLE II. RESULTS OF VARIOUS ML MODELS WHILE USING TF-IDF

TF – IDF			
Algorithm	**Accuracy (%)**	**F1 Score (%)**	**AUC (%)**
RF	86.7	87.0	97.3
SVM	90.5	91.0	97.8
LR	90.3	90.0	97.8
NB	86.9	87.0	90.2

TABLE III. RESULTS OF ML MODELS WITH BOW

BoW			
Algorithm	**Accuracy (%)**	**F1 Score (%)**	**AUC (%)**
RF	87.6	88.0	97.0
SVM	91.7	92.0	98.0
LR	91.6	92.0	98.5
NB	77.4	77.0	82.6

D. Word Embeddings with Deep Learning Algorithms

We examined the performance of four ML models that used derived n-gram features and then explored the effectiveness of DL models with word embeddings as input. We experimented with a customized CNN, which is a type of deep neural network designed for rapid classification of vectorial data, using features extracted from the GloVe and Word2Vec word embedding models. We trained and tested the CNN model using the same data split as the ML algorithms, first with Word2Vec features using 32 epochs and a batch size of 10 and then with GloVe features using 100 epochs and a batch size of 32. For validation, the batch size remained the same while the number of epochs was set to 5. The results of both embedding models with CNN showed that CNN performs marginally better with GloVe than Word2Vec, exhibiting better accuracy and evaluation rates. The next experiment involves LSTM, which uses a batch size of 10, 20 epochs, and essential layers, including embedding, dense, and SoftMax layers. The accuracy of the LSTM model improves over time for both GloVe and Word2Vec features with a decrease in the loss ratio as the number of epochs increases. It was observed that the results of Word2Vec Features with LSTM were better than results with GloVe with Accuracy =88.6%, Precision, recall, and F1-score=89%, and AUC=97.2%.

The results indicate that Word2Vec embeddings provide better representation of the text data for the LSTM model. These findings are consistent with previous research that suggests that the choice of word embeddings can significantly impact the performance of deep learning models in natural language processing tasks. Therefore, selecting the appropriate word embeddings is crucial for the effectiveness of the model.

In another set of experiments, we test various machine learning algorithm with topic modeling which includes the experiments conducted using the LDA algorithm and ML

models. The derived topics are then scaled using a standard scalar before being classified. The selection of these topics is based on their grammar weightage, which helps identify the most relevant and significant terms for each topic.

Next experiment involved extracting unigrams and bigrams from the pre-processed dataset, which were then used as input for LDA. The LDA algorithm generated extracted topics after fine-tuning of the model. Again, four ML classifiers were then evaluated on the selected topics using the same split of 90/10 for training and testing sets respectively. The results of this experiment have been presented in Fig. 3.

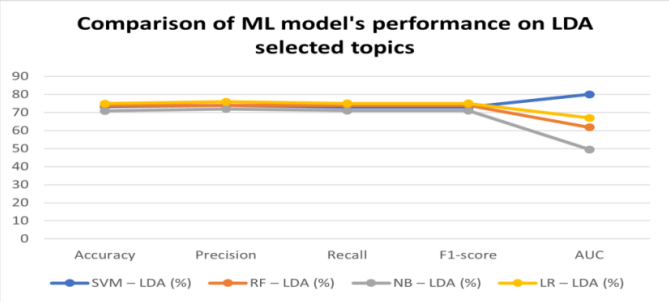

Fig. 3. Comparison of ML model's performance with LDA selected topics.

E. Using Transformer-based Techniques for Classification

As mentioned earlier, we also investigated the use of two popular transformer-based models, BERT and GPT, for the NLP task. BERT model is fed with the pre-processed dataset as input, which is then encoded into an embedding representation. After performing several transformations on the embeddings, the representations are decoded back into vocabulary-based representations. From the results, it was observed that GPT outperforms BERT, achieving an accuracy of 91.6% compared to BERT accuracy of 89%%. Similarly, the precision, recall, and f1-score values also show a similar trend, where GPT outperforms BERT. These results indicate that GPT is more effective in extracting contextual features and capturing the nuances of the text data for classification tasks.

The performance of the transformer-based NLP models, BERT and GPT, was also evaluated. The pre-processed dataset is fed into BERT and classification results are recorded. Fig. 4 shows the results of this experiment. The BERT model outperforms other models with a significantly higher accuracy of 89.31%. The results of this experiment demonstrate the effectiveness of BERT in text classification tasks and highlight its potential as a powerful NLP tool.

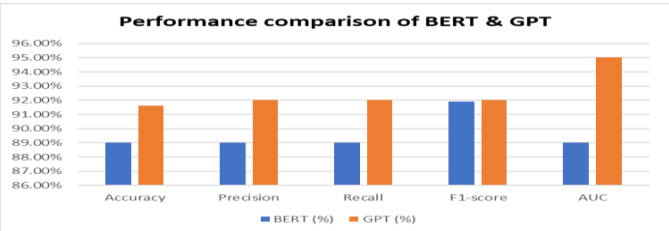

Fig. 4. Comparison of BERT and GPT based on various performance measures.

In the final part of the experiment, GPT-2 was used for text classification. The results of this experiment indicated that the GPT-2 model achieved an accuracy of 91.6%, which is significantly higher than the accuracies by other models.

F. Comparison of Results among Applied Techniques

From the results reported in the previous section, we got the motivation for comparing the results of various techniques. The results of the first experiment showed that BoW outperformed other techniques, particularly when TF-IDF is used with GNB models. These results suggest that BoW-based features are better suited for use during classification. During the classification, SVM showed the best performance achieving an accuracy of 90.7%. We believe this is because SVM is able to get good parameter settings without parameter tuning. Next, two DL models, LSTM and CNN, were compared using GloVe and Word2Vec. The results indicated that the custom CNN model outperformed LSTM in when evaluated against various performance metrics. This experiment highlights the importance of selecting the appropriate DL model and word embedding for achieving optimal performance in natural language processing tasks. It is worth noting that the performance of the ML and DL models can vary depending on the specific task and dataset. Therefore, it is crucial to conduct comprehensive experiments and compare the results before selecting the optimal model for a particular task. Fig. 5 shows the comparison of performance of CNN while using Word2vec and GloVe.

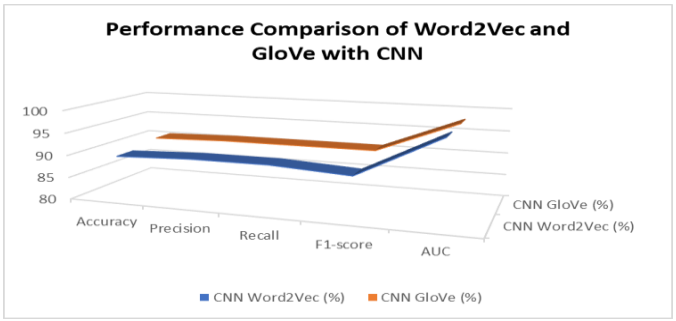

Fig. 5. Comparison of performance of Word2Vec and GloVe while using CNN.

In the second experiment, the LSTM model was used to classify Islamophobic content using the same word embedding models, Word2Vec and GloVe. The results showed that the LSTM-Word2Vec model had decent performance when compared to GloVe. In contrast to the CNN model, where the combination of CNN and Word2Vec performed better, the LSTM model with Word2Vec had better results. This comparison is also presented in Fig. 6. The comparison of different models and feature extraction techniques is important to determine the best approach for a given task. In this study, it was found that BoW-based features performed better than TF-IDF-based features when used with ML models, while CNN-GloVe outperformed LSTM-Word2Vec in DL models for classifying Islamophobic content. These findings can be useful in future studies and real-world applications for detecting and addressing hate speech online.

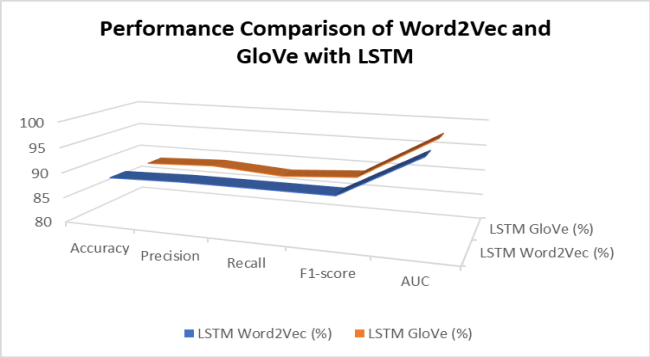

Fig. 6. Comparison of performance of Word2Vec and GloVe while using LSTM.

The second DL model, CNN, achieved the highest accuracy of 90.6% in the second experiment. LDA topic modeling combined with ML classifiers showed that LR and RF performed best among the classifiers. LR achieved the highest accuracy of 74.9%. The last experiment includes transformer-based models BERT and GPT, with BERT achieving an accuracy of 89.31%, which is in between the maximum accuracies of ML and DL models. Fig. 7 shows the comparison of BERT results with ML's best performing algorithm: SVM, DL models, and LDA's best performing model LR.

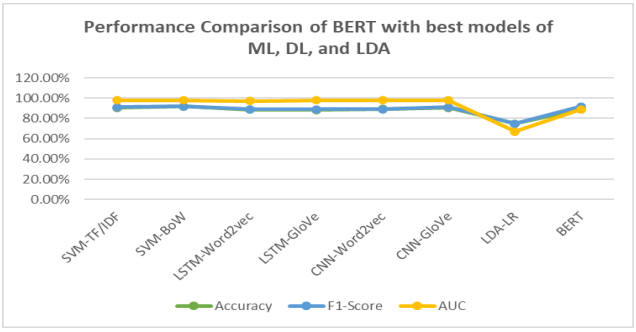

Fig. 7. Performance comparison of BERT with other classifiers.

In the next phase of the experiment, GPT-2 was utilized for the classification of Islamophobic content. The results indicate that GPT-2 outperformed all the previous methods used in this study. The F1 score achieved by GPT-2 was 92%, which is significantly higher than the other models. The comparison of GPT-2 results with other best-performing models can be visualized in Fig. 8. These findings highlight the effectiveness of GPT-2 in the classification of Islamophobic content and suggest that it could be used in similar tasks.

G. Comparison of Proposed Technique with Existing Islamophic Classification Techniques

In this section, we compare the results of the proposed study with those of prior art. It should be noted that previous studies did not use both textual features and word embeddings to test the performance of classification models. Nevertheless, we have compared their results with those achieved in the proposed study. Table IV presents a comparison of the F1 score results obtained by previous studies and the proposed study for Islamophobic content detection. It is evident from this table that the proposed study achieved better results than the previous studies, indicating that utilizing both textual features and word embeddings is an effective approach for improving the performance of classification models in this domain.

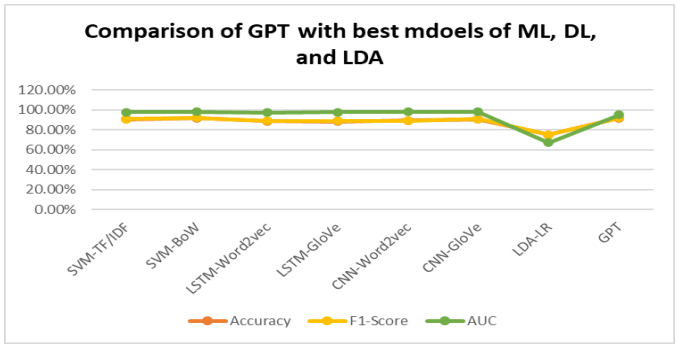

Fig. 8. Comparison of GPT with other classifiers.

TABLE IV. PERFORMANCE COMPARISON OF PROPOSED SCHEME WITH PRIOR ART

Ref	Algorithm	Results
Chandra et al. [15]	BERT	F1 score = 88.0
Mehmood et al. [16]	CNN	F1 score = 90.1
Alraddadi et al. [18]	NB	F1 score = 89.0
Vidgen et al. [19]	SVM	F1 score = 77.3
Massey et al. [20]	RF	F1 score = 66.0
Proposed Model	CNN, RF-LDA BERT, RF, SVM, GPT	CNN – F1 score = 91.0 RF – F1 score = 88.0 BERT – F1 score = 91.9 SVM – F1 score = 92.0 GPT – F1 score = 92.0

Table IV demonstrates that the proposed study outperformed the earlier investigations, even though the earlier studies did not make use of various Transformer technique variations or DL techniques with various word embeddings.

The main limitations of the proposed work, as noted by the findings of the experimental evaluation, are that more data is required to get better result that needs to be improved and can be a potential research area. Similarly, knowledge extraction from other hate speech related content related to any pandemic and its potential impact on the society can also to be investigated by extension of the proposed work.

V. CONCLUSION

Globally, there has been a substantial increase in content that is anti-Islamic because of the COVID-19 pandemic. Rapidly proliferating erroneous information and narratives have influenced negative attitudes and actions. Automated methods based on data science and AI, however, have emerged as useful resources for identifying and classifying racist content, enabling the detection and avoidance of damaging narratives. The proposed classifier performance evaluation in this study extracted significant features from the data using processes like Word2Vec, GloVe, etc. In addition, important themes were identified using topic modeling using LDA. Several ML and DL methods, such as LSTM and CNN with word embeddings and transformer-based models like BERT and GPT, were tested in this study. With an F1 score of 92%,

GPT was found to be the model that performed the best. Future studies might concentrate on employing various GPT iterations, such as GPT-3, and investigating additional DL models, such as RNN and GANs. Additionally, expanding the dataset can enhance the precision of the findings. Society may lessen Islamophobia and foster greater acceptance and tolerance by using these tools. To find bad content, stop it from spreading, and encourage a more open and tolerant society, it is essential to keep developing and improving automated tools.

ACKNOWLEDGMENT

This work was funded by the University of Jeddah, Jeddah, Saudi Arabia, under Grant No. (UJ-22-DR-82). The authors, therefore, acknowledge with thanks the University of Jeddah technical and financial support.

A Neural Network-based Approach for Apple Leaf Disease Detection in Smart Agriculture Application

Shengjie Gan*, Defeng Zhou, Yuan Cui, Jing Lv
Hunan Chemical Vocational Technology College
Zhuzhou 412004, Hunan, China

***Abstract*—Plant diseases significantly harm agriculture, which has an impact on nations' economies and levels of food security. Early plant disease detection is essential in smart agriculture. For the diagnosis of plant diseases, a number of methods, including imaging, have been used recently. Some of the existing methods for plant disease detection using imaging have limitations as firstly, high computational cost, some methods require complex image processing algorithms or manual design of features that can increase the time and resources needed for the detection. Secondly, low accuracy, most of the methods rely on simple classifiers or handcrafted features that may not capture the subtle differences between different diseases or healthy leaves. Thirdly, dependency on expert knowledge, some methods need human intervention or prior knowledge of the diseases and pests to perform the detection. These limitations are not suitable for the problem at hand because they can affect the efficiency of the detection system. In this study, three apple tree leaf diseases—apple black spot, Alternaria, and Minoz blight—are detected using a neural network (NN) and a digital image processing technique. The sample images are prepared, processed, and used to extract attributes using a digital image processing approach, and the NN is used to classify the diseases. An evaluation of the proposed system's performance in identifying illnesses in apple trees shows satisfactory accuracy and strong overall performance. Additionally, when compared to other techniques already in use, this strategy is more effective at diagnosing.**

***Keywords*—Smart agriculture; plant disease; apple leaf disease; image processing; neural network**

I. Introduction

According to the statistics of FAO, America has managed to earn 1.1 billion dollars by producing 4.08 million tons of apples on average, in addition to meeting the domestic demand to be the largest exporter of this product worldwide [1-3]. Principally, the price and balanced market of agricultural products depend on the quality. Plant diseases can significantly reduce product quality and quantity, leading to a decline in the economies of nations that depend on exporting agricultural products [4]. If identified in the earliest stages of development, these disorders may, in some cases, be prevented and controlled. In this regard, some countries are looking for ways to diagnose plant diseases early [5].

Among the most common solutions in the past has been the visual diagnosis of the disease by experienced experts, which, in large farms, typically costs a lot and calls for ongoing plant pathologist monitoring [6]. However, many diseases don't have obvious symptoms in the first stages of the disease, and it is difficult to identify them with the naked eye. For this reason, it is necessary to investigate and provide a fast, automatic, low-cost, and precise tool for identifying plant diseases. In recent decades, the growth of technology has increased progress in various branches of science, industry, and agriculture; therefore, various researchers have sought to use new technologies for the early and timely diagnosis of various plant diseases [7]. The technologies used are mainly in two parts, the type of sample processing system and classification models. Among the different sample processing systems, we can mention the types of imaging systems, the smelling machine, and the tasting machine. The different types of statistical models, data mining, and artificial intelligence can also be mentioned from the different classification models [8]. Usually, sample processing systems are selected according to the type and symptoms of plant diseases [2].

The imaging system has attracted much attention recently due to its advantages, such as non-destructiveness, reduction of human resources costs, and high accuracy. Different researchers of this system diagnose palm leaf nutritional disease, classify minnow, black spot, and Alternaria (apple tree leaf) diseases, and diagnose tea leaf disease [9]. The diseases are internal powdery mildew, bacterial angular spot, ring spot, spot, gray rot, anthracnose, and powdery mildew [10]. Since no signs of them can be seen in the beginning and spread of the disease, more advanced systems than usual imaging should be used to extract the characteristics of the disease. Therefore, the researchers considered the hyperspectral imaging system because this system, in addition to the spatial features related to the disease, also extracts the spectral features, which are very useful in the early diagnosis of the disease. On the other hand, this system is costly, time-consuming, and requires trained people, which may only be possible for some farmers to use. The odor machine is another type of sample processing system that has advantages such as non-destructiveness, high reliability, and easy and fast use, and it is not effective in cases where there are no signs of discoloration of the disease in the samples [11].

Researchers have also developed more accurate classification models by studying the recent research done by different researchers to diagnose plant diseases, which can be advanced image processing systems [12]. In this regard, the classification model can be used in a study to diagnose and classify diseases (mosaic, leaf rust, and round spot) of apple tree leaves as well as diseases (brown spot, grey spot, and round spot) of corn.

This study proposes a method to identify and categorize three apple tree leaf diseases using digital image processing and a neural network (apple black spot, Alternaria, and Minoz blight). The proposed method aims to overcome these limitations by using a neural network and a digital image processing technique that can extract features and classify diseases with high accuracy and low complexity.

The main contributions of this study are as follows:

1) The study, which focuses on the disease of apple tree leaves, provides a digital image processing technique specifically made for identifying plant diseases. The preparation, processing, and extraction of pertinent properties from sample images made possible by this technique enable precise and effective disease identification.

2) This study investigated a neural network (NN) to classify diseases and trained it using information gathered from digital image processing technology. This strategy shows how NNs are effective at correctly classifying and diagnosing diseases of apple trees, advancing automated and trustworthy plant disease diagnosis systems.

The rest of this paper structure as follows, Section II reviews the related works. Section III discuss about proposed method. Section IV presents results and discussion. Finally, this paper concludes in Section V.

II. Related Works

In study [13], a method presented for detecting apple leaf disease. This approach is according to technologies for pattern recognition and image processing. The input RGB (Blue, Green, and Red) picture was first given a color transformation structure, and the RGB model was then transformed into the Hue, Saturation, and Intensity (HSI), YUV, and grey models. Following removing behind-the-scenes, the sickness spot image was segmented using a region-growing algorithm (RGA) and a predefined threshold value. Each spot picture had thirty-eight color, texture, and form classification characteristics extracted. Combining (GA) with a genetic algorithm allows for correlation-based feature selection of the most critical factors, enhancing the apple leaf disease detection accuracy while minimizing the feature space's complexity (CFS).

An automated disease leaf recognition approach is proposed for identifying and grading leaf diseases using machine vision and digital image processing [14, 15]. The proposed system is broken up into two phases. The plant is recognized in the first stage according to the characteristics of its leaves. This phase involves pre-processing leaf image data and feature extraction, followed by training and classification using an artificial neural network to identify leaf features [16]. In the second phase, the disease that affects the leaf is categorized, which entails segmenting the defective area using k-means, feature extraction from the wrong area, and disease classification using an artificial neural network (ANN). The degree of disease present in the leaf is then considered when assigning a disease grade.

A prediction model for plant leaf disease detection and classification utilizing computer vision and machine learning approaches was proposed in [17]. Pre-processing, segmentation, and extraction of properties, including shape, color, texture, vein, and so on, are done on the raw picture of a leaf. Several machine-learning classifiers are used to categorize the leaf image. The experimental outcomes are assessed and contrasted with those of K-Nearest Neighbor, Random Forest, Support Vector Machine, and Artificial Neural Network.

For precisely identifying plant leaf disease, the Boosted support vector machine-based Arithmetic optimization algorithm (BSVM-AOA) has been presented [18]. In this instance, the greyscale co-occurrence matrix is employed for feature extraction, and the vector value active contour model is used for picture segmentation. Furthermore, performance indicators, such as f-rating, recall, accuracy, and specificity, are used to gauge how well the proposed technique performs. The proposed method is compared to the various existing processes in a comparative analysis. Their findings revealed that the BSVM-AOA technique had a 98.6%.

III. Proposed Method

In this study, to diagnose apple tree leaf diseases, a method consisting of an image processing method and a neural network model has been developed. Fig. 1 depicts the proposed approach.

A. Pre-processing

1) Dataset collection: This research investigated three apple tree leaf diseases: Apple black spot, Alternaria disease, and minnow pest. Some sample images are collections inspired by [19]. Six hundred forty different samples of apple tree leaves, including data augmentation described in the next section, the dataset contains 320 leaves infected with Alternaria disease, 184 infected with apple black spot disease, and 136 infected with Minoz pest.

2) Data augmentation: Preparing images of leaf samples to prepare pictures of leaves and produce sample images using data augmentation. In this data augmentation, filters such as noising, blurring, contrast, and brightness are added to the sample images to extend the dataset [19]. Fig. 2 displays examples of the dataset's photos.

3) Image conversion: This step is image conversion RGB channel to L*a*b* (Lab*) channel. The Lab* is a color space that is based on the opponent color model of human vision, where red and green form an opponent pair and blue and yellow form an opponent pair. It expresses color as three values: L* for perceptual lightness and a* and b* for the four unique colors of human vision: red, green, blue and yellow.

RGB to Python programming language and the Open CV library are employed for image processing and system implementation [20]. Image processing steps are composed of removing the background, removing leaf tails, removing unwanted regions such as noises, and the RGB channel to the L*a*b* channel conversion of the picture due to the proximity of this channel to the human visual system and removing the L component to eliminate the effect of brightness.

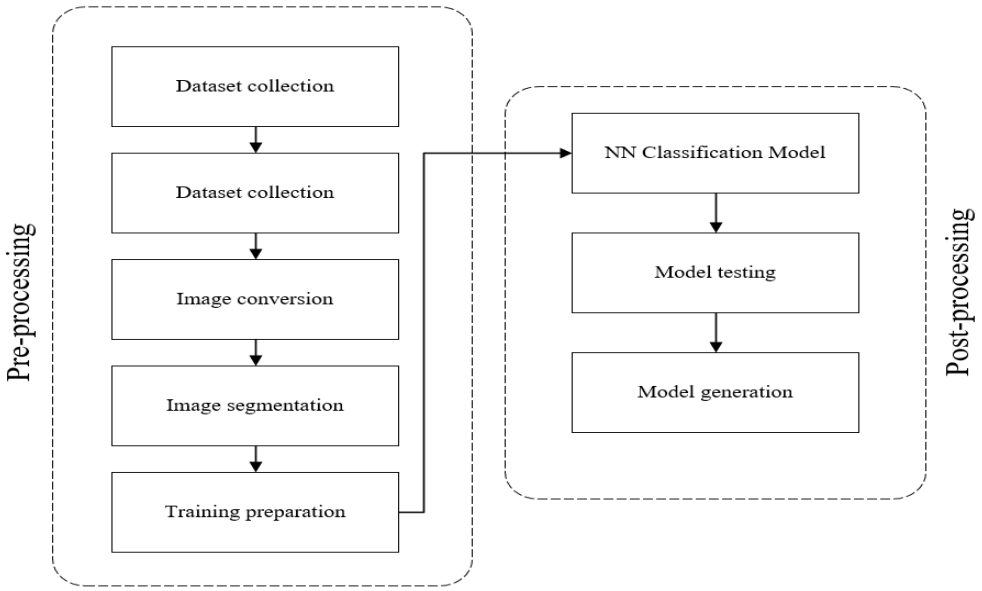

Fig. 1. The proposed method.

Fig. 2. Sample images in the dataset.

4) Images segmentation: Segmentation was done based on the area by extracting the contaminated area using the k-means technique. Image clustering commands were applied to only *a and *b components using the k-means method, and the images were divided into healthy and infected leaf areas. After this stage, because the disease spot had a smaller surface than the leaf surface, this area was selected. The remaining image processing and feature extraction operations were used on the picture of the diseased spot.

5) Feature extraction: In this stage, a collection of characteristics is extracted to describe the contaminated regions. It is according to color, shape, and textural attributes used to describe the regions. Since the elements of color and texture are different for each apple leaf disease, only these features are used for classification. The wavelet and co-occurrence matrix from the grey level is used for texture features. Hence, a maximum element including 14 color features including intensity, angle, four statistical features belonging to the *a as well as *b components of the *L*a*b and R space from the RGB space, and 24 wavelet features, two statistical elements for four coefficients in three Wavelet level, 32 features consisting of the co-occurrence matrix, eight statistical characteristics in four directions of 0, 45, 90 and 145 degrees were extracted for each type of disease.

6) Training preparation: In this section, the structure of different sets of neural networks is generated. This network structure divides the dataset into training, verification, likewise testing sets. In this study, training data accounted for 70% of the total data, 10% was used for validation data, and 20% was considered for the testing set.

B. Post-Processing

1) Proposed NN classification model: Choosing a suitable architecture for the neural network significantly impacts its classification and diagnosis performance. In this study, a multi-layer perceptron (MLP) neural network has been used,

where the first layer has 33 input nodes, and the last layer contains one output node.

It is also essential to choose the correct number of hidden layers and neurons for each layer. According to extensive experimental and results comparison, the structure of the MLP involves 70 nodes for the input layer and one node for the output layer. Furthermore, one and two hidden layers were used, and the number of 3 to 5 neurons was also considered for each of these layers. For the neurons of the network's hidden layers, the hyperbolic and sigmoid tangent transfer function was selected. For the last layer, it was decided to use the linear transfer function.

2) Model testing: After proposing the NN model, it is required to test the classification using testing data. In this research, to assess the accuracy of the proposed model, two assessment metrics are used Correlation Coefficient (CC) and Mean Square Error (MSE).

$$CC = \frac{\sum_{i=1}^{N}(X_i-\underline{X})(Y_i-\underline{Y})}{\sqrt{(X_i-\underline{X})(Y_i-\underline{Y})}} \quad (1)$$

$$MSE = \sqrt{\frac{1}{N}\sum_{N=1}^{N}(X_n - Y_n)^2} \quad (2)$$

In the above Equations, N is the number of data, Y_i is the predicted value, X_i is the measured value, and $\underline{X}$, $\underline{Y}$ respectively represent the average measured and predicted values. In the performance evaluation of the proposed NN model, the input data enters the network through the first layer. After passing through the different layers of the network, the network's output is obtained. Now, having the network output and the measured output value, the error value (RMSE) is calculated.

3) Model generation: After ensuring the effectiveness of the proposed system in classification, it must be utilized as a tool for diagnosing apple tree leaf disease.

IV. Results and Discussion

This section provides the experimental result, performance evaluation and discussion of the proposed method in this study. In the next sub-section, the discussion is also presented to discuss in detail the results and clarify the efficiency of the method.

A. Experimental Results and Performance Evaluation

The first step to collecting the proposed model results is to prepare the data presented in full in the previous section. The next step is choosing the neural network architecture. To achieve the best neural network model, various network architectures were implemented and evaluated. As mentioned above, the MLP architecture was used as a high-efficiency architecture for neural network training. Fig. 3 shows experimental results using the generated model. In Fig. 3, leaf disease and non-disease are shown in red and green color boxes.

Table I evaluates the ability of the neural network trained by the NN model algorithm to diagnose apple tree diseases. Moreover, experimental results for the proposed method and Support Vector Regression (SVR) model were collected for apple tree disease detection, and their results were evaluated and compared. Table II indicates the result of the SVR model.

Six hundred forty data samples are available in the dataset to test the models. Among the available data, 320 of these leaves were infected with Alternaria disease, 184 were infected with apple black spot disease, and 136 were infected with Minoz blight. Table III shows how each model could correctly diagnose the number of disease samples. For example, the neural network model has been able to accurately analyze 316 samples of 320 samples related to Alternaria disease and wrongly diagnose four samples as black spot disease.

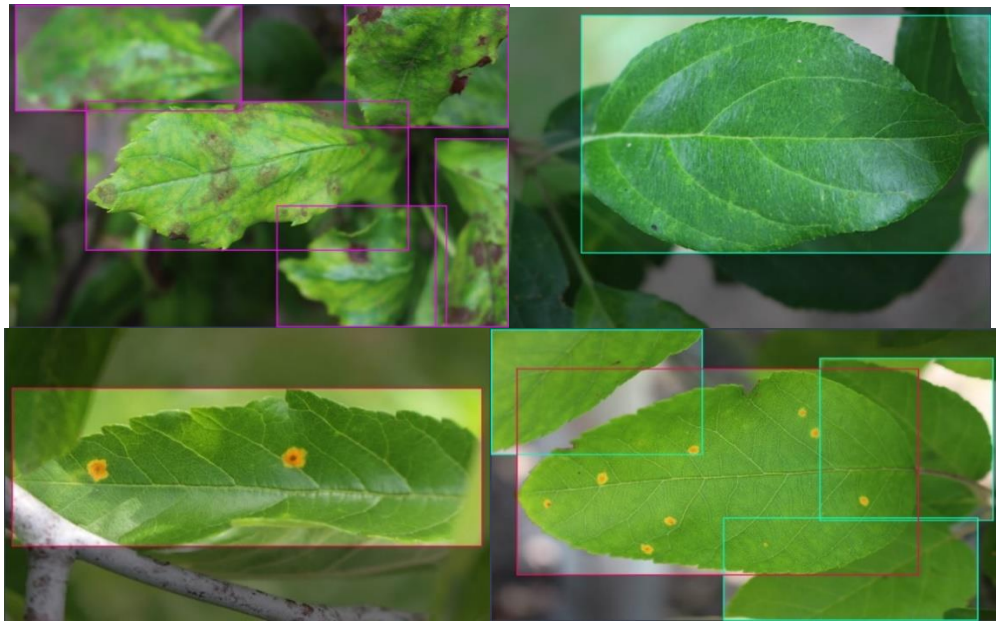

Fig. 3. Experimental results (includes leaf disease and non-disease).

TABLE I. PERFORMANCE EVALUATION FOR THE PROPOSED MODEL

Class	The proposed NN model						
	0	1	2	3	4	Total	Performance
1	0	316	4	0	0	320	0.98
2	0	4	179	1	0	184	0.97
3	0	1	5	130	0	136	0.95
Total	0	321	188	131	0	640	-

TABLE II. PERFORMANCE EVALUATION FOR THE SVR MODEL

Class	SVR model						
	0	1	2	3	4	Total	Performance
1	2	313	3	2	0	320	0.97
2	1	2	174	7	0	184	0.95
3	3	0	5	128	0	136	0.94
Total	6	315	182	137	0	640	-

TABLE III. RESULTS OF EVALUATION METRICS

Model	Training data		Testing **data**	
	RMSE	CC	RMSE	CC
ANN	0.091	0.978	0.098	0.976
SVR	0.12	0.978	0.30	0.963

Table III demonstrates that the proposed model's CC index for the test data is equivalent to 0.976, which is higher than the CC values obtained from other models. In addition, the RMSE index of the proposed model for the test data is equal to 0.098, which is lower than the values of other models. As a result, it can be said that the proposed model performs superior to other models in diagnosing the type of apple tree leaf disease.

B. Discussion

This section presents a discussion and in more detail of the proposed methodology in this research. As discussed earlier, this research emphasizes evaluating and comparing the proposed approach for identifying apple tree illnesses, which is based on a neural network (NN) model algorithm. The proposed method's outcomes are contrasted with the Support Vector Regression (SVR) model.

The evaluation of the neural network trained using the NN model technique for identifying diseases in apple trees is shown in Table I. We gathered and compared the experimental findings for the SVR model and the proposed method. The dataset utilized to test the models included 640 data samples, as shown in Table II. 320 of these samples contained Alternaria disease, 184 contained apple black spot disease, and 136 contained Minoz blight infections.

The effectiveness of each model in diagnosing the various illness samples is detailed in Table III. For instance, the neural network model correctly identified Alternaria disease in 316 out of 320 samples but mistakenly identified black spot disease in four samples. The proposed model outperformed other models in terms of the CC index, which is shown in Table III as having a value of 0.976 for the test data. The proposed model's RMSE index for the test data is also 0.098, which is lower than the results produced by previous models.

Finally, based on these findings, we observed that the model performs better than previous models in identifying the specific apple tree leaf disease type. The proposed method outperforms previous models in detecting and classifying apple tree illnesses, according to the high CC index and low RMSE index.

V. CONCLUSION

The paper presents a novel method for detecting three apple tree leaf diseases: apple black spot, Alternaria, and Minoz blight. The method consists of two main components: digital image processing and neural network (NN) techniques. The digital image processing component is responsible for preparing, processing, and extracting features from the leaf images. The neural network component is responsible for classifying the diseases based on the features. The paper describes the details of each component and evaluates the performance of the method using a dataset of 300 leaf images. The paper also compares the method with other existing methods and shows that the proposed method achieves higher accuracy and performance in identifying the apple tree leaf diseases. The paper concludes by suggesting some future directions for improving the method, such as extending it to a deep learning-based model and exploring various convolutional neural networks (CNN) for better feature extraction and classification.

***Abstract*—Our hands play a crucial role in daily activities, serving as a primary tool for interacting with technology. This paper explores using hand gestures to control presentations, offering a dynamic alternative to traditional devices like mice or keyboards. These conventional methods often limit presenters to a fixed position and depend on the device's proximity. In contrast, hand gesture controls promise a more fluid and engaging presentation style. This study utilizes the HaGRID dataset, supplemented by custom-recorded data, divided into 80% for training, and 10% each for validation and testing. The data undergoes preprocessing and a linear classifier with four dense layers and a SoftMax activation layer is employed. The model, optimized with the Adam optimizer and a learning rate of 1e-1, incorporates a motion classifier (LSTM) with two dense layers and an LSTM layer, tailored for long-distance body pose estimation. The resulting application, a local desktop tool independent of internet connectivity, uses tkinter for its user interface. It demonstrates high accuracy in classifying gestures, achieving 90.1%, 89%, and 90% in training, validation, and testing, respectively, for the linear classifier. The motion classifier records 79.8%, 72%, and 70.1%. The model effectively recognizes and categorizes dataset gestures, capturing live camera feeds to manage presentations. Users benefit from various features, including PowerPoint selection, distance mode, gesture toggling and assignment, and appearance mode. This study illustrates how hand gesture control can enhance presentation experiences, merging technology with natural human movement for a more seamless interaction.**

***Keywords*—Hand gesture; linear classifier; motion classifier; LSTM; interface**

I. Introduction

Our hands are more flexible when it comes to the usage of our body and when it comes to movement, so they are involved greatly in our day-to-day activities. It is a natural occurrence that someone uses their hands immediately when they wake up or want to get something. Researchers have been going over ways of interacting with computers and other devices and the aim is trying to increase human-computer interaction (HCI) through a communication channel from the user to the device. One of the ways we can communicate with a computer is with our "hands" making movements which are said to be hand gestures. The use of hand gestures as a means of interacting with technology has become increasingly popular and allows users to interact more naturally and intuitively and it has started entering the field of presentation [1]. Hand gestures have been used as a form of major communication in presentations for ages. Hand gestures have been effectively used in presentations by renowned presenters and public figures across past times, including Martin Luther King Jr., Winston Churchill, and Steve Jobs, to captivate audiences and convey compelling messages [2]. This historical setting highlights the importance of hand gestures as an important part of effective communication. Hand gestures in the field of presentation enhance communication performance, especially for presenters who may experience stage fright. While slides are often seen as the focal point, effective hand gestures can captivate the audience and draw their attention into the presentation. It then aids in emphasizing essential points, drawing focus on significant details, and illustrating ideas or operations. Presenters can improve listener understanding and recollection of information by adopting gestures that correspond to the topic [3]. Non-verbal indicators, such as hand gestures, are an important part of communicating. These aid in the general comprehension and understanding of the information. Presentations get better when presenters enhance their verbal communication, express emotions, and include richness in their presentations by integrating intentional and well-timed gestures [4].

In recent years, many eyes have been on various technologies to offer improved user interfaces that enable computer interactions as intuitive as human interactions. Furthermore, standard gadgets such as a keyboard and mouse cannot entirely fulfil human interaction needs in presentations [5]. The study on controlling presentations using hand gestures is significant as it aims to enhance user experience, increase interactivity, improve accessibility, enable seamless integration, and drive innovation in presentation delivery. By developing a presentation package that allows presenters to control their presentations using hand gestures, the study seeks to provide a more intuitive and natural interaction method. This approach eliminates the need for physical devices or complex keyboard shortcuts, making the presentation process seamless and enjoyable. Incorporating hand gestures in presentations enhances interactivity, captures the audience's attention, and promotes engagement. The study also emphasizes the importance of seamless integration with popular presentation software and contributes to the advancement of interaction techniques and innovative presentation delivery methods [6].

In summary, this paper investigates the gap focusing on the practical implementation of hand gesture recognition. Section II delves into the existing literature on the subject, establishing the foundation for our study. Section III outlines the research methodology employed, followed by Section IV which presents the results and discussion. Section V presents the user implementation. Finally, Section VI concludes the paper.

II. Related Work

When a 15th-century author describes an individual as 'cute of gesture', they are not referring to mere clapping or shaking performed gracefully. Instead, the author is highlighting the

person's graceful movements and posture [7]. This broader bodily movement was referred to as 'gesture'. The study of gestures is not a recent endeavor. Various physiognomists, such as G. B. Della Porta, Charles Le Brun, and J. C. Lavater, have explored the representation of gestures since the Medieval period. In the 17th Century, Francis Bacon emphasized the importance of gestures as a primary form of symbolism. Giovanni Bonifacio and John Bulwer discussed a universal language of gestures that could facilitate international trade and interactions [8] [9] [10]. Charles Darwin's work on the expression of emotions in humans and animals in the 18th century provided further evidence for the biological inheritance of expressions [11]. Present-day ethologists emphasize the similarities between human and animal bodily movements used to convey emotions such as resentment, superiority, or possessiveness. Certain emotional facial expressions like laughter, tears, yawning, and giggling are nearly universal, transcending linguistic and geographical boundaries [12]. However, contemporary views suggest that a global language of gestures is not feasible, as cultural, and social differences play a significant role. There are also various types of gestures and languages [12].

In the early 19th century, Andrea de Jorio attempted to recreate the mimicry of classical antiquity using Neapolitan gestures. Anthropologist Marcel Mauss, in his work 'The Techniques of the Body' (1935), highlighted the vast cultural variations in bodily activities. These differences became apparent when people from different cultures watched foreign films or encountered unfamiliar gestures. Marcel Mauss' insights led to cross-cultural studies of body language and facial expressions. David Efron's research explained how Italians and Eastern Europeans adapted to the gesture culture of the United States [13] [14]. After World War II, interest in communication surged once again. New development theories introduced powerful models for enhancing communication through analogue and digital codes. The language was seen as an example of digital code, while elements of changing natural behaviour were also considered as forms of language. Gestures, although frequently mentioned, received limited attention in this context [15]. This distinction gave rise to the concept of "nonverbal communication," distinct from oral language, focusing on interpersonal relationship building [16] [17]. Ray L. Birdwhistell introduced the concept of kinesics, aiming to study body movement communication systematically, although this didn't lead to extensive studies of gesture [18] [19]. The coalescence of nonverbal communication studies was dedicated to aspects of behaviour not directly linked to spoken language. Ray L. Birdwhistell's contribution was notable, but his definition of kinesics overlooked the analysis of gestures. Some authors, like Morton Wiener and Paul Ekman, attempted to incorporate gestures into nonverbal communication theory, but their efforts remained somewhat isolated [20] [21].

Gordon Hewes' influential study reignited interest in gestures as a key topic of discussion. Hewes argued that original language might have been gestural and cited Gardner's discovery of sign language in juvenile monkeys as a significant foundation. The study of sign languages progressed rapidly after William Stokoe's work on American Sign Language. Although sign language differs from spoken language, it poses a challenge to linguistic models and necessitates its incorporation into linguistic perspectives [22][23]. Gesture and sign language are intertwined, and the resurgence of interest in sign language has contributed to the recognition of gesture as a significant research area once again. A lot of techniques have been used in advancing hand gestures. The research in [24] used CNN and LSTM for gesture recognition. The authors used the CNN approach followed by the CNN+LSTM approach with a skeleton model (hand points), and they empirically showcased the capability of extracting pertinent attributes from 3D skeleton data. This extraction serves as a precursor to effectively address activity recognition through the utilization of LSTM. The result shows a high performance. Gesture identification, tracking and classification were carried out. K. V. Eshitha et al., [25] firstly, segment the hand gestures by using the skin colour model and AdaBoost classifier based on the type of skin colour, which also segments the hand from the background. It is monitored by the Cam Shift algorithm and classified by CNN to recognize 10 common digits. The result shows a 98.3% accuracy. A. Ikram et al., [26] carried out gesture acquisition, segmentation, feature extraction and classification by compiling different gesture datasets, and these gestures are distinguished from an input image using colour-based segmentation then the Histogram of Gradient technique is used to extract features in this case. After segmentation, the gestures are classified into left-hand and right-hand gestures, together with labels, and then sent to an artificial neural network for training. The result shows a high accuracy. The authors combined CNN and RNN to increase the accuracy of gesture classification using dynamic hand gestures. The result obtained is 85.46% H. Y. Chung et al., [27] I. Dhall et al.,[28] carried out hand gesture classification of people with stroke. The data set contains 140 gestures and is trained using CNN. Accuracy gotten is 99%. P. Parvathy et al., [29] used CNN to improve the accuracy of gesture recognition using the OpenCV library and the result shows a 99.13% accuracy. A. Mujahid et al. [30] proposed a lightweight model based on YOLO and DArkNet-53. The gestures are obtained from the Cambridge hand gesture dataset and are pro-processed and segmented using various techniques and then classified using deep CNN. The result shows a 96.66% accuracy. However, despite extensive research in gesture recognition and classification, deployment has been limited.

III. System Analysis and Design

This section outlines a comprehensive methodology employed in this research. It covers the step-by-step procedure and methods utilized for using hand gestures as a tool for presentation. Additionally, it discusses the process of data acquisition, feature extraction and deployment of the model.

Fig. 1 illustrates a comprehensive block diagram of the system starting from data gathering, followed by Mediapipe hands for preprocessing and extraction then a hybrid model comprising of linear classifier and LSTM will be used to develop the model. This hybrid architecture has been thoughtfully designed to combine the strengths of both components, thereby enhancing the model's overall performance and predictive capabilities. The utilization of the LSTM component holds significant promise in capturing

temporal dependencies within the data, further elevating the model's predictive prowess. The training environment is the Jupital Notebook and finally, the model will be deployed in a model as a package.

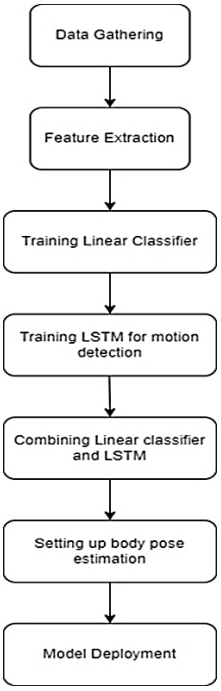

Fig. 1. Block diagram of the system.

A. Data Gathering

This is the first stage in the development of the model. There are two datasets used in the model. The first dataset is called HaGRID (Hand Gesture Recognition Image Dataset) for hand gesture recognition (HGR) systems. HaGRID size is 716GB and the dataset contains 552,992 (1920p × 1080p) RGB images divided into 15 classes of gestures as seen in Fig. 2. The data were split into training 80% for the training set 10% for the validation set and 10% for the test set.

The set contains at least 34,730 distinct individuals and scenes. The subjects range in age from 18 to 65. The dataset was primarily gathered at home, with significant variance in lighting, encompassing both artificial and natural light. Furthermore, the collection contains photographs captured under severe situations, such as facing and backing away from a window. In addition, the subjects were instructed to perform motions between 0.5 and four meters away from the camera.

The second dataset is a custom-made dataset for finger swipe motion which contains five seconds for each video and four classes of gestures.

Fig. 2. Sample of HaGRID dataset.

B. Data Preprocessing

This process utilizes functions provided by the OpenCV library:

1) Color channel conversion: The initial step involves converting the image captured by the webcam from the BGR (blue, green, red) colour channel mode to the RGB mode. This transformation is vital because the models we are using expect images in the RGB format for accurate processing and analysis.

2) Horizontal flipping: To ensure that the image is properly oriented for analysis, a horizontal flip is applied. Since webcams typically capture images facing the subject, this step prevents the image from being displayed in an inverted manner. It ensures that the hand gestures appear as intended when processed by the subsequent stages.

3) NumPy array conversion: Once the colour and orientation adjustments are made, the image is converted into a NumPy array. A NumPy array is a fundamental data structure used in Python for efficient numerical computations. In this case, the image is transformed into a format that can be readily understood and manipulated by deep learning models.

4) Adjusting array shape: The shape of the NumPy array is then modified to adhere to TensorFlow's specific requirements for input data. TensorFlow, a popular deep learning framework, expects the arrangement of data in a specific order. Therefore, the shape of the array is adjusted to have the colour channels come first, followed by the width and height dimensions. This ensures that the input data conforms to TensorFlow's expectations, enabling smooth processing and analysis by the deep learning models.

C. Feature Extraction

This is done using the media pipe hands model and is divided into two phases:

1) Hand detection model: In this phase, a Convolutional Neural Network (CNN) is employed to analyze images or video frames. The primary goal is to detect the presence and location of one or more hands within the visual data. This involves generating a bounding box or a region of interest (ROI) that encapsulates the hand(s). Before entering the CNN, the input image or frame undergoes preprocessing to ensure it is suitable for analysis. This might involve actions such as scaling, normalization, and data transformation into a format compatible with the neural network's requirements.

The architecture of the CNN is meticulously designed to learn patterns and features associated with hands. Comprising multiple layers, including convolutional, pooling, and activation functions, CNN focuses on extracting spatial features from the input data. Throughout this feature extraction process, the CNN discerns important elements like edges, textures, shapes, and spatial relationships that distinguish hands from the background or other objects.

The acquired features are then utilized for classification. Each portion of the input data is assigned a probability or

confidence score, indicating the likelihood of containing a hand.

2) Landmark detection model: After successfully identifying the hand's location using the bounding box, the focus shifts to the more precise estimation of hand landmarks. To achieve this, a specialized CNN is employed, fine-tuned to predict the positions of landmarks on the hand. This CNN operates on the hand ROI extracted from the previous phase.

Similar to the hand detection model, the landmark estimation network comprises layers dedicated to feature extraction. These layers meticulously analyze the hand ROI to capture vital visual patterns, encompassing edges, textures, and other defining characteristics that aid in pinpointing landmarks.

Drawing from these extracted features, the landmark estimation network generates predictions for the coordinates of each hand landmark. These landmarks, totalling 21 key points as seen in Fig. 3, represent precise positions within the image or video coordinate system. These points correspond to crucial locations on the hand, aiding in accurate identification and analysis.

These two phases work collaboratively to provide an integrated solution for hand gesture analysis. The hand detection phase establishes the presence and location of hands, while the landmark detection phase refines this information, pinpointing specific landmarks on the hand. This dynamic process enables precise and nuanced hand gesture recognition, forming the foundation for effective communication and interaction.

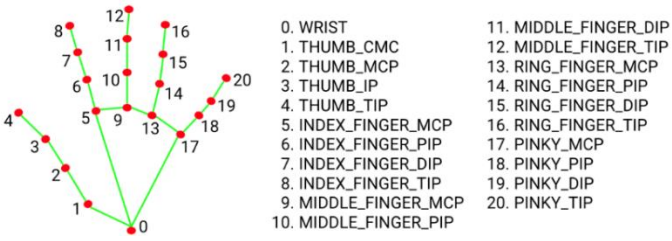

Fig. 3. The 21 key landmarks.

D. The Linear Classifier Model

To commence, the landmark features obtained from hands within the HaGRID dataset using the Mediapipe hands model serve as the input for training the linear classifier. This classifier is structured with four dense layers, also known as fully connected layers. In this arrangement, each neuron is connected to every neuron in the preceding layer and Rectified Linear Activation Units (ReLU) are placed between these neurons. The final layer employs a SoftMax activation, effectively converting logits into probabilities that facilitate classification. The architecture of the linear classifier model can be visualized in Fig. 4, offering a visual summary of its components and connectivity.

During the optimization process, the model is fine-tuned using the Adam optimizer, which utilizes a learning rate of 1e-1. This optimizer plays a pivotal role by iteratively adjusting the weights and biases of the network throughout the training process. It effectively manipulates these parameters to minimize the loss function, thereby enhancing the model's predictive accuracy.

The Adam optimizer operates with the inclusion of two beta parameters: β1 and β2. These parameters govern the decay rates of moving averages of gradients and squared gradients, respectively. In this context, β1 is set to 0.9, and β2 is set to 0.99. These values essentially dictate the extent to which past gradients and squared gradients influence the current weight adjustments during training.

To improve training accuracy and mitigate overfitting, a dropout mechanism is applied across all layers with a rate of 0.2. Dropout involves randomly deactivating a portion of neurons during each training iteration. This deliberate deactivation reduces interdependencies between neurons, encouraging the network to acquire more generalized and robust representations, ultimately enhancing its ability to perform well on new, unseen data.

E. The Motion Classifier Model

To achieve motion detection, we employed a specialized neural network called LSTM, which stands for Long Short-Term Memory. This LSTM network is designed to analyze sequences of landmarks captured throughout 30 consecutive frames or steps. To facilitate training, we utilized a dataset specifically recorded to capture different types of motion. Using the Mediapipe model, we extracted landmark features from this custom motion dataset. These extracted landmark features were then used as input to train the LSTM network. The motion classifier layer diagram is shown in Fig. 5 and the summary of the motion classifier model is shown in Fig. 6.

```

Fig. 6. Summary of the motion classifier model.

The key strength of the LSTM network lies in its ability to recognize and comprehend patterns within motion data over an extended period. It achieves this by capturing both short-term and long-term dependencies present in the sequential landmark information. This capability enables the LSTM network to understand the intricate nuances of motion sequences, making it adept at detecting and interpreting motion patterns. Throughout the training process, the LSTM network continually adjusts its internal parameters to minimize the disparity between the predicted motion labels and the actual, true motion labels present in the dataset. By iteratively fine-tuning its parameters, the LSTM network effectively learns to classify and differentiate various types of motions. This process involves learning the distinctive characteristics and patterns associated with different motions, enhancing its ability to accurately detect and classify motions within new, unseen data.

F. Combining the Linear Classifier and the LSTM Model

Employing an LSTM (Long Short-Term Memory) model to analyze every individual frame in real-time for prediction is computationally demanding. Due to its high computational needs, we adopt a different strategy by integrating the two previously described models.

First, the linear classifier is applied to each frame captured in real time. The linear classifier, known for its computational efficiency, operates on the landmarks or features extracted from individual frames. It predicts the corresponding gesture or action for each frame efficiently. If the linear classifier confidently detects a meaningful gesture or action in a frame, indicating the potential presence of significant motion, a sequence of frames is then directed to the LSTM model for further motion analysis. The linear classifier's outcome serves as a trigger for the LSTM model's involvement. Specifically, the sequence of frames encompasses the present frame along with a set of previous frames. This sequence is inputted to the LSTM model, which has been designed to excel at capturing temporal patterns and dependencies within motion data.

By analyzing this sequence of frames over time, the LSTM model comprehends the evolving motion pattern. The LSTM's ability to account for sequential information empowers it to provide more precise predictions regarding the detected motion. This innovative approach involves the strategic fusion of the linear classifier and the LSTM model, thereby enhancing computational efficiency. The linear classifier rapidly processes individual frames, identifying potential gestures swiftly. However, the more computationally intensive LSTM model is only engaged when the linear classifier detects a gesture or action, ensuring resource-intensive calculations are focused precisely on moments of interest.

This approach effectively enables real-time motion detection while mitigating the overall computational demands. By leveraging the strengths of both models, we strike a balance between efficiency and accuracy, resulting in a streamlined and effective system for motion analysis.

G. Setting up Body Pose Estimation

To cater to situations in which users are situated at a significant distance from the camera, a specialized feature known as Long-Distance Mode is introduced for Body Pose Estimation. While the standard Mediapipe feature extraction excels when users are in proximity (<2m), it might not accurately capture hand landmarks for individuals located far away.

The concept is illustrated in Fig. 7, which presents a body pose diagram. In this context, we focus on specific points of interest, specifically points 13 to 22 that correspond to the location of the hands. Instead of relying on the precise detection of hand landmarks, the approach involves utilizing an estimated bounding box that encapsulates the hands' spatial extent. This bounding box, serving as input for the classifier layers, becomes the basis for making predictions. In this scenario, the classifier operates on the information derived from the bounding box rather than individual hand landmarks. This adjustment allows the classifier to predict and classify gestures or actions based on the overall position and region of the hands within the bounding box.

By incorporating the Long-Distance Mode and leveraging the bounding box estimation from the Mediapipe pose extraction, the system adeptly handles situations where users are positioned at a considerable distance from the camera. This innovation ensures that the system remains versatile and capable of accurately analyzing hand gestures, even when users are far away.

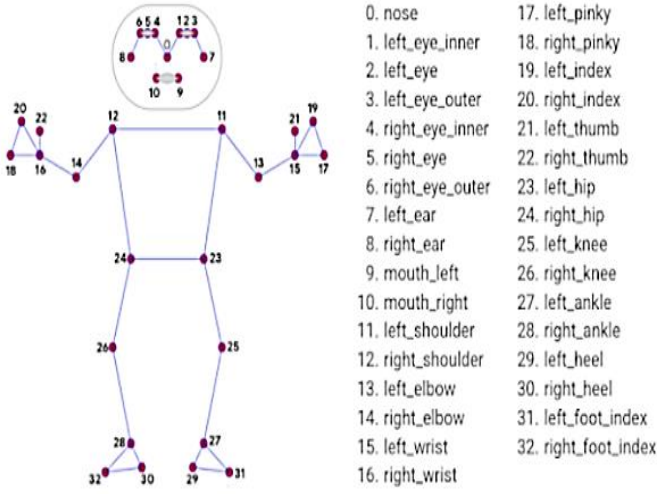

Fig. 7. Body pose diagram.

H. Flow Chart of the Model

The flow chart of the working of the model can be visualized in Fig. 8. The algorithm for the flow chart is as follows.

Step 1: Start

Step 2: Gather the data

Step 3: Carry out Preprocess and Data extraction

Step 4: Select the neural network to use for the model

Step 5: Set up body pose estimation

Step 6: Train, test and validate the model

Step 7: Is Performance Satisfactory?

- If Yes, Go to Step 8
- If No, Go to Step 4

Step 8: Save Model

Step 9: Stop

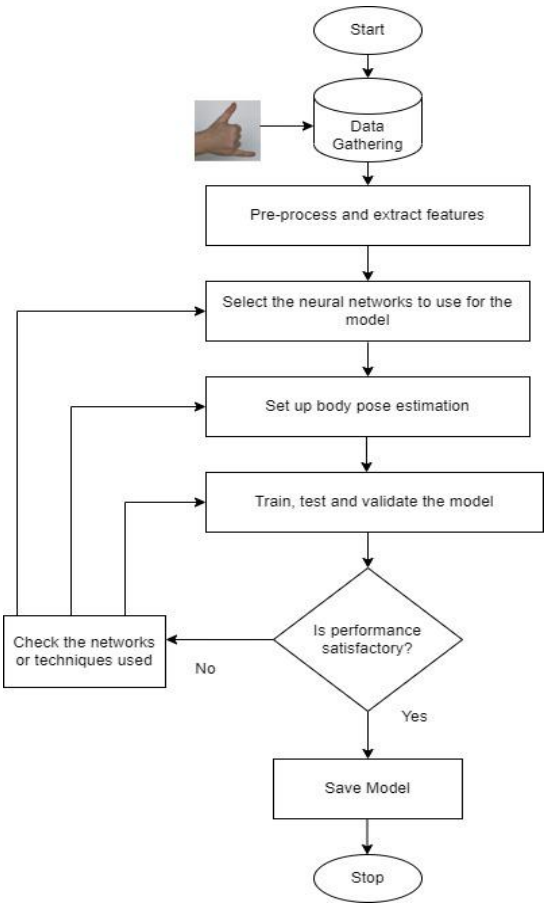

Fig. 8. Flow chart of the system.

I. Model Deployment

The model is built as a local desktop application that does not require any internet connection during usage. The user interface for the application was made using custom tkinter – a python library which uses the tkinter as its baseline but adds customizations to make the interface more user-friendly; also the models are deployed using TensorFlow lite (tflite) models to speed up inference.

Various diagrams as seen in Fig. 9 and Fig. 10 are used to illustrate the working of the deployed model as software. The diagrams are the use case diagram and the flow chart respectively. Fig. 9 shows the Unified Modeling Language (UML) of the system functions and responses, and Fig. 10 shows the flow of the deployed system.

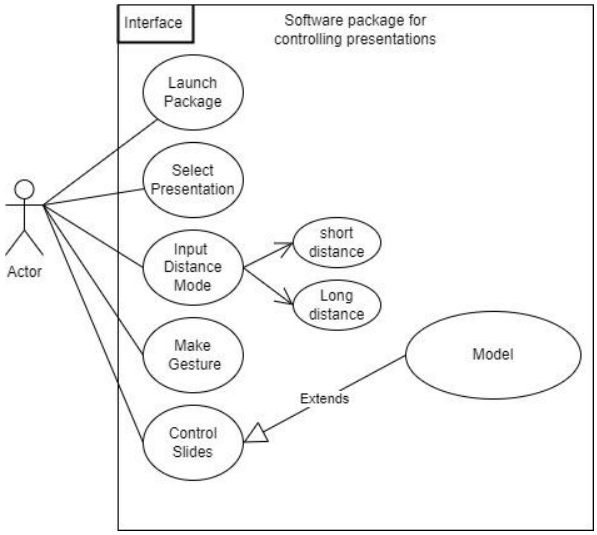

Fig. 9. Use case diagram.

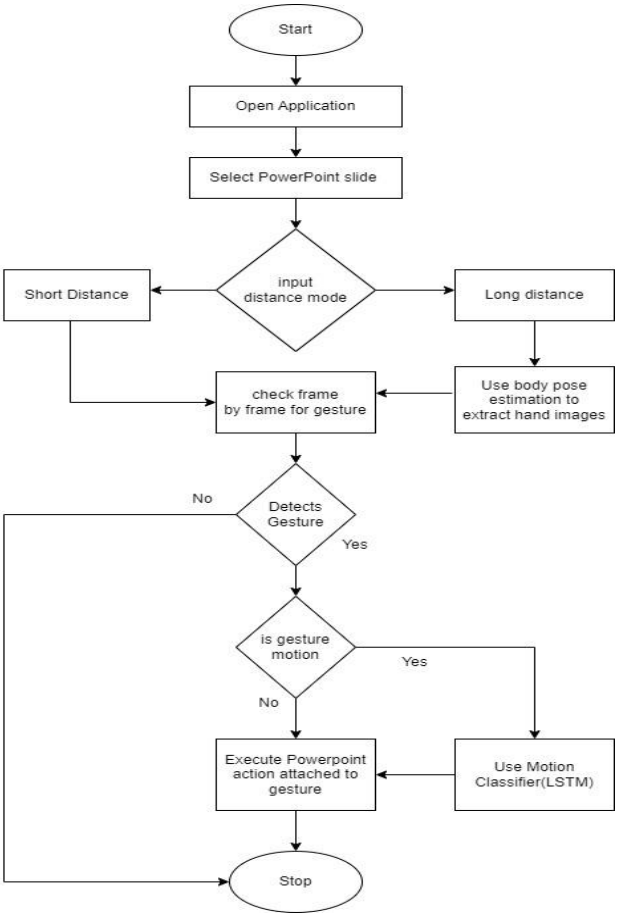

Fig. 10. Model deployed flow chart.

IV. Result and Discussion

This section discusses the results and execution of the model from the previous section and the performance of the system when evaluated. It defines the system constraints and tells us a bit more about the effectiveness of the system.

A. Model Training and Validation

The linear classifier model was trained using a strategy of 10 epochs, which means the entire dataset was processed 10 times. In each epoch, a batch of 128 data points was used for training. The entire training process took approximately three minutes, with each epoch lasting about 16 seconds. Notably, as the epochs progressed, the accuracy of the model consistently improved while the loss decreased. This is a positive sign that the model was learning effectively without becoming overfitted.

Throughout the training phase, the model achieved high levels of accuracy across different datasets: the training dataset, the validation dataset, and the testing dataset. Specifically, after the completion of 10 epochs, the model achieved accuracy rates of 90.1%, 89%, and 90% on the training, validation, and testing datasets, respectively. This indicates that the model had become well-acquainted with the dataset and was capable of accurately classifying the gestures within it.

Fig. 11 illustrates the model's training progress over each epoch. This visualization focuses on key metrics: loss, accuracy, val_loss (loss on the validation dataset), and val_accuracy (accuracy on the validation dataset). These metrics are tracked and displayed after every epoch to provide insight into the model's performance.

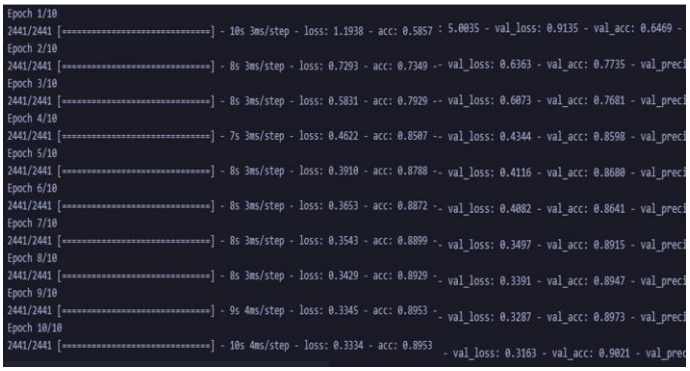

Fig. 11. Output of the linear classifier model's training process.

Here's a breakdown of what these metrics represent:

1) Loss: This metric indicates how much the model's predictions deviate from the actual values (labels) in the training dataset. It quantifies the error between predicted and actual values.

2) Accuracy: This metric represents the proportion of correctly classified data points in the training dataset. It shows how well the model is performing in terms of correctly predicting gestures.

3) Val_loss: Similar to the loss metric, val_loss measures the error between predicted and actual values, but it specifically pertains to the validation dataset.

4) Val_accuracy: Like accuracy, val_accuracy indicates the proportion of correctly classified data points, but on the validation dataset. It provides insight into how well the model generalizes to unseen data.

Fig. 12 and Fig. 13 provide a visual representation of the trends highlighted in Fig. 11, offering a closer look at the training and validation accuracy of the model as well as the corresponding training and validation loss throughout the 10 epochs. The x-axis on these figures denotes the number of epochs, while the y-axis illustrates the model's accuracy and loss.

From Fig. 12, it becomes evident that during the initial stages of training, the model's training accuracy starts at a relatively low point. At this early phase, the model lacks the understanding to accurately identify static hand gestures and is essentially making random guesses. However, as training progresses through each epoch, there is a steady and gradual improvement in accuracy. This trend signifies that the model is learning and becoming more adept at recognizing and distinguishing various hand gestures over time.

Examining Fig. 13, the graph portrays the trajectory of the model's loss on both the training and validation datasets across the epochs. Initially, during the early epochs, the training loss was notably high. This is attributed to the model's nascent stage, where it generates random and unrefined predictions, resulting in higher discrepancies between predicted and actual values. However, as the number of epochs advances, the training loss consistently diminishes. This decline indicates that the model is progressively honing its ability to accurately identify hand gestures within the training dataset.

Furthermore, the graph reveals the validation loss, which pertains to the model's accuracy in recognizing hand gestures on unseen validation data. As the epochs unfold, the validation loss follows a similar downward trajectory, signifying the model's enhanced capacity to generalize its learning from the training dataset to effectively identify hand gestures in new, previously unseen data.

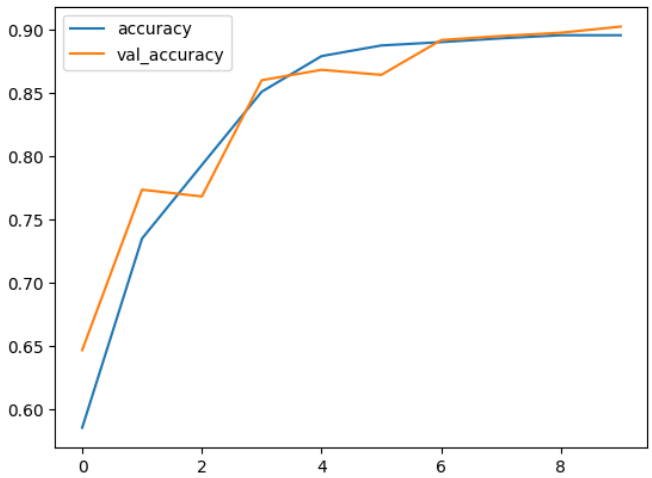

Fig. 12. Training and validation accuracy curves of the linear classifier model.

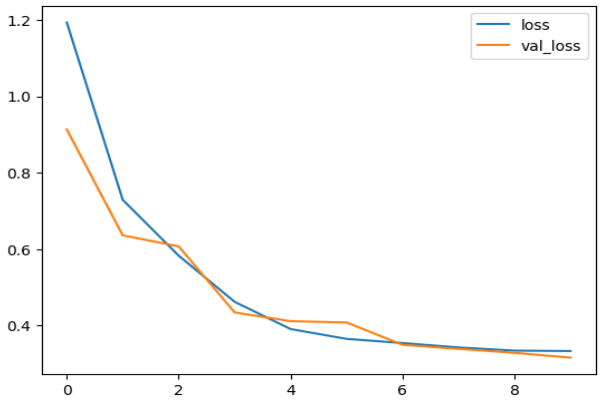

Fig. 13. Training and validation loss curve of the linear classifier model.

In essence, these graphical representations within Fig. 12 and Fig. 13 align with the narrative conveyed in Fig. 11, collectively providing a comprehensive insight into the model's iterative learning process. The figures underscore the model's journey from initial uncertainty and randomness to increasingly accurate and refined hand gesture recognition, ultimately attesting to its growing proficiency in this specific task.

The motion classifier model (LSTM) underwent training with a total of 200 epochs, where each epoch involved processing a batch of 64 data points. The entire training process took approximately 33 minutes, with each epoch lasting about 10 seconds. Similar to the linear classifier, the accuracy of the motion classifier increased while the loss decreased consistently with each successive epoch.

Throughout the training phase, the motion classifier model demonstrated high accuracy levels across different datasets: the training dataset, the validation dataset, and the testing dataset. Specifically, after the completion of the training process, the model achieved accuracy rates of 79.8%, 72%, and 70.1% on the training, validation, and testing datasets, respectively. This performance indicates that the model had become well-acquainted with the dataset and was proficient in correctly classifying different types of motions.

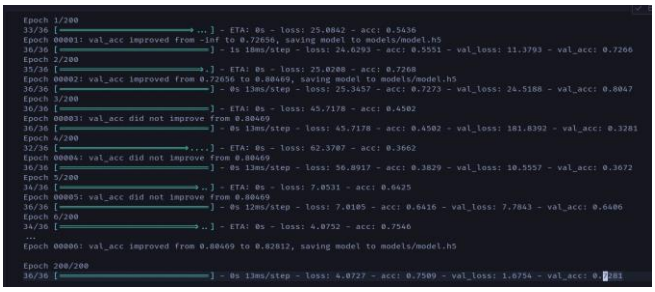

Fig. 14. Output of the motion classifier (LSTM) model's training process.

The training progress and performance of the motion classifier model are visualized in Fig. 14, 15, and 16. Fig. 14 provides an overview of the model's output during the training process, highlighting key metrics such as accuracy and loss across epochs. Fig. 15 and 16 depict the training and validation accuracy curves, as well as training and validation loss curves respectively, providing a graphical representation of the model's learning journey.

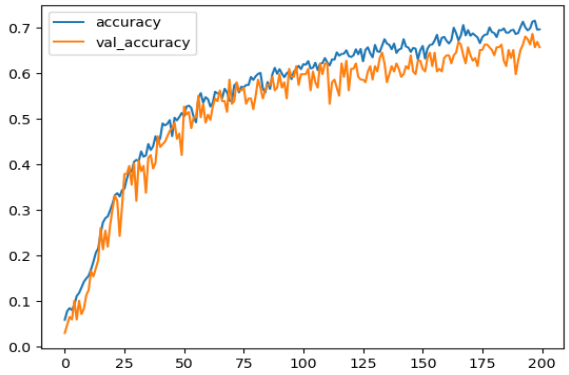

Fig. 15. Training and validation accuracy curve of the LSTM model.

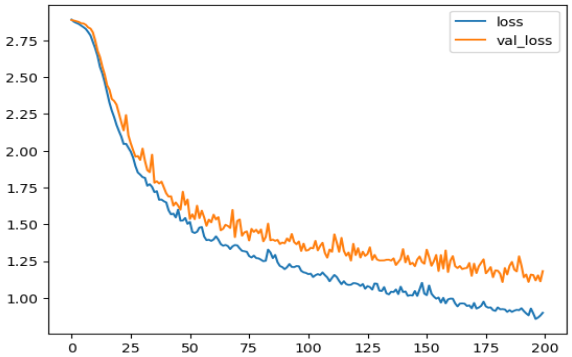

Fig. 16. Training and validation loss curves of the LSTM model.

In Fig. 15, it is observable that the accuracy initially starts at a lower point, similar to the linear classifier model. As training progresses over the epochs, the accuracy gradually improves, reflecting the model's increasing ability to recognize and classify motion patterns.

Fig. 16 displays the training and validation loss curves, illustrating a similar pattern observed in the linear classifier. At the start of training, the training loss is relatively high due to the model's random guesses. However, as the epochs advance, the training loss consistently decreases, indicating improved accuracy in recognizing motion patterns. The validation loss also follows a similar trajectory, indicating the model's enhanced ability to generalize its learning to unseen data.

B. Performance Index

Table I presents a comprehensive summary of how well the linear classifier model performed using various evaluation metrics. These metrics provide insights into the model's ability to accurately classify hand gestures.

- Accuracy: This metric measures the overall correctness of the model's predictions. The reported accuracy of 90% indicates that the model correctly classified 90% of the gestures in the dataset.
- Precision: Precision refers to the ratio of true positive predictions to the total number of positive predictions made by the model. In this case, the precision score of 92% implies that when the model predicts a gesture as positive (i.e., a certain hand gesture), it is correct 92% of the time.

- Recall: Recall, also known as sensitivity or true positive rate, calculates the ratio of true positive predictions to the total number of actual positive instances in the dataset. A recall of 90% indicates that the model correctly identified 90% of the actual hand gestures.
- F1-score: The F1-score is the harmonic mean of precision and recall, providing a balanced measure of the model's performance. An F1 score of 91% suggests that the model achieves a balanced trade-off between precision and recall.

TABLE I. PERFORMANCE OF THE LINEAR CLASSIFIER MODEL

Accuracy	*Precision*	*Recall*	*F1-score*
90%	92%	90%	91%

Fig. 17 visually represents the model's performance in terms of accuracy, precision, recall, and F1 score using a bar chart. This chart offers a clear overview of the model's strengths in terms of accuracy and precision, indicating its ability to make accurate predictions, particularly with high precision. However, it may miss some positive cases, as indicated by the relatively lower recall score.

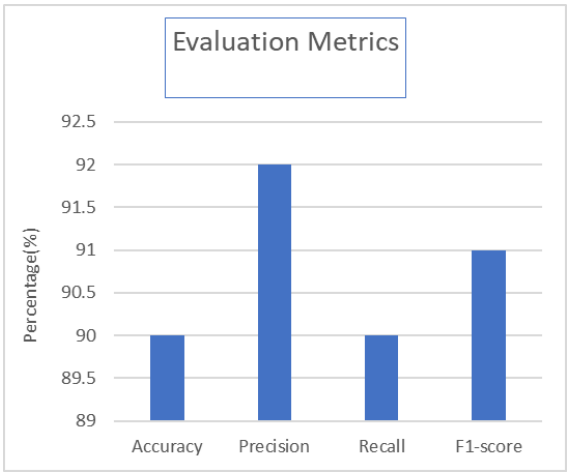

Fig. 17. Bar chart showing the linear classifier's performance.

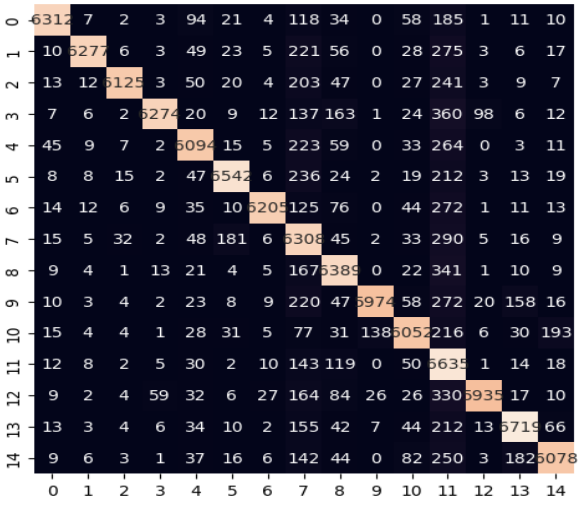

Fig. 18. The confusion matrix of the linear classifier model.

Fig. 18 and Fig. 19 present confusion matrices for the linear classifier model and the LSTM model, respectively. These matrices provide a visual depiction of the model's classification performance across different classes. They allow us to see how well the model correctly predicted each class and where it might have made errors.

Table II delves into the performance of individual classes. It provides a breakdown of precision, recall, and F1-score metrics for each class. For instance, for class 0, the precision score of 0.97 means that when the model predicted class 0, it was correct 97% of the time. The recall score of 0.92 indicates that the model correctly identified 92% of instances belonging to class 0. The F1-score of 0.94 represents a balanced measure of precision and recall for class 0.

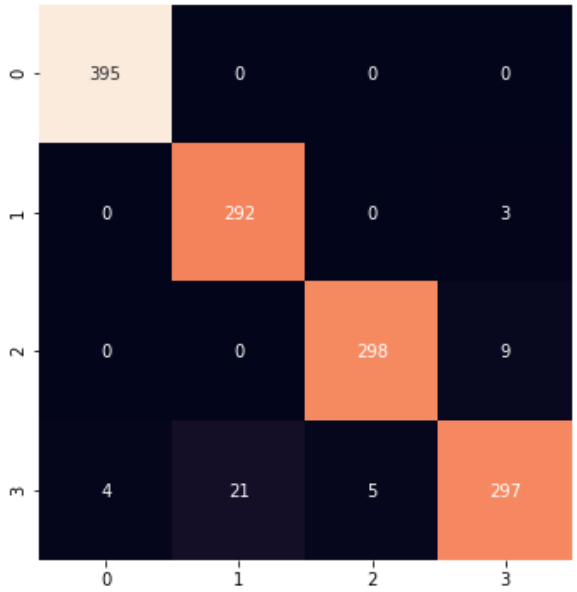

Fig. 19. The confusion matrix of the LSTM model.

TABLE II. PRECISION, RECALL AND F1-SCORE OF THE CLASSES

Class	*Precision*	*Recall*	*F1-Score*
0	0.97	0.92	0.94
1	0.99	0.90	0.94
2	0.99	0.91	0.94
3	0.98	0.88	0.93
4	0.92	0.90	0.91
5	0.95	0.91	0.93
6	0.98	0.91	0.94
7	0.73	0.90	0.81
8	0.88	0.91	0.90
9	0.97	0.88	0.92
10	0.92	0.89	0.90
11	0.64	0.94	0.76
12	0.97	0.88	0.93
13	0.93	0.92	0.92
14	0.94	0.89	0.91

V. User Implementation

A. The PowerPoint Selection

The interface permits users to choose which presentation file to open. The file browser approach is used to do this. The interfaces include a file browser which enables users to search the file system of their device for the desired PowerPoint presentation file. When selected, the slides pop up in the background as shown in Fig. 20.

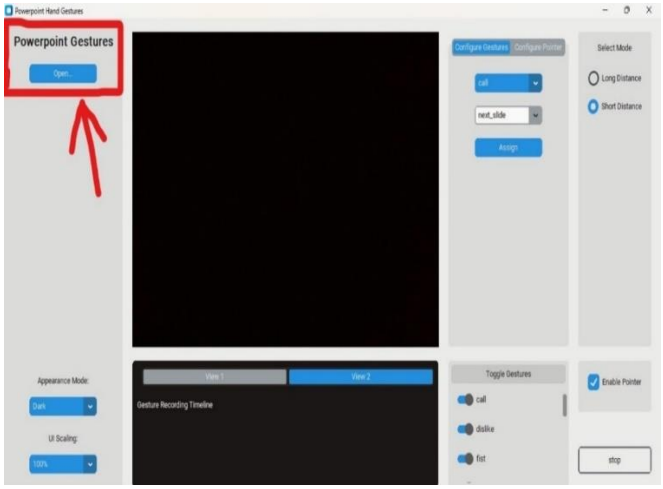

Fig. 20. Power point selection.

B. Distance Mode Selection

The user can select which mode is needed based on his/her distance from the system. A short distance is used in this operation. This can be visualized in Fig. 21.

C. Gesture Selection and Assignment

The interface allows the user to select gestures, and their functions and then assign them. In Fig. 22, the gesture used in this case is "call" and it is assigned to a function called "next_slide" which moves the slides page by page, the other 17 gestures in this model can also be assigned to other functions.

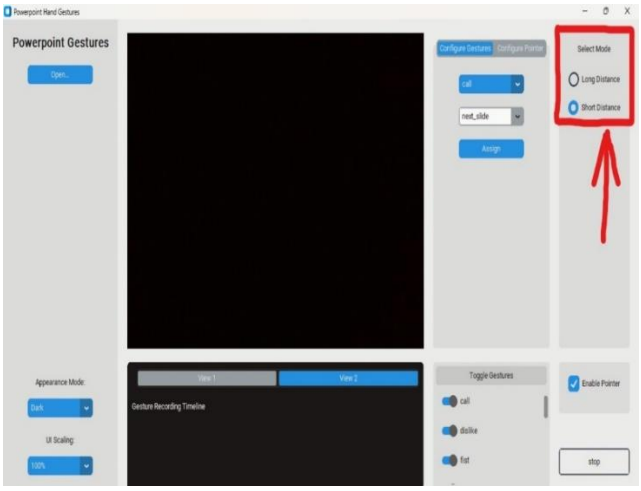

Fig. 21. Input distance mode.

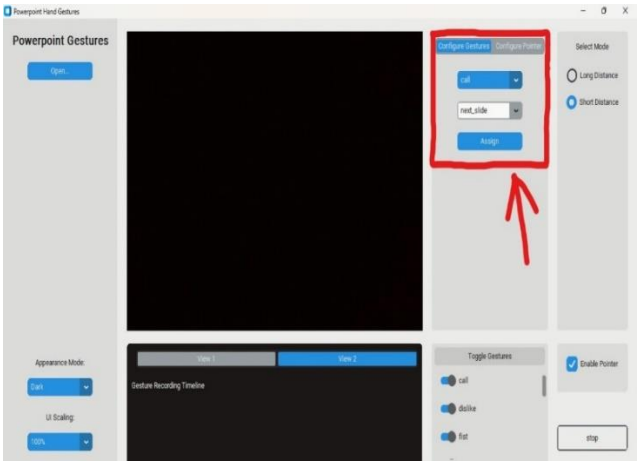

Fig. 22. Gesture selection and assignment.

D. Gesture Toggler

After assigning the gesture needed by the user, the user can turn on or off gestures based on their preferences as shown in Fig. 23, Fig. 24 And Fig. 25 shows that when the user toggles off a gesture, the gesture can no longer be recognized by the system and cannot perform its assigned function on the slides. When the gesture is toggled on, the system recognizes the gesture and the action assigned to it on the slides.

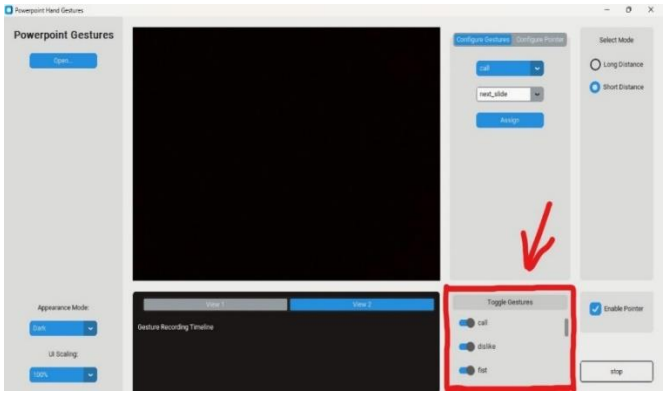

Fig. 23. Gesture toggler.

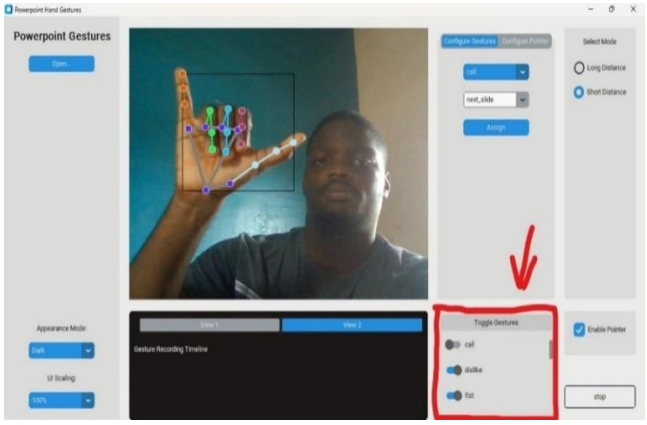

Fig. 24. Toggling OFF a gesture.

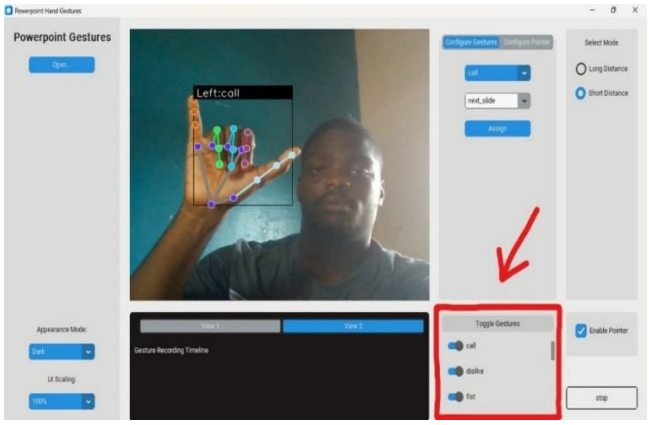

Fig. 25. Toggling ON a gesture.

E. Flow Chart

Fig. 26 shows the flow of the working of the package from the first stage to the end. This shows how the user should operate the software package.

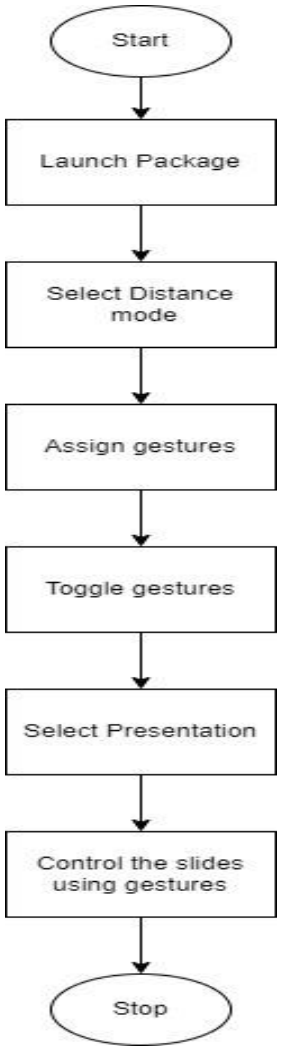

Fig. 26. Interface flowchart.

VI. Conclusion

In this study, we developed a software package that controls presentations using hand gestures. The system's performance was thoroughly examined through various evaluation metrics and visualization tools. Our findings highlight the effectiveness of the developed models in accurately identifying and classifying hand gestures.

The linear classifier model demonstrated impressive results, achieving an overall accuracy of 90%. This model's strong precision and recall scores further emphasize its ability to make accurate predictions while effectively identifying positive cases. The bar chart depicting the model's performance underscored its proficiency in precision, shedding light on its potential for minimizing false positive predictions. The confusion matrix provided valuable insights into the model's classification patterns. By analyzing true positives, true negatives, false positives, and false negatives, we gained a clearer understanding of where the model excelled and where improvements could be made. This granular analysis helps guide future refinements and optimizations of the system. Additionally, the LSTM model, designed to capture temporal patterns in motion data, demonstrated its efficacy in motion detection. While achieving lower accuracy compared to the linear classifier model, the LSTM model's performance remained solid, with an accuracy of 70.1% on the testing dataset. This model's potential for capturing long-term dependencies and recognizing complex motion patterns positions it as an asset for more nuanced applications. The study also addressed challenges related to distance by implementing Long-Distance Mode, which enhanced the system's adaptability to users situated far from the camera. This innovation showcases the system's robustness in accommodating varying scenarios and environments.

In conclusion, the developed system, consisting of a linear classifier and LSTM model, exhibits strong potential for real-time and accurate hand gesture identification. The combination of efficient classification and temporal analysis provides a comprehensive approach to gesture recognition. As a result, this system holds promise for a wide range of applications, from interactive presentations to virtual reality interfaces, enhancing user experience and interaction. Further research and optimization can propel this system towards even greater accuracy and utility in real-world settings.

***Abstract*—SMS facilitates the transmission of concise text messages between mobile phone users, serving a range of functions in personal and business domains such as appointment confirmation, authentication, alerts, notifications, and banking updates. It plays a vital role in daily communication due to its accessibility, reliability, and compatibility. However, SMS unintentionally generates an environment where smishing can occur. This is because SMS is extensively available and reliable. Smishing attackers exploit this trust to trick victims into divulging sensitive information or performing malicious actions. Early detection saves users from being victimized. Researchers introduced different methods for accurately detecting smishing attacks. Machine Learning models, coupled with Language Processing methods, are promising approaches for combating the escalating menace of SMS phishing attacks by analyzing large datasets of SMS messages to differentiate between legitimate and fraudulent messages. This paper presents two methods (SmishGaurd) to detect smishing attacks that leverage machine learning models and language processing techniques. The results indicate that TF-IDF with the LDA method outperforms Weight Average Word2Vec in precision and F1-Score, and Random Forest and Extreme Gradient Boosting demonstrate higher accuracy.**

***Keywords*—Smishing; phishing; SMS; machine learning; natural language processing; TF-IDF**

I. INTRODUCTION

SMS (Short Message Service) is a pervasive mode of communication that spans geographic boundaries and device types in the digital world. It delivers information, warnings, and notifications quickly and reliably, making it essential for personal and professional interactions. However, this convenience raises the risk of smishing. Smishing, a malicious combination of "SMS" and "phishing," represents a grievous and pervasive threat to cybersecurity [1]. It is a particularly effective vector for cybercriminals due to the prevalence of mobile phones and the inherent trust in text messages, that causes serious harm to both individuals and organizations. Many victims are tricked into giving over personal information, clicking on harmful links, or unintentionally installing malware on their mobile devices, compromising their financial security, privacy, and digital identity [2]. The compromise of sensitive personal information can lead to identity theft, unauthorized account access, and additional intrusions. Smishing is especially dangerous because attackers are constantly changing their strategies, and with the low technical barrier to entry, attackers of all ability levels can participate, making this danger widespread. They use social engineering and psychological tricks to make text messages that look real and trustworthy. Even the most cautious people can be tricked by urgent messages posing as from banks, governments, or well-known businesses, forcing them to take steps that would benefit the attackers [3]. Additionally, when personal and financial information is stolen, it makes people more likely to be victims of hacking in the future, since attackers can use this information for damaging purposes.

In this dynamic environment, machine learning (ML) arises as a formidable ally in the defense against smishing attacks [4]. By their very nature, machine learning algorithms excel at pattern recognition, allowing for the detection of nuanced clues within text messages that reveal fraudulent intent. Most importantly, machine learning systems always learn from new data and adapt to the changing strategies used by smishing attackers. This adaptability is crucial because smishing attacks evolve to avoid detection and capitalize on emergent trends. Furthermore, machine learning scales well, enabling real-time analysis of enormous amounts of SMS messages across large mobile networks, enabling proactive detection and prevention. One of the main goals of machine learning in smishing detection is to reduce false positives, which prevents valid SMS messages from being inadvertently tagged as suspicious and protects the integrity of communication channels. Machine Learning with Natural Language Processing (NLP) methods enhance the detection of smishing attacks. ML-NLP models excel at identifying linguistic anomalies and patterns within SMS messages, distinguishing smishing-specific keywords, phrases, and grammatical inconsistencies [5].

Researchers introduced several smishing detection strategies using deep and machine learning techniques. Most methodologies use machine learning or deep learning models to extract features from textual content for classification. Generating features from textual data, such as counting the number of words or special characters in a document, provides structural insights and facilitates data representation. However, these features are not concerned with the context or semantics of the text but rather with its structural characteristics. Sometimes, the generated features may not optimize the potential of the dataset. Particularly in smishing detection, the context of the textual content is more critical than structural characteristics. By capturing the relationships

between words and contextual meaning, NLP methods for fully vectorizing text, such as TF-IDF (Term Frequency Inverse Document Frequency) or word embeddings, provide a richer grasp of the text's semantic content and make complicated analysis and machine learning tasks possible [6]. This paper introduces two novel methods (SmishGuard), which use TF-IDF with LDA (Latent Dirichlet Allocation) topic proportion score and Average Word2vec with TF-IDF score as weight for smishing detection and compares the performances. The results show that algorithms using random forest and extreme gradient boosting attain higher accuracy.

Contribution of the work:

- Two novel methods (SmishGuard) for smishing detection.
- The first method combines TF-IDF with LDA topic proportion scores to improve smishing detection by providing a comprehensive view of SMS messages that captures both term-level and underlying topics.
- The second method uses Average Word2Vec with TF-IDF scores as weights for smishing detection capitalizing on the strengths of both approaches, capturing semantic information and term importance.
- Proposed methods decrease false positives and enhance cybersecurity by enabling more precise and context-aware detection.
- Experimental evaluation and Performance Comparisons.

The research work's sections are arranged as follows. Section I delineates the problem's significance and outlines the proposed research works. The background is in Section II. In Section III, related works are highlighted. Section IV describes the proposed methodologies in detail. Experimental results are explained in Section V. The paper concludes with Section VI.

II. BACKGROUND

Smishing attacks, a form of phishing that utilizes SMS or text messaging, pose a serious cybersecurity risk. In these attacks, scammers typically send false communications to victims to coerce them into disclosing personal information, opening malicious links, or downloading dangerous files. Machine learning analyses content, sender information, and message context to detect smishing using natural language processing methods. Through training models on labeled datasets that include examples of both smishing and real messages, machine learning systems can identify patterns, language indications, and typical behavioral oddities. This proactive approach enhances the capability to automatically identify and flag suspicious messages, thereby protecting users from smishing frauds and boosting the security of mobile communication channels. This section describes the key technologies utilized in the proposed methods.

- TF-IDF Vectorizer: Using vectorizers, the unstructured text data are transformed into a numerical representation that machine learning algorithms can process. They convert text to numerical vectors. TF-IDF vectorizer creates a matrix where each document is a row, and each distinct word is a column from a set of text documents. A term's TF-IDF score is calculated by multiplying TF and IDF. TF counts how frequently a term appears in a document, while IDF measures a word's rarity across the corpus [7].
- Latent Dirichlet Allocation (LDA): LDA plays a key role in detecting smishing (SMS phishing) by revealing hidden themes and topics in SMS communications. It enables the identification of underlying linguistic patterns frequently observed in fraudulent messages, enabling the classification of incoming texts as either legitimate or potentially malevolent. By leveraging LDA, smishing detection systems acquire the ability to distinguish context and content nuances, making them more adept at recognizing attacker's deceptive techniques [8] [9].
- Average Wor2Vec Word Embedding: It expands on Word2Vec word embeddings by providing a method for representing entire sentences or documents as dense vectors. Average Word2Vec computes the vector representation of a sentence by calculating the average of the word vectors in it rather than considering each word separately. The approach involves converting each sentence word to its Word2Vec form and determining the mean of these vectors. Thus, the whole phrase is a short, fixed-length vector that captures its meaning. Average Word2Vec efficiently represents sentences while preserving semantic links and context from the Word2Vec model. It helps machine learning algorithms understand sentences and documents of different lengths by providing a constant vector dimension [10].
- Machine Learning Algorithms (ML): In detecting smishing messages, machine learning models are quite effective [11]. They are essential in recognizing and classifying smishing messages with dangerous or harmful information, which helps to improve cyber security and shield users from potential risks. Most of the research work utilizes different machine learning algorithms for smishing detection using SMS text, such as Logistic Regression (LogR), Support Vector Machine (SVM), Multinomial Naive Bayes (MNB) Gaussian Naive Bayes (GNB), Naïve Bayes (NB), Decision Tree (DT), Random Forest (RF), Gradient Boosting (GB), Ada Boosting (AB), Extra Tree (ET) and Extreme Gradient Boosting (XGB).

III. RELATED WORKS

Detecting and preventing smishing attacks is essential for safeguarding individuals and organizations from potential harm. Effective methods for detecting smishing attempts have been developed using machine learning and deep learning (DL) approaches. The most recent findings from research conducted in this area are presented in this section.

Boukari et al. [12] proposed a fraud detection system that utilizes the TF-IDF method to convert SMS text into a vectorized representation. A dataset of 5000 emails was used

for smishing. The importance of each word in the SMS is determined using the TF-IDF algorithm. The experiment's findings indicate a high level of accuracy, with the RF algorithm achieving an accuracy of 98.15% and the NB approach achieving an accuracy of 90.59%. Mishra et al. [13] developed an efficient smishing detection system using an artificial neural network. The dataset utilized in the experiment consisted of 5858 messages, with 538 classifieds as smishing messages and 5320 as valid messages. Seven distinctive features were extracted from the dataset. The neural network was implemented with seven features, including email, URL, phone number, etc. The performance results for NB, DT, and Neural Network were 96.29 %, 93.40 %, and 97.40 %, respectively. Ulfath et al. [14] employed the N-grams and TF-IDF techniques for feature extraction and the statistical feature selection method. The vocabulary only includes the top 10,000 terms across the SMS dataset. The dataset was obtained from UCI's machine learning library. Five machine learning algorithms, XGB, DT, RF, SVM, and AB were employed. The outcome reveals that the SVM classifier obtains a higher accuracy of 98.39%. Smishing messages from various Internet sources were collected by Mishra et al. [15]. There are 638 smishing, 489 spam, and 4844 ham messages in the 5971 samples. Finally, five features were extracted and used in the experiment. ML algorithms such as NB, RF, and DT were employed. The performance outcomes for NB were 94.06%, RF 94.64%, and DT 93.96%. Maqsood et al. [16] used both ML and DL classifiers to detect spam SMS. The dataset was obtained via Kaggle, (SMS Spam Collection Dataset). The process of extracting features was conducted via the Bag-of-Words and TF-IDF methodologies. The gathered features served as input for three distinct machine learning models and CNN in deep learning. The SVM demonstrated a high level of accuracy, outperforming the other models with a performance of 99.6% for spam SMS. Ramanujam et al. [17] compiled a multiple languages SMS dataset, which encompasses both spam and non-spam messages in English and four distinct Indian languages. The SMS data contains 2,757 ham and 525 spam messages. A deep learning hybrid model (CNN-LSTM) has been proposed without feature engineering. The model exhibits a 97.7% accuracy rate. Jain et al. [18] presented a method to classify messages as smishing messages. The model was trained using multiple machine learning techniques with the Almeida spam data collection of 5169 messages, 362 of which are smishing and 4817 non-smishing. In addition, the model's accuracy has been determined for across datasets. The voting classifier that integrates KNN, RF, and ET Classifier (ETC) achieves an accuracy of 99.03% and a precision of 98.94%. Using machine learning, Mishra et al. [19] extracted the five most effective text message features for smishing detection. The dataset used for smishing detection contains 5858 text messages, 538 of which are smishing and 5320 valid. For the experimental results, RF, NB, DT, and Backpropagation Algorithm were used. The Backpropagation Algorithm outperformed the competition with a 97.93% accuracy rate. Sjarif et al. [20] used an algorithm incorporating TF-IDF and machine learning algorithms to identify SMS spam messages. The UCI Repository provided the dataset. The collection includes 5,574 English raw text messages categorized as ham or spam. Of these messages, 4,827 are classified as ham and the remaining 747 as spam. Five ML algorithms were used combined with the TF-IDF method for experimental purposes. The TF-IDF and RF combination produced an impressive 97.50% accuracy rate.

In existing research, feature extraction and vectorization from the SMS dataset are prioritized. Understanding the content of the message is essential for improved classification. The existing related works summary is shown in Table I.

TABLE I. RELATED WORKS SUMMARY

Author	Dataset	Feature generation method	Accuracy	Issues
Boukari et al. [12]	Smishing dataset 5000 messages	TF-IDF Vectorizer	Naïve Bayes: 90.59% Random Forest: 98.15%	Contextualization of text is not included.
Mishra et al. [13]	Smishing dataset Smishing messages=538 Legitimate messages=5320	Feature Extraction	Naïve Bayes: 96.29 Decision Tree: 93.40 Neural Network:97.40	A limited number of features. The system does not fully utilize the dataset.
Ulfath et al. [14]	UCI Dataset (SMS-Spam Collection) Spam messages=1197 Legitimate messages=4377	TF-IDF Vectorizer	Support vector machine: 98.39	Contextualization of text is not included.

Maqsood et al. [16]	Kaggle- SMS Spam Collection Dataset. Spam messages=750, Legitimate messages=4250	Count (BoW) and TF-IDF Vectorizer	Support vector machine: 99.6	Contextualization of text is not included.
Ramanujam et al. [17]	Multilingual SMS Dataset. Legitimate messages=2,757, Spam messages=525	--	CNN-LSTM model: 97.7	Ne specific feature engineering was adopted.
Jain et al. [18]	Almeida spam data set. Spam Messages=362, Legitimate Messages=4817	TF-IDF Vectorizer	Voting classifier with KNN, RF, and ET Classifier (ETC) =99.03	Time-consuming method
Mishra et al. [19]	Smishing dataset Smishing messages=538 Legitimate messages=5320	Feature Extraction	Backpropagation Algorithm: 97.93	A limited number of features. The system does not fully utilize the dataset.
Sjarif et al. [20]	UCI Dataset Legitimate message=4,827 Spam messages= 747	TF-IDF Vectorizer	RF:97.50	Contextualization of text is not included.

IV. PROPOSED METHODS

Our proposed methods (SmishGuard) include two different systems for smishing (SMS phishing) detection that employ ML and NLP methods to improve mobile communications security. Most of the existing methodologies extract features from textual content for classification using ML or DL models. Generating features from textual data, such as counting the number of words or special characters in a document, provides structural insights and facilitates the representation of data. However, these features are not concerned with the context or semantics of the text, but rather with its structural characteristics. Sometimes, the generated features may not optimize the potential of the dataset. The primary goal of the proposed system is to maximize the utilization of the dataset through the implementation of several natural language processing methods, including TF-IDF with LDA and average Word2Vec with TF-IDF. NLP methods fully vectorizing text, such as TF-IDF or word embeddings, provide a richer grasp of the text's semantic content and make complicated analysis and machine learning tasks feasible. The outcomes of both methods exhibit a higher level of performance in comparison to the currently available methods. The process flow of the proposed system is shown visually in Fig. 1.

A. Dataset

For experiments, two distinct data sources are combined. Table II provides information about the data sources. Combining data from multiple sources necessitates the elimination of duplicate entries from the dataset. After removing duplicates, the final dataset used for our experiment is presented in Table III.

TABLE II. DATA SOURCES

Data Set	Features
SMS Phishing Dataset [21]	Smishing =1127 Legitimate messages=4844.
SMS Spam Collection [22]	Legitimate Messages=4825 Spam messages=747

TABLE III. COMBINED DATASET

Data Set	Features
SMS_PHISH	Smishing Messages =1627 Legitimate messages=5634

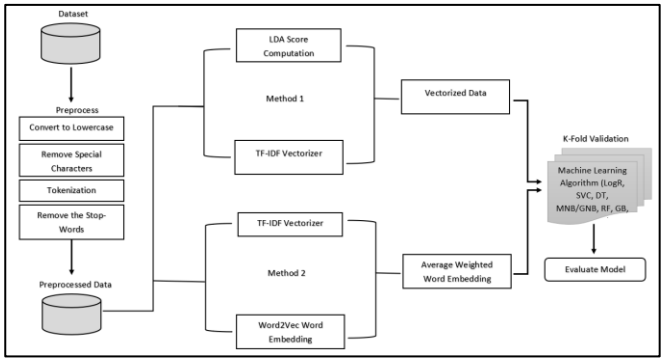

Fig. 1. Process flow of the proposed system.

B. Preprocessing

Text preprocessing is a crucial initial stage for Natural Language Processing and Machine Learning tasks that involve textual data. Effective text preprocessing is essential for maintaining data integrity and eliminating irrelevant information, enabling NLP and ML models to concentrate on extracting valuable insights and discerning patterns from textual data [23] [24]. Common procedures include lowercasing, tokenization, stop word elimination, and special character handling, etc. Algorithm 1 describes the preprocessing procedures.

Algorithm 1: Processing

1. Input: Raw Text
2. Output: Preprocessed Text
3. Import required libraries (nltk for natural language processing and re for regular expressions).
4. Load the raw text data.
5. Convert text to lowercase for consistency.
6. Remove any special characters, punctuation, and numerical values using regular expressions.
7. Break the text down into individual words or tokens.
8. Eliminate stop words as they do not contribute much to the meaning.
9. Join the tokens back into a preprocessed text string.

C. Method 1: TF-IDF Vectorization with LDA Topic Proportion Score (TF-IDF-LDA)

Combining TF-IDF vectorization and LDA text proportion scores is an effective approach. Through TF-IDF, text messages are transformed into numerical feature vectors that highlight the significance of phrases in each message, allowing machine learning algorithms to identify patterns suggestive of attempted smishing. Along with LDA topic proportion scores (The number of topics is set to 2 for our experiment) improve the identification accuracy of fraudulent messages. These scores provide a numerical representation of the subjects present in each message by applying LDA to SMS content. Smishing attempts often use certain language patterns or themes. LDA can reveal hidden motifs in smishing efforts, helping models distinguish between authentic and suspect communications. High proportions of topics relating to fraud, urgency, or deceptive content can serve as strong indicators of smishing, enabling the development of robust detection systems that protect users from phishing threats concealed within text messages.

Term Frequency (TF) for a word in a document [25]

$$\text{TF}(w, d) = \frac{n_{w,d}}{N_d}$$

$n_{w,d}$ = The frequency of occurrences of the term w in document d.

N_d = Total word count in document d.

Inverse Document Frequency (IDF) for a word in the corpus:

$$\text{IDF}(w) = log\left(\frac{\text{N}}{n_w}\right)$$

N= Number of documents contained in the corpus

n_w = Count of documents that contain the word w

TF-IDF Score for a word in the document is obtained by multiplying TF and IDF.

Topic Proportion Calculation for a Document [26]

For a given document D and topic T:

$$P(T|D) = \frac{P(T).P(D|T)}{P(D)}$$

where:

P(T|D) is the probability (proportion) of topic T in document D.

P(T) is the topic's prior probability over the entire corpus. It represents the proportion of documents within the entire dataset that are assigned to topic T.

P(D|T) is the probability of document D being generated from topic T. It determines the probability that the words in document D are generated by topic T.

P(D) is the probability of observing document D in the corpus.

D. Method 2: Weighted Average Word Embedding Generation

After preparing the raw textual contents, preprocessed data is prepared for the experiment. To determine the weight of words within a corpus through the utilization of TF-IDF vectorization, the initial step involves the computation of TF-IDF scores for every individual word encompassed within the entirety of the corpus. The TF-IDF metric quantifies the significance of a word within a particular document by considering its frequency in that document and inversely comparing it to its frequency across all documents. After obtaining these TF-IDF scores, the next step is to compute the weighted average Word2Vec embedding for machine learning using these scores as weights. The Word2Vec model is utilized to represent words as continuous vectors that capture semantic relationships. To calculate the weighted average Word2Vec embedding for a document, the vector of Word2Vec for each word is multiplied by its corresponding TF-IDF score. The result is a weighted vector. Then the sum of all weighted vectors of the document is divided by the sum of all weights of a document. Every document in the corpus finally gets a single weighted average word vector. This weighted average Word2Vec representation includes word importance and semantic context for downstream machine-learning tasks. The entire process is presented in Algorithm 2.

Weighted Average Word2Vec Computation for a document 'd' [27]

Multiply each word's Word2Vec vector by its corresponding TF-IDF score. The weighted average word embedding is calculated using the equation below:

Weighted Average Word2Vec (d) =

$$\frac{\sum_{w \in d} \left(TF - IDF_{(w,d)} \times Word2Vec\,(w) \right)}{\sum_{w \in d} \left(TF - IDF_{(w,d)} \right)}$$

where, w represents the word and d represents the document.

Where n is the number of words in a document.

Algorithm 2: Weighted Average Word2Vec

Input: TF-IDF matrix, Word2Vec embeddings

Output: Weighted Average Word2Vec representation for a document.

1. Multiply each word's Word2Vec vector by its TF-IDF score in the matrix.
2. Calculate the weighted average word embeddings for each of the document's words.

E. Training and Testing

Finally, K-fold validation trains and tests machine learning models using vectorized data/ word embedding. K-fold cross-validation is a widely employed technique utilized for the assessment of a model's performance and the mitigation of overfitting [28]. In this technique, the dataset is partitioned into K subsets, sometimes referred to as "folds," which are approximately of similar size. K-fold cross-validation trains and evaluates the model K times. For each iteration, one-fold is marked as the validation set, and K-1 folds are used for training. The performance metric is determined by calculating the average of K evaluation results.

V. Experiments and Results

The experiments employ Jupyter Notebook and Python's sklearn package on Windows 10. Accuracy, precision, recall, and the f1-score are performance parameters that are considered. Table IV presents the experimental result of the TF-IDF Vectorization with the LDA Topic Proportion Score (TF-IDF-LDA) method. Fig. 2 shows the ROC AUC curve.

The outcome demonstrates that the methods used in Random Forest and Extreme Gradient Boosting attains accuracy levels of 98.42% and 98.47%, respectively. Additionally, they obtained respective F1-Scores of 96.52% and 96.30%.

Table V presents the parameter details of the Word2Vec model. Table VI presents the experimental result of the weighted average word2vec (WAW2Vec) method. Fig. 3 shows the ROC AUC curve for the Random Forest and Extreme Gradient Boosting Algorithm.

TABLE IV. Performance of TF-IDF-LDA Method

ML Algorithm	Accuracy %	Precision %	Recall %	F1-Score %
LogR	96.97	95.26	91.03	93.07
SVC	98.33	98.33	94.16	96.17
MNB	97.52	98.58	90.22	94.19
DT	97.42	94.60	93.85	94.20
RF	**98.42**	**99.53**	**93.36**	**96.30**
GB	97.08	95.85	90.90	93.27
AB	97.22	94.97	92.50	93.70
XGB	**98.47**	**97.91**	**95.20**	**96.52**

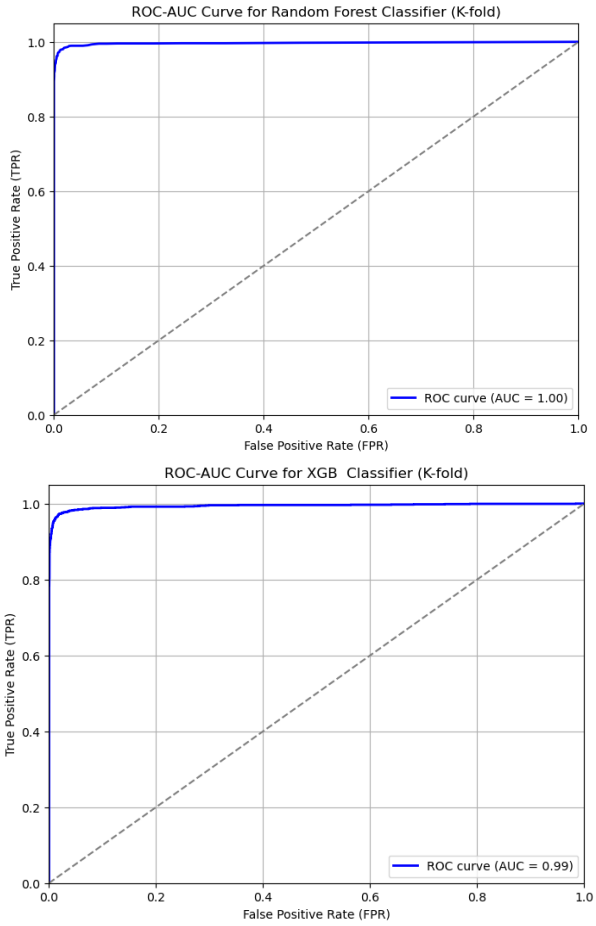

Fig. 2. ROC-AUC curve for TF-IDF-LDA method.

TABLE V. PARAMETER OF WORD2VEC MODEL

Parameter	Value
Vector Size	100
Window	5
Min_count	1
Sg	0

TABLE VI. PERFORMANCE OF WAW2VEC METHOD

ML Algorithm	Accuracy	Precision	Recall	F1-Score
LogR	86.08	85.35	90.07	87.34
SVC	91.23	91.23	92.55	91.78
GNB	82.83	87.58	79.18	82.53
DT	94.13	85.61	88.62	87.05
RF	**96.09**	**92.50**	**89.79**	**91.07**
GB	94.33	88.67	85.61	87.09
AB	93.04	84.94	83.83	84.34
XGB	**96.21**	**92.23**	**90.71**	**91.42**

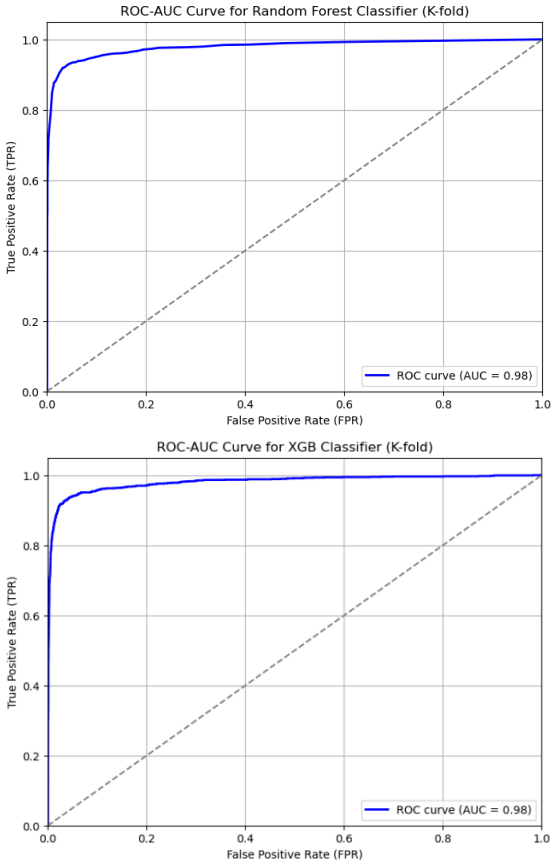

Fig. 3. ROC-AUC curve for WAW2Vec method.

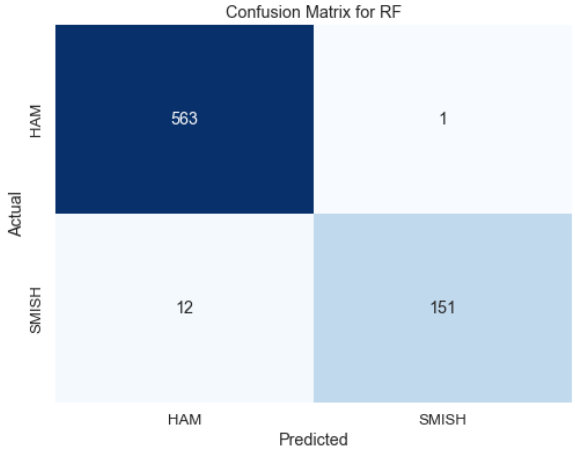
The results indicate that Random Forest and Extreme Gradient Boosting obtained an accuracy of 96.09% and 96.22%, respectively. They also obtained respective F1-Scores of 91.07% and 91.42%.

Confusion matrix is crucial to classification model evaluation as it provides extensive insights into model performance. It divides the predictions and actual outcomes of the model into four categories: true positives, true negatives, false positives, and false negatives. Fig. 4 and Fig. 5 illustrate the performance of the proposed model by displaying fewer false positives and false negatives.



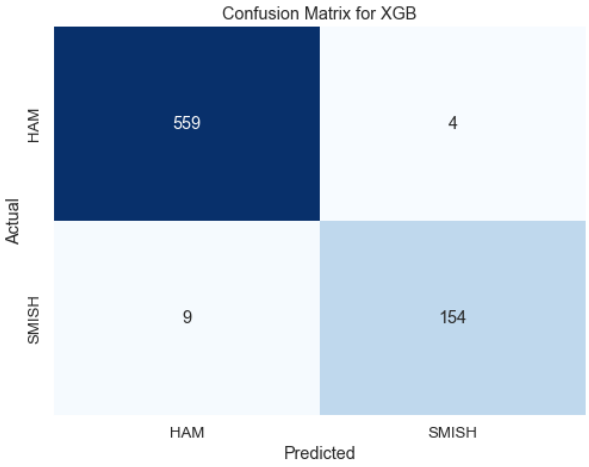


Fig. 4. Confusion matrix for TF-IDF-LDA method.

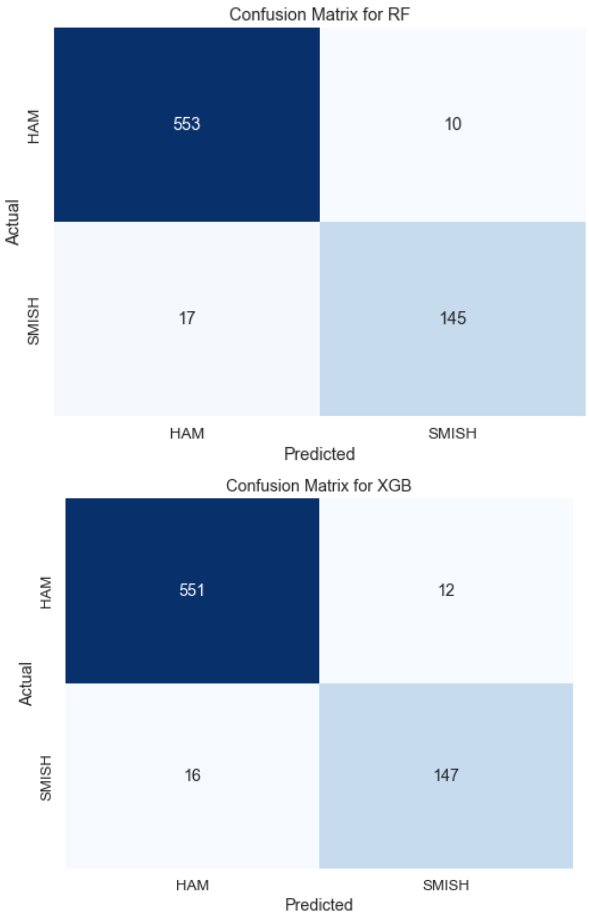

Fig. 5. Confusion matrix for WAW2Vec method.

The results demonstrate that the TF-IDF with LDA approach (Method-1) exhibits superior accuracy and F1-Score compared to the Weight Average Word2Vec method (Method-2). However, both methods produce better outcomes than existing methods as shown in Fig. 6.

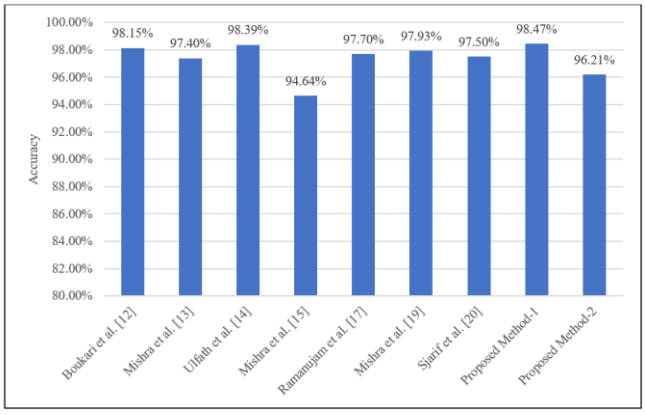

Fig. 6. Performance comparison (accuracy).

VI. Conclusion

Cybercriminals are increasingly using smishing, also known as SMS phishing, as a sneaky way to trick and deceive people and businesses. The expanding usage of mobile devices and text messaging for communication and transactions has increased the risk of smishing attacks. Attackers typically imitate reputable organizations to trick victims into disclosing critical information or committing crimes. So, smishing detection systems are vital for maintaining the security of vital infrastructure, protecting private and financial information, and maintaining public confidence in digital communication. Using ML and NLP methods for Smishing Detection is a promising way to counter the growing menace of SMS phishing attempts. This approach improves smishing detection by analyzing message content and contextual information.

This paper presents two methods based on ML algorithm and NLP methods for smishing detection. The results indicate that the TF-IDF with LDA approach (Method-1) achieves greater precision and F1-Score than the Weight Average Word2Vec technique (Method-2). Nevertheless, both methodologies yield outcomes that exhibit enhancements compared to current approaches. This empirical evidence is crucial to cybersecurity research since it refines methods and guides future study. Proposed method enhances the overall security of digital communication and transactions by contributing to the development of effective tools to counter evolving cyber threats.

Despite the potential of the proposed smishing detection system to mitigate the exponential growth of the smishing threat, the current system's capabilities are restricted to smishing messages in the English language. The task of managing diverse languages is progressively becoming more difficult.

Sleep Apnea Detection Method Based on Improved Random Forest

Xiangkui Wan, Yang Liu, Liuwang Yang, Chunyan Zeng, Danni Hao*
Hubei Key Laboratory for High-efficiency Utilization of Solar Energy and Operation Control of Energy Storage System, Hubei University of Technology, Wuhan, 430068, China

***Abstract*—Random forest (RF) helps to solve problems such as the detection of sleep apnea (SA) by constructing multiple decision trees, but there is no definite rule for the selection of input features in the model. In this paper, we propose a SA detection method based on fuzzy C-mean clustering (FCM) and backward feature rejection method, which improves the sensitivity and accuracy of SA detection by selecting the optimal set of features to input to the random forest model. Firstly, FCM clustering is performed on the RR interval features of ECG signals, and then the backward feature rejection method is used to combine the intra-cluster tightness, inter-cluster separation and contour coefficient metrics to eliminate redundant features to determine the optimal feature set, which is then inputted into the RF to detect SA. The experimental results of this method on Apnea-ECG database data show that the SA detection accuracy is 88.6%, sensitivity is 90.5%, and specificity is 85.5%, and the algorithm can adaptively select a smaller number of more discriminative features through FCM to reduce the input dimensions and improve the accuracy and sensitivity of the RF model for sleep apnea detection.**

***Keywords*—Sleep apnea; fuzzy c-means; backward feature elimination method; random forest**

I. INTRODUCTION

Sleep apnea (SA) leads to nocturnal hypoxia and hypercapnia, which makes elevated blood pressure and heart rate [1], and may lead to cardiovascular diseases such as hypertension, coronary artery disease, and cardiac arrhythmia, and even cause serious consequences such as heart failure and sudden death [2-3]. Studies have shown that SA is also associated with neurological disorders such as Alzheimer's, Parkinson's disease and depression. Owen, et al. first identified Alzheimer's-like amyloid plaques in the brains of people who are clinically proven to have obstructive SA [4]. Patients with SA in middle age are more likely to develop Alzheimer's disease in old age [5]. Parkinson's disease patients have degeneration in the brain stem area that controls breathing, which can cause reduced respiratory muscle function, and sleep-disordered breathing. Yang, et al. propose a method to detect Parkinson's disease and predict disease severity by breathing at night [6]. SA can also cause neurasthenia, which affects the classification of autistic patients using electroencephalography [7]. Therefore, timely, accurate and convenient detection of SA is of great significance.

Scholars have carried out a lot of exploration and research in SA monitoring. Tagluk, et al. proposed a SA detection method based on wavelet transform and artificial neural network [8], which utilizes multi-resolution wavelet transform to decompose the abdominal breathing signal into multiple spectral components, and these spectral components are inputted into the artificial neural network to classify the SA condition of patients. However, detecting abdominal breathing often requires the use of larger devices, which impacts the patient's daily life. Mendez, et al. investigated a method for detecting SA based on empirical mode decomposition (EMD) and wavelet analysis (WA) of ECG signals [9], whereby features are extracted from the decomposition results, a heart rate variability time-domain measure and three additional nonlinear measures are used as inputs to a linear discriminant classifier. However, this method requires lot input feature parameters and complex computational model, thus the robustness needs to be improved. Iwasaki, et al. analyzed the adjacent R-wave intervals in the ECG signals and used a long and short-term memory model to detect SA [10]. Urtnasan, et al. proposed a deep learning architecture based on a convolutional neural network using a single-lead ECG signal for SA classification [11]. However, such deep learning models usually require multiple experiments to get the algorithm parameters and lack of interpretability.

Among the commonly used machine learning algorithms, the random forest (RF) algorithm has been widely used in biomedical signal processing due to its ability to handle high-dimensional data, capture nonlinear relationships, reduce the risk of overfitting, and possess the advantages of noise immunity [12-13]. The RF algorithm can also help to solve the problems of signal classification and anomaly detection [14-15]. However, the RF algorithm has no definite rules for input features selection. Although the algorithm itself measures the contribution of each feature by means of feature importance assessment [16], this is only a relative metric, which does not reflect which features are absolutely important and should be selected. Selecting appropriate features is a relatively subjective process that depends on the specific dataset and problem domain [17].

To address the problem of how to select appropriate input features, this paper proposes a SA detection method based on Fuzzy C-means clustering (FCM) and backward feature rejection method, which selects appropriate input features through FCM clustering index, reduces the dimensionality of the input features, reduces the complexity of model training and prediction, and avoids too much noise and irrelevant information from causing model Interference. Feature selection allows the model to focus more on important features, thus better capturing patterns and relationships in the data and

*Corresponding Author.

improving the accuracy and sensitivity of the RF model for SA detection.

The focus of this paper is to improve the random selection process of input features in the traditional RF method. FCM was applied to the input features, and the index of intra-cluster tightness, inter-cluster separation and contour coefficient of the samples were calculated. Combined with the method of reverse feature elimination, redundant features are eliminated to determine the optimal selection. Better classification accuracy of SA can be obtained by using only a small number of distinct features. The structure of this paper is as follows: Section II describes the data set and the method used in this paper, Section III is the experimental results and analysis, Section IV is the discussion, and Section V is the conclusion.

II. Materials and Methods

A. Datasets

Apnea-ECG database [18]: the database consists of 70 records divided into a training set containing 35 records (a01 to a20, b01 to b05 and c01 to c10) and a test set of 35 records (x01 to x35). The individual records in the database range in length from seven to ten hours and are sampled at a frequency of 100 Hz. Each record consists of the ECG signal, a set of manual apnea annotations and a set of machine-generated QRS annotations. In addition, eight records (a01 to a04, b01, and c01 to c03) were accompanied by four additional signals: chest and abdominal respiratory signals obtained using respiratory inductive plethysmography, oronasal airflow and oxygen saturation recorded with nasal thermistor.

B. Extracting ECG Signal Features

SA causes changes in the autonomic nervous system and cardiovascular regulation, leading to prolongation or shortening of the RR interval [19]. In this paper, the Pan-Tompkins algorithm was adapted to identify QRS wave clusters [20], and the RR interval was determined by the time difference between adjacent R peaks, and the feature information was extracted from the RR interval sequence.

QRS wave detection: the raw ECG signals were processed in one-minute segments according to the annotation file. Per-segment SA detection determines whether each one-minute segment is SA or normal, and it is an important basis for SA diagnosis in suspected patients [21]. Band-pass filtering, differential amplification, squaring operation, moving window integration and threshold detection were performed on each segment using the Pan-Tompkins algorithm to locate the R-wave, as shown in Fig. 1.

Feature extraction: combined with the results of literature [22-23], we per-formed feature extraction on the obtained RR intervals as shown in Table I.

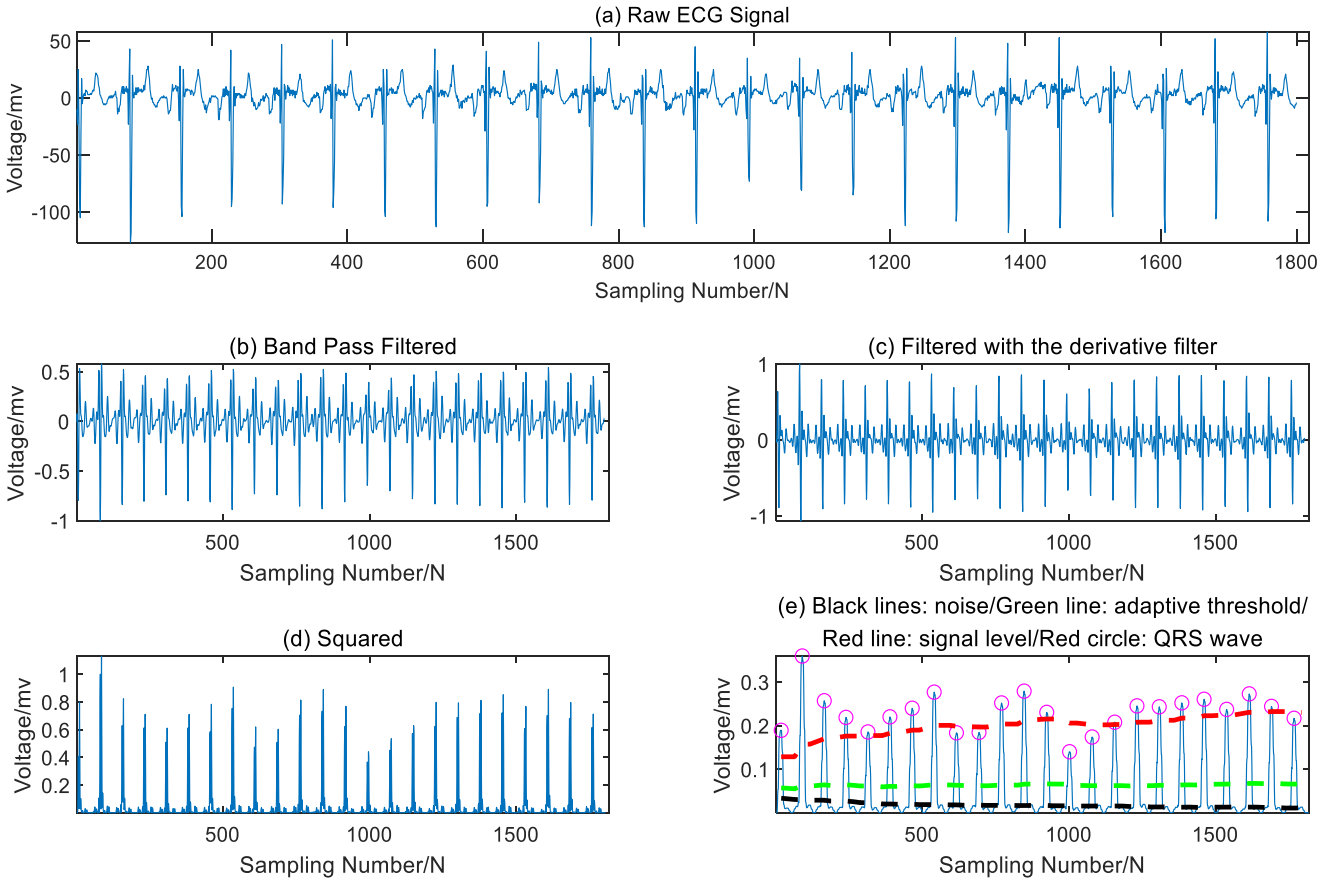

Fig. 1. QRS wave detection of ECG signals.

TABLE I. LIST OF RR INTERVAL FEATURES

No	Feature	Description
1	AVRR	$AVRR = \frac{1}{N}\sum_{j=1}^{N} RR_j$ (1) The average of all RR intervals.
2	SDRR	$SDRR = \sqrt{\frac{1}{N-1}\cdot\sum_{j=1}^{N}\left(RR_j - \overline{RR}\right)^2}$ (2) The standard deviation of all RR intervals.
3	RMSSD	$RMSSD = \sqrt{\frac{1}{N-1}\cdot\sum_{j=1}^{N-1}\left(RR_{j+1} - RR_j\right)^2}$ (3) The root mean square value of the difference between all neighboring RR intervals.
4	PRR	$PRR = max(RR_1、RR_2、\ldots、RR_n)$ (4) The peak value of all RR Intervals.
5	PNN50	$PNN50 = \frac{NN50}{N}\cdot 100$ (5) Percentage of the number of heartbeats where the difference between two neighboring RR intervals is greater than 50ms.
6	KRR	$KRR = \frac{diff(AVRR)}{diff(SDRR)}$ (6) The degree of bias and kurtosis of the RR interval signal.
7	SDHR	$SDHR = \frac{1}{N}\cdot\sqrt{\sum_{j=1}^{N}\left(60/RR_j - \overline{HR}\right)^2}$ (7) The standard deviation of heart rate.
8	LHFHRatio	$LFHFRatio = \frac{LF}{HF}$ (8) LF：Total power of 0.04 to 0.15Hz; HF：Total power of 0.15 to 0.4Hz.

C. Determining the Best Subset of Features

There is redundancy among the RR interval features, which affects the accuracy of classification [24-25], therefore feature selection is needed before classification. The backward feature elimination method used in this paper is a kind of greedy algorithm [26], which and obtains a feature set that has the smallest number of features and the highest correct classification rate. The specific process of the method is described as follows:

- Initialization: Determine the complete feature set containing all features.
- Random feature elimination: Randomly eliminate one feature from the feature set to form a new feature set.
- FCM feature clustering [27]: It make the new feature sample into n fuzzy clusters $X = \{x_1, x_2, \ldots, x_n\}$. Utilizing the fuzzy cluster's degrees of membership ranging from 0 to 1, iteratively optimize the objective function S to find the minimum value.

$$S(X, u_1, u_2, \ldots, u_c) = \sum_{k=1}^{n}\sum_{i=1}^{c}(v_{ik})^m (d_{ik})^2 \quad (9)$$

$$\begin{cases} u_i = \sum_{k=1}^{n}(v_{ik})^m x_k \,/\, \sum_{k=1}^{n}(v_{ik})^m \\ v_{ik} = 1/\sum_{i=1}^{n}(\frac{d_{ik}}{d_{jk}})^{\frac{2}{m-1}} \\ \sum_{i=1}^{n} v_{ik} = 1 \\ 0 \le v_{ik} \le 1 \\ d_{ik} = \|x_k - u_i\| \end{cases} \quad (10)$$

- u_i denotes the clustering centroid of the ith class; v_{ik} denotes the degree of membership between the kth sample and the ith class; d_{ik} denotes the euclidean distance between the center of the ith class and sample k. Compare the degree of membership $v_{ik}^{(b)}$ and $v_{ik}^{(b+1)}$, if $\|v_{ik}^{(b+1)} - v_{ik}^{(b)}\| \le \varepsilon$ (the given sensitivity threshold), it means that the objective function S has reached the minimal value, and the final clustering result has been obtained; otherwise, continue iterating until the convergence condition is satisfied.
- Calculate the clustering metrics: calculate the average intra-cluster compactness (AIC), average inter-cluster separation (AIS) and average silhouette coefficient (ASC) for each cluster.
- AIC indicates the degree of compactness of the sample points within the FCM clusters. The lower the value, the more compact the sample points within the clusters.

$$\begin{cases} AIC = \frac{1}{K} * \sum_{n=1}^{K} (IC)_n \\ IC = \frac{1}{N-1} * \sum_{i \ne j}^{N} d(i,j) \end{cases} \quad (11)$$

- Where N is the number of samples in the cluster, K is the number of clusters, and $d(i,j)$ is the distance between the ith sample and the jth sample, and IC denotes the average distance of each data point to the clustering center.
- AIS measures the separation between different clusters, and higher values indicate higher separation between different clusters, clearer boundary between clusters.

$$\begin{cases} AIS = \frac{1}{K} * \sum_{n=1}^{K} (IS)_n \\ IS = \frac{2}{K(K-1)} * \sum_{i \ne j}^{N} d(Ci, Cj) \end{cases} \quad (12)$$

- Here, $d(Ci, Cj)$ is the distance between the center of the ith cluster and the center of the jth cluster, and IS denotes the average distance between two clustering centers.
- AIS measures the separation between different clusters, and higher values indicate higher separation between different clusters, clearer boundary between clusters.

$$ASC = \frac{1}{M} * \sum_{i=1}^{M} \frac{IS(i) - IC(i)}{max\{IS(i), IC(i)\}} \quad (13)$$

- Here, M is the total number of samples, $IS(i)$ average distance between sample point i and all the samples in the nearest cluster, and $IC(i)$ denotes the average

distance between sample point i and the other samples within the same cluster.

- Determine the best feature subset: It compare the clustering metrics before and after the removal of features, if the metrics after the removal of features are increased, then continue to perform steps (2) ~ (4); otherwise, keep the feature. Go through remaining features until all the corresponding metrics are reduced, then stop the search process and determine the set of features before removal as the best feature subset.
- The overall flow chart of the backward feature elimination method is shown in Fig. 2.

D. Detecting Sleep Apnea

The best feature subset determined from the last step was used as input to the RF classifier, and the classification accuracy of SA was calculated using the 10-fold cross validation method and the confusion matrix.

- Extraction of the best feature subset. From the best feature subset D, n samples (sub-training set) are drawn randomly with put-back to form a new training set as samples at the root node of the decision tree. The remaining samples form the out-of-bag dataset (OOB) as the final test set.
- Attribute selection. Assume each sample has M attributes, m attributes are randomly selected from these M attributes when each node of the decision tree needs to be split (where m is less than M).
- Calculate the Gini index and node splitting. Assume A is an attribute of data set D. Attribute A has k different values $\{a_1, a_2, \dots a_k\}$. Under the condition $A = a_j (j = 1,2, \dots, k)$, the dataset D is partitioned into two parts D_1 and D_2, and the Gini index of this partition is:

$$Gini(D, A = a_j) = \frac{|D_1|}{n}\left(1 - \sum_{i=1}^{m}\left(\frac{|D_1|}{n}\right)^2\right) + \frac{|D_2|}{n}\left(1 - \sum_{i=1}^{m}\left(\frac{|D_2|}{n}\right)^2\right) \quad (14)$$

- Select the attribute with the smallest Gini index and its corresponding splitting node as the optimal attribute and optimal splitting node, generate two child nodes, and distribute the remaining training data into the two child nodes.
- Construct a random forest. Repeat step (3) in the sample subset of each child node, and recursively perform node splitting until all leaf nodes are generated; repeat (2) to (4) to obtain k different decision trees.
- Sleep apnea detection. Each decision tree performs a 10-fold cross validation calculation for each piece of data in the test set, and the category with the most votes in k classification results is the final category for that sample.

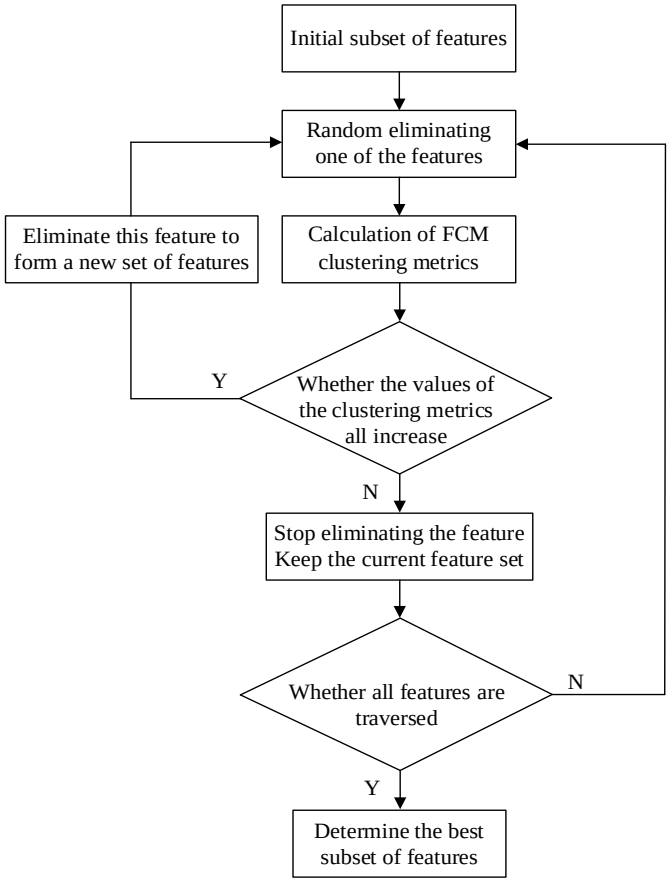

Fig. 2. Flowchart of backward feature elimination method.

E. Evaluation Criteria

The performance of the method was evaluated by calculating the metrics of accuracy, sensitivity and specificity for SA detection through a confusion matrix.

$$Accracy = \frac{TP+TN}{TP+TN+FP+FN} \quad (15)$$

$$Sensitivity = \frac{TP}{TP+FN} \quad (16)$$

$$Specificity = \frac{TN}{TN+FP} \quad (17)$$

Where TP denotes the number of true samples classified as positive (true positive); TN denotes the number of true samples classified as negative (true negative); FP denotes the number of false samples classified as positive (false positive); and FN denotes the number of false samples classified as negative (false negative).

III. Results

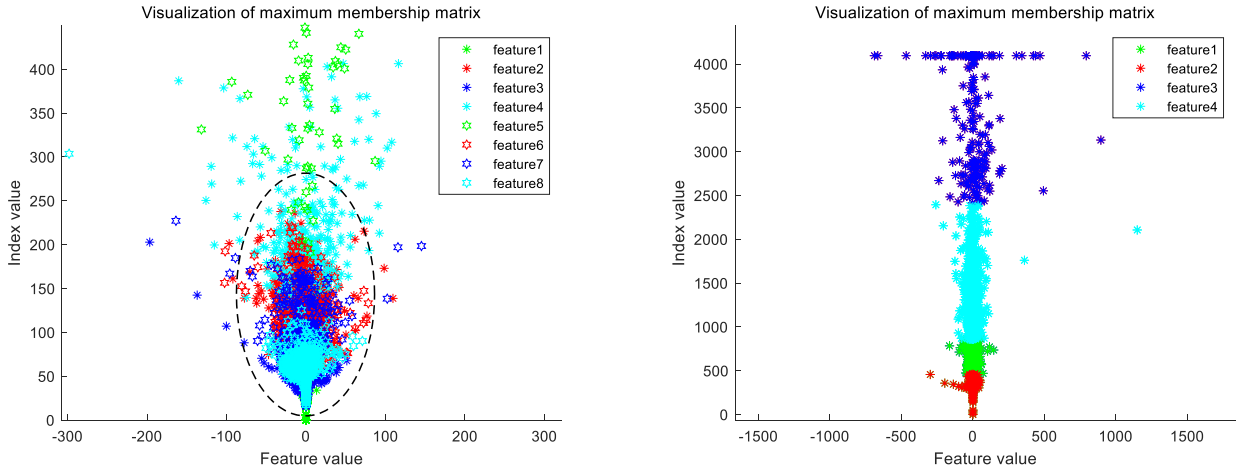
In this paper, 70 records from the Apnea-ECG database are used as experimental samples, and each ECG signal of these records is segmented into one-minute segment by annotation file. The RR interval features of ECG signals are extracted by Pan-Tompkins algorithm. The best subsets of features are selected using the backward feature elimination method as: AVRR, RMSSD, PRR and KRR.

In Fig. 3, by visualizing the membership matrix U, the membership distribution of the data points between the clusters before and after the removal of features are illustrated. The data membership distribution in Fig. 3(a) is more centralized, and the feature points have fuzzy attribution relationships among multiple clusters, which make it difficult to be clearly classified into specific clusters. In contrast, the distribution of data membership in Fig. 3(b) is more dispersed, and the attribution of feature points is more explicit and differentiated.

Features with greater divergence are more favorable, since they allow the classifier capture and represent the characteristic patterns of different types of SA events with higher accuracy.

The average intra-cluster tightness, average inter-cluster separation, and average contour coefficient were calculated before and after the removal of the features, and the two sets of features were input into RF classifier to evaluate the SA detection accuracy, as shown in Table II, respectively:

The above four RR period features were matched with apnea labels to reconstruct the database as input to the RF classifier, and the classification accuracy of SA detection is calculated using the 10-fold cross validation method and the confusion matrix. The performance comparison with existing studies using the Apnea-ECG dataset is given in Table III.



(a) Visualization of the affiliation matrix for 8 features

(b) Visualization of the affiliation matrix for 4 features

Fig. 3. Visualization results of the affiliation matrix of RR interval features.

TABLE II. Comparison of Clustering Metrics and SA Classification Performance before and after Feature Removal

Subset of features	Feature number	AIC	AIS	ASC	Acc (%)	Sen (%)	Spe (%)
Features before elimination	8	98.42	232.65	0.58	87.7	89.1	85.3
Features after elimination	4	190.44	816.17	0.77	88.6	90.5	85.5

TABLE III. Comparison of SA Detection Accuracy of Different Methods

Method	Feature number	Acc (%)	Sen (%)	Spe (%)
WA+HT [9]	40	90.5	84.9	93.7
EMD+RAS [9]	20	88.9	80.6	94.4
MLP [28]	18	81.4	74.3	85.7
SVM [29]	11	85.6	79.1	88.9
Proposed method	4	88.6	90.5	85.5

IV. DISCUSSION

As shown in Table II, the feature clustering metrics are all increased by using backward feature elimination, indicating that the optimal feature subset has greater variability and differentiation, which is consistent with the visualized membership matrix in Fig. 3 Inputting the features after elimination to the RF classifier yields a classification with higher accuracy, sensitivity, and specificity, it is shown that the method adaptively removes irrelevant features and reduces the dimensionality of the input features so that the RF classifier can better capture patterns and relationships in the data and improve the accuracy of the detection of SA.

Table III compares the SA detection results of different methods. Although the method based on WA and Hilbert transform can achieve the detection accuracy of up to 90.5%, the number of features used in it is as high as 40, which undoubtedly increases signal pre-processing process and the overall algorithm complexity. The methods based on EMD and redistributed spectra require half the number of features to achieve similar results, indicating that the nonlinear features calculated by the former do not play an important role in classification [9]. The number of hidden layers and neurons in the Multilayer Perceptron classifier depends on experience, and the detection accuracy of sleep apnea is only 81.4%. Support Vector Machine also has problems with optimization of regularization coefficient and kernel function parameters. Compared with the above method, the number of features used by SA is the least, but the detection performance is not ideal.

Under the same dataset, the accuracy of our method for SA detection is 88.6%, sensitivity is 90.5% and specificity is 85.5%. It outperforms other existing methods in terms of sensitivity, high sensitivity means that the model can detect as many true apnea events as possible, reducing the possibility of underreporting, and is comparable to WA and EMD methods in terms of accuracy. This method reduces the computation and storage requirements by selecting fewer and more discriminative features using the FCM method. Moreover, it improves the model's sensitivity to key information and enhances the robustness of the model.

The discussion and evaluation of proposed algorithm on different data sets will be carried out in the future. Driving by the need of integrating the algorithm into wearable devices, how to further improve the running speed and efficiency of the algorithm is our improving direction.

V. CONCLUSION

In this paper, an improved RF-based SA detection method is proposed. FCM and backward feature elimination method are used to select the RR interval features of ECG signals. And a small number of the best feature subsets with obvious differences are obtained as inputs to the RF classifier, which improve the sensitivity of the RF model to key information and obtain a better SA detection accuracy.

Graph Anomaly Detection with Graph Convolutional Networks

Aabid A. Mir, Megat F. Zuhairi, Shahrulniza Musa
Malaysian Institute of Information Technology, Universiti Kuala Lumpur, Kuala Lumpur, Malaysia

***Abstract*—Anomaly detection in network data is a critical task in various domains, and graph-based approaches, particularly Graph Convolutional Networks (GCNs), have gained significant attention in recent years. This paper provides a comprehensive analysis of anomaly detection techniques, focusing on the importance and challenges of network anomaly detection. It introduces the fundamentals of GCNs, including graph representation, graph convolutional operations, and the graph convolutional layer. The paper explores the applications of GCNs in anomaly detection, discussing the graph convolutional layer, hierarchical representation learning, and the overall process of anomaly detection using GCNs. A thorough review of the literature is presented, with a comparative analysis of GCN-based approaches. The findings highlight the significance of graph-based techniques, deep learning, and various aspects of graph representation in anomaly detection. The paper concludes with a discussion on key insights, challenges, and potential advancements, such as the integration of deep learning models and dynamic graph analysis.**

***Keywords*—Anomaly detection; deep learning; dynamic graphs; Graph Convolutional Networks (GCNs); Graph Neural Networks (GNNs); network data**

I. Introduction

Graph anomaly detection has gained significant attention in various domains, including insider threat detection, fraud detection, and network security [1]. The increasing prevalence of complex network data, such as social networks, financial transactions, and blockchain networks, has posed challenges for traditional anomaly detection approaches in capturing the inherent structural dependencies and contextual information encoded in graph-structured data [2]. As a result, there has been a growing interest in leveraging deep learning techniques, particularly graph convolutional networks (GCNs), to address these limitations and achieve more effective anomaly detection [3]. The primary objective of graph anomaly detection is to identify abnormal patterns, behaviors, or entities within a given graph. This involves analyzing the connections, relationships, and attributes of the nodes and edges in the graph to distinguish between normal and anomalous instances [4]. Deep learning-based approaches, especially GCNs, have shown promising results in capturing the complex dependencies and learning meaningful representations from graph-structured data [2].

In this paper, we aim to provide a comprehensive introduction to graph anomaly detection, with a particular focus on GCN-based methods. We will discuss the foundational concepts and techniques in anomaly detection, highlighting the unique challenges posed by graph-structured data. Additionally, we will look into the advancements made in the field, with a specific focus on the utilization of GCNs for modeling and analyzing graphs. We will explore how GCNs leverage graph convolutions to propagate information between nodes, enabling them to capture both local and global structural information.

This study analyzes the field of graph-based anomaly detection in network data in the subsequent sections, beginning with the background and motivation in Section II. Section III explores the details of anomaly detection in network data, establishing the foundation for an in-depth comprehension of its complexities. Section IV then expands on the fundamental backbone of this study, Graph Convolutional Networks (GCNs), providing insights into its structure and pivotal role in anomaly detection. Section V, describes the methodology used for analysis. Section VI then presents a comprehensive overview of the existing literature, focusing on GCN-based techniques and their comparative analysis. Section VII summarizes the findings and conclusions obtained from the review and the discussion section VIII discusses the essential insights, limitations, and issues encountered in graph-based anomaly detection, answering the three research questions of this study. Section IX provides a concise summary of the findings and future research prospects. Finally, in Section X, the conclusion summarizes the findings and implications established during the study.

II. Background and Motivation

Graph anomaly detection has emerged as a critical task in various domains, including network security, fraud detection, and anomaly monitoring in dynamic systems. Traditional methods often rely on handcrafted features or statistical techniques, which may lack the ability to capture complex patterns and hidden anomalies. In recent years, the advent of deep learning and graph convolutional networks (GCNs) has provided new opportunities for more effective and automated graph anomaly detection [1] [5].

The motivation behind this research stems from the growing need to develop advanced techniques that can effectively detect anomalies in complex graph-structured data. With the increasing scale and complexity of real-world networks, there is a pressing demand for anomaly detection methods that can handle large-scale graphs and capture intricate relationships between entities [4] [45]. By leveraging the power of GCNs and deep learning, it is possible to extract high-level representations from graphs and capture both local and global patterns, leading to more accurate and robust anomaly detection [6].

III. Anomaly Detection in Network Data

A. Overview of Anomaly Detection Techniques

Anomaly detection is a critical task in network data analysis, aiming to identify abnormal patterns or behaviors that deviate from the expected norm. Various techniques have been proposed to tackle this problem. Traditional approaches include statistical methods, clustering algorithms, and rule-based systems [1] [2]. However, these methods often struggle to capture complex dependencies and subtle anomalies in large-scale network data. Recent advancements in deep learning and graph theory have led to the emergence of novel anomaly detection techniques that leverage the structural information of networks. These techniques have shown promising results in detecting anomalies in diverse domains, including cybersecurity, fraud detection, and insider threat detection [5].

B. Importance and Challenges of Network Anomaly Detection

Network anomaly detection plays a vital role in maintaining the security and integrity of network systems. Anomalies in network data can indicate malicious activities, system failures, or emerging threats. However, detecting anomalies in complex networks poses several challenges. First, networks often exhibit dynamic behavior, making it difficult to distinguish between normal fluctuations and anomalous events [6]. Second, network data is high-dimensional and heterogeneous, containing various attributes and interdependencies. Third, anomalies can manifest in different forms, such as structural changes, attribute deviations, or unusual patterns. These challenges highlight the need for advanced anomaly detection techniques that can effectively capture the complex characteristics of network data and adapt to evolving network dynamics [7] [8] [9]. Furthermore, the work of [11] proposes new approaches to address these challenges.

C. Graph-based Anomaly Detection Methods

Graph-based anomaly detection methods have gained significant attention due to their ability to model and exploit the inherent structure of network data. These methods represent network data as graphs, where nodes represent entities (e.g., users, devices) and edges capture relationships or interactions. By leveraging graph theory and network analysis techniques, graph-based anomaly detection methods can effectively capture local and global dependencies, identify abnormal patterns, and distinguish between different types of anomalies [12]. These methods often utilize graph-based features, such as node degrees, clustering coefficients, and centrality measures, to detect anomalies [5]. Furthermore, [21] introduced a novel graph-based anomaly detection algorithm that incorporates additional attributes and contextual information associated with nodes and edges.

D. Introduction to Graph Convolutional Networks (GCNs)

Graph Convolutional Networks (GCNs) have emerged as a powerful deep learning technique for graph-based anomaly detection [13]. GCNs extend convolutional neural networks (CNNs) to operate directly on graph-structured data. They leverage a localized aggregation scheme, where each node aggregates information from its neighboring nodes, capturing the graph's structural properties. By stacking multiple graph convolutional layers, GCNs can capture hierarchical representations of the network data [14]. This hierarchical representation allows GCNs to learn discriminative features and identify anomalous patterns in the network. Moreover, GCNs can handle attributed graphs, where additional features are associated with nodes or edges, enabling the integration of both structural and attribute information for more accurate anomaly detection [11] [16]. The researchers in [41] propose an enhanced version of GCNs for graph-based anomaly detection.

IV. Graph Convolutional Networks (GCNs)

A. Fundamentals of Graph Convolutional Networks (GCNs)

Graph Convolutional Networks (GCNs) have emerged as a powerful deep learning technique for analyzing graph-structured data. GCNs extend the convolutional operation from regular grids, such as images, to irregular graph structures, enabling effective representation learning and analysis of complex relational data [48]. Graph Convolutional Networks provide a powerful framework for learning representations and analyzing graph-structured data. Through graph convolutional layers, spectral-based or spatial-based approaches, and effective training techniques, GCNs enable deep learning on complex relational data, offering promising solutions in diverse application domains [47] [49].

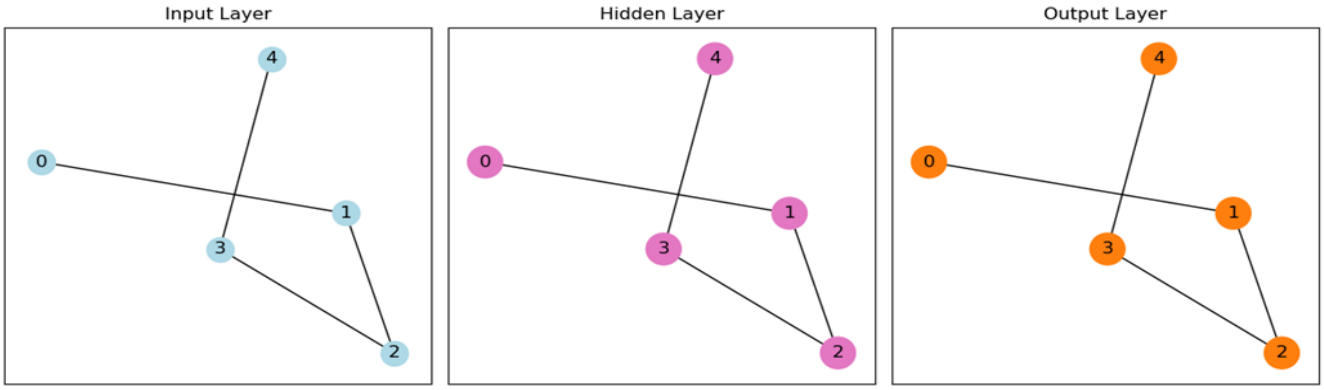

Fig. 1. Graph Convolutional Network (GCN) applied to a sample graph.

B. Graph Representation

A graph is a mathematical representation that consists of nodes and edges, where nodes represent entities or elements, and edges capture relationships or connections between nodes. Graphs are widely used to model various real-world systems, such as social networks, citation networks, and biological networks. Formally, a graph can be represented as G = (V, E), where V denotes the set of nodes and E represents the set of edges connecting pairs of nodes [47].

C. Graph Convolutional Operations

The core operation in GCNs is the graph convolution, which generalizes the convolutional operation to graph-structured data. In traditional convolutional neural networks (CNNs), convolutions are performed on regular grids using fixed-size filters. In contrast, GCNs leverage the graph structure to define a neighborhood aggregation scheme. Given a graph G = (V, E) with node features $X \in R^{N \times D}$, where N is the number of nodes and D is the feature dimension, the graph convolution operation aims to update the node representations by aggregating information from their neighboring nodes [48].

D. Graph Convolutional Layer

The graph convolutional layer is the building block of GCNs. It combines the graph convolution operation with non-linear transformations to learn expressive node representations. The output of a graph convolutional layer can be computed as $H = \sigma(AXW)$, where $H \in R^{N \times F}$ is the output matrix of node representations, A is the adjacency matrix that encodes the graph structure, X is the input node feature matrix, W is the learnable weight matrix, and σ denotes the activation function. By iteratively stacking multiple graph convolutional layers, GCNs can capture increasingly complex and abstract features [48].

E. Spectral-based and Spatial-based Approaches

GCNs can be categorized into spectral-based and spatial-based approaches based on the underlying mathematical framework. Spectral-based GCNs leverage the graph Laplacian matrix to transform the graph convolution operation into the spectral domain, where the eigenvectors of the Laplacian matrix serve as the basis for filtering the node features. Spatial-based GCNs, on the other hand, operate directly on the spatial relationships between nodes without relying on the eigenvalue decomposition. They typically employ local neighborhood aggregation schemes to capture information propagation on the graph [45] [46].

F. Training and Learning

GCNs are trained using labeled data through a supervised learning process. The training objective typically involves minimizing a loss function that measures the discrepancy between the predicted labels and the ground truth labels. To mitigate overfitting and enhance generalization, regularization techniques such as dropout and weight decay can be applied. Moreover, the backpropagation algorithm, coupled with gradient descent optimization, is employed to update the parameters of the GCN model iteratively [48].

G. GCNs in Anomaly Detection

Graph Convolutional Networks (GCNs) have gained significant attention in anomaly detection due to their ability to capture complex relational information and extract meaningful features from graph-structured data. GCNs leverage graph convolution operations to propagate information among nodes and learn node representations that encode both local and global structural characteristics of the graph. By exploiting the relational dependencies encoded in the graph, GCNs can effectively capture complex patterns and identify anomalies that would be challenging to detect using traditional methods. Several studies have demonstrated the effectiveness of GCNs in anomaly detection across various domains, such as insider threat and fraud detection [1], Ethereum blockchain network [5], and network anomaly detection [7]. Researchers have explored techniques like adaptive graph convolutional layers, local and global aggregation strategies [4], data augmentation [8], and community detection [9] to enhance the performance of GCNs in anomaly detection. Continued research aims to develop novel GCN architectures and techniques to further improve accuracy and robustness in diverse application domains.

Fig. 1 represents a Graph Convolutional Network (GCN) model applied to a sample graph. The visualization consists of three subplots: the input layer, the hidden layer, and the output layer. In the input layer, nodes are shown as circles with light blue colors representing the input features. In the hidden layer, nodes are colored based on the features extracted by the GCN model using the 'coolwarm' colormap. Finally, in the output layer, nodes are colored according to the predicted class labels using the 'Set1' colormap. This visualization helps understand how the GCN model transforms the input features, captures meaningful representations in the hidden layer, and makes predictions in the output layer, providing insights into the model's inner workings. Anomaly detection using GCNs involves computing anomaly scores, which quantify the likelihood of an anomaly, by comparing predicted representations with reconstructed representations. Training on labeled data allows GCNs to learn normal patterns and discriminate between normal instances and anomalies. The mathematical equations that underpin GCN-based anomaly detection provide a formal framework for understanding the key components of the approach.

1) Graph convolutional layer: Node Representation Update: The update rule for a single graph convolutional layer can be defined as:

$$h_v^{(l+1)} = \sigma\left(\sum_u \quad h_u^{(l)} W^{(l)}\right) \qquad (1)$$

Here,

$h_u^{(l)}$ represents the representation of node *v* at layer *l*,

$W^{(l)}$ denotes the learnable weight matrix at layer *l*,

σ is an activation function, and the sum is taken over the neighboring nodes *u* of *v*.

2) Hierarchical representation learning: Stacked Graph Convolutional Layers: Multiple layers of graph convolutions

can be stacked to capture increasingly complex patterns and higher-order relationships. The hierarchical representation learning can be expressed as,

$$h_v^{(L)} = GCN(h_v^{(L-1)}, A) \quad (2)$$

Here,

$h_v^{(L)}$ represents the final representation of node *v* after *L* layers of graph convolutions,

GCN denotes the graph convolutional operation, and

A is the adjacency matrix representing the graph structure.

3) Anomaly detection anomaly score calculation: Anomaly detection can be performed by computing anomaly scores for nodes based on their predicted representations and reconstructed representations. The anomaly score can be calculated as:

$$s_v = f(h_v^{(L)}, h_v^{(L")}) \quad (3)$$

Here,

s_v represents the anomaly score assigned to node *v*,

$h_v^{(L)}$ is the predicted representation of node *v* using the GCN,

$h_v^{(L")}$ is the reconstructed representation of node *v*, and

f is a function that measures the difference between the predicted and reconstructed representations.

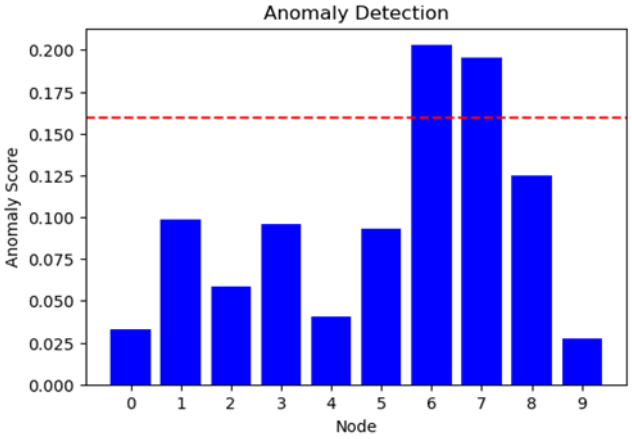

Fig. 2. Bar chart visualization of the anomaly detection results, allowing for quick identification of nodes with higher anomaly scores and potential outliers in the graph.

Fig. 2 provides a visualization of anomaly scores for each node in the graph. The x-axis represents the nodes, numbered from 0 to 9, and the y-axis represents the anomaly scores. The height of each bar corresponds to the anomaly score of the respective node.

The blue bars in the chart represent the anomaly scores of the nodes, indicating the level of deviation from the expected pattern. Higher bars indicate higher anomaly scores, suggesting nodes with more significant deviations. The red dashed line represents the anomaly threshold, separating the nodes into normal and anomalous categories. Nodes above the threshold are considered anomalous, while nodes below the threshold are considered normal.

4) Training and evaluation training on labeled data: GCNs can be trained on a labeled dataset containing normal and anomalous instances to learn to distinguish between them. The training objective can be defined as:

$$min \sum \quad Loss(y_v, GCN(h_v^{(L)}, A)) \quad (4)$$

Here, Loss is a loss function that compares the predicted labels y_v^ with the ground truth labels, and the sum is taken over all nodes in the training dataset.

V. Methodology

This systematic literature review (SLR) follows the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) [10] guidelines to investigate the topic of "Graph Anomaly Detection with Graph Convolutional Networks." Fig. 3 shows the PRISMA flow diagram. The purpose of this SLR is to provide a comprehensive analysis and synthesis of the existing literature on the application of graph convolutional networks (GCNs) for detecting anomalies in graph-structured data.

A. Research Questions

The following research questions guide this review:

RQ1. What are the current approaches and techniques for graph anomaly detection using GCNs?

RQ2. What are the challenges and limitations of existing GCN-based graph anomaly detection methods?

RQ3. What are the emerging trends and future directions in this field?

B. Search Strategy

Our search strategy, which initially relied on automated techniques using logical operators, was followed by rigorous manual curation. We have exercised our expertise to select articles that met our stringent criteria for quality and relevance. This dual approach ensures the inclusion of the most relevant and high-quality sources. A systematic search was conducted in major academic databases, including IEEE Xplore, ACM Digital Library, Springer, Elsevier, Scopus, and Google Scholar. The search terms used included variations of "graph anomaly detection," "graph convolutional networks," "graph neural networks," and "anomaly detection in graph data." The search was limited to articles published between 2019 and 2023.

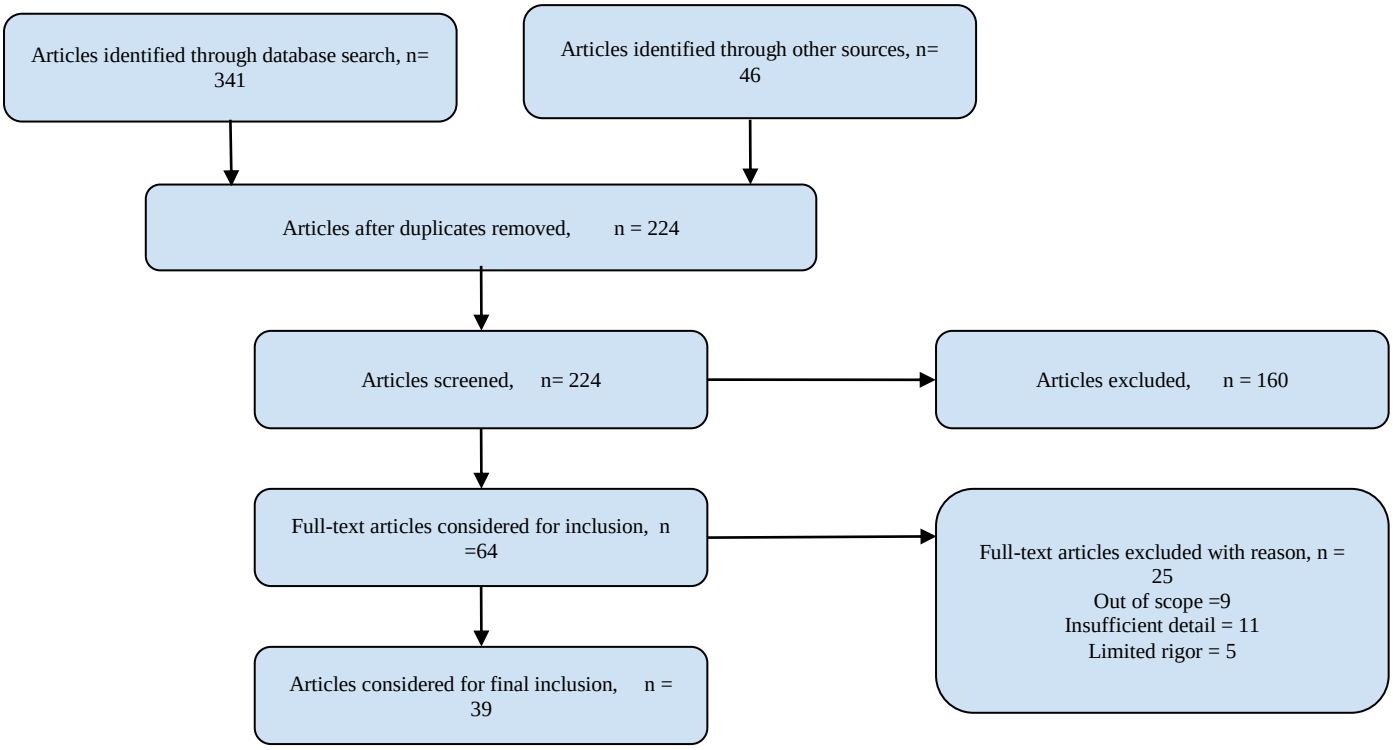

Fig. 3. PRISMA flow diagram.

C. Study Selection

The inclusion and exclusion criteria were defined to ensure the relevance and quality of the studies. Included studies were required to:

- Focus on the application of GCNs for graph anomaly detection.
- Present novel methodologies, techniques, or frameworks.
- Include evaluation metrics and datasets.
- Be published in peer-reviewed journals or conference proceedings.

Studies that did not meet the inclusion criteria, such as review articles, tutorials, or studies unrelated to graph anomaly detection, were excluded.

D. Data Extraction

Data from the selected studies were extracted using a standardized form. The extracted information included:

- Author(s) and publication details.
- Key contributions.
- Methodologies, techniques, and algorithms used.
- Datasets employed for evaluation.
- Evaluation metrics and performance results.
- Limitations and future research.

E. Data Synthesis

A qualitative synthesis was performed to analyze the findings from the selected studies. The key themes, methodologies, challenges, and trends in graph anomaly detection with GCNs were identified. The studies were analyzed to identify commonalities, differences, and gaps in the existing literature.

F. Quality Assessment

The quality and rigor of the selected studies were assessed using predefined criteria. The criteria included aspects such as research design, clarity of methodology, use of appropriate datasets, and statistical analysis.

G. Results Presentation

The findings of this SLR will be presented in a narrative format, organized thematically based on the identified research areas, methodologies, challenges, and trends. The results will be accompanied by tables, figures, and visual representations to enhance understanding and facilitate comparisons.

H. Limitations

The limitations of this SLR include potential publication bias, language limitations, and the possibility of missing relevant studies despite the comprehensive search strategy.

VI. Review of Literature

A. Overview of Selected Studies

Anomaly detection has become a critical task in various domains, such as cybersecurity, finance, healthcare, and industrial systems. Researchers have been investigating the

use of graph-based methods for anomaly detection, leveraging the power of graph neural networks (GNNs) and deep learning techniques. A comprehensive survey by [2] provides an extensive overview of graph anomaly detection with deep learning, highlighting the advancements and challenges in this field. Several studies have focused on leveraging GNNs for anomaly detection, such as the work by [1], who proposed using graph convolutional networks (GCNs) for insider threat and fraud detection. The researchers in [3] also explored graph anomaly detection with graph neural networks, discussing the current state and challenges in this area. Various approaches have been proposed to enhance the performance of graph anomaly detection. For instance, Ding and Li (2022) presented AnoGLA, an efficient scheme for improving network anomaly detection, while [5] developed a graph deep learning-based anomaly detection model specifically for Ethereum blockchain networks. The researchers in [6] introduced graph fairing convolutional networks for anomaly detection, aiming to address the fairness issue in graph-based models. The researchers in [7] proposed a rethinking of graph neural networks for anomaly detection, exploring novel architectures and techniques. The researchers in [8] developed DAGAD, a data augmentation method for graph anomaly detection, to enhance the performance of anomaly detection models. Furthermore, researchers have focused on incorporating domain-specific features and knowledge into graph anomaly detection. The researchers in [9] proposed COMGA, a community-aware attributed graph anomaly detection method that considers community structures in graphs. The researchers in [11] introduced GCCAD, a graph contrastive learning approach for anomaly detection, which leverages the contrastive learning framework. The researchers in [13] developed a high accuracy and adaptive anomaly detection model using a dual-domain graph convolutional network for insider threat detection. The researchers in [18] proposed Guard Health, a secure data management system that combines blockchain technology with graph convolutional networks for anomaly detection in smart healthcare. The literature also includes studies focusing on temporal aspects of graph anomaly detection. For example, the paper [19] addressed motif-level anomaly detection in dynamic graphs, while [21] proposed structural temporal graph neural networks for anomaly detection in dynamic graphs. The researchers in [41] introduced a multi-scale contrastive learning network with augmented view for graph anomaly detection. The researchers in [39] presented a synergistic approach that combines pattern mining and feature learning for graph anomaly detection. The researchers in [44] explored addressing heterophily in graph anomaly detection by considering the graph spectrum.

These selected studies highlight the diverse approaches and advancements in graph anomaly detection using deep learning techniques. From leveraging GNNs and GCNs to incorporating domain-specific knowledge and addressing temporal aspects, researchers are continuously striving to improve the accuracy and effectiveness of graph-based anomaly detection methods.

B. Comparative Analysis of GCN-based Approaches

A comprehensive comparative analysis of various Graph Convolutional Network GCN-based approaches for anomaly detection is presented in this section. The analysis is conducted in a tabular format, considering several key parameters to evaluate and compare the different approaches. The parameters include the reference source, graph type, method, category, objective function employed, measurement metrics used for evaluation, and the outputs of the approaches. This comparative analysis provides insights into the similarities, differences, and effectiveness of different GCN-based approaches in addressing anomaly detection tasks. By examining these parameters, we aim to identify the strengths and limitations of each approach, facilitating a better understanding of their performance and applicability in real-world scenarios.

Table I provides an analysis of various studies focused on anomaly detection using graph-based approaches. It includes information about the types of graphs used, specific methods employed, categories of anomaly detection, objective functions used measurement metrics for evaluation, and the outputs of these approaches. The table offers a comprehensive overview of different studies, highlighting their techniques, evaluation criteria, and intended applications. These studies utilize diverse types of graphs, such as attribute graphs, social graphs, blockchain transaction graphs, dynamic graphs, etc., and employ methods like Graph Convolutional Networks (GCNs), graph deep learning, community-aware attributed graph anomaly detection, contrastive learning, among others. The evaluation metrics primarily consist of precision, recall, F1-Score, AUC-ROC, and accuracy, showcasing the effectiveness of these approaches in detecting anomalies across various domains and graph types.

C. Gaps in the Existing Literature

The existing scenario of graph-based anomaly detection has advanced significantly, employing machine learning, specifically Graph Convolutional Networks (GCNs), to identify complex relationships and patterns. However, persistent constraints highlight critical gaps in existing literature. Scalability concerns [39] exist in large-scale graph processing, demanding more efficient techniques for real-time anomaly detection. The reliance on domain expertise [1] to perform feature engineering poses challenges, reducing detection accuracy. Existing approaches are mostly focused on static graphs, making it difficult to capture dynamic patterns adequately [27]. Heterogeneous graph structures [4] present modeling and analysis challenges, requiring advanced integration of various data sources. Furthermore, the interpretability [9] of graph-based models, such as GCNs, is still a challenge. These challenges and limitations will be examined in detail in the subsequent section. Addressing these limitations represents a significant gap in current understanding, necessitating the development of novel methodologies to improve scalability, reduce dependability on expertise, manage dynamic graphs effectively, accommodate heterogeneous structures, and enhance model interpretability, establishing the possibility of robust anomaly detection in real-world scenarios.

TABLE I. ANALYSIS OF INCLUDED STUDIES

Reference	Graph Type	Method	Category	Objective Function	Measurement	Outputs
Jiang et al. (2019) [1]	Attribute Graph	Graph Convolutional Networks (GCNs)	Insider Threat, Fraud	Binary Cross-Entropy Loss	Accuracy, Precision, Recall, F1-Score	Anomaly Detection

VII. RESULTS

A. Summary of Reviewed Studied

An overview of the percentage-wise distribution of literature based on the parameters; anomaly detection, graph-based techniques, machine/deep learning, static graphs, dynamic graphs, and graph representation, is presented in the form of a pie chart (see Fig. 4). This comprehensive analysis offers valuable insights into the common practices and trends in the field.

1) Anomaly detection: Anomaly detection is a crucial aspect addressed in all the included studies, indicating its significance in identifying and flagging unusual patterns or events. This aligns with the primary objective of anomaly detection, which is to distinguish abnormal behavior from normal patterns in various domains such as cybersecurity, fraud detection, and system monitoring

2) Graph-based techniques: Graph-based techniques emerge as a prominent approach across the included studies, illustrating their effectiveness in capturing complex relationships and structures within data. These techniques leverage graph representations to model interconnected entities and interactions, enabling the detection of anomalies based on their deviations from the expected graph patterns.

3) Machine/Deep learning: Machine and deep learning methods are predominantly utilized across the literature,

showcasing their ability to handle large volumes of data and extract meaningful patterns. These techniques leverage neural networks and advanced algorithms to learn complex representations and detect anomalies based on the learned patterns.

4) Static graphs: Static graphs, which represent pre-defined structures, are widely employed in the literature to model relationships and dependencies. These static graph representations enable the analysis of anomalies by comparing observed patterns against expected graph structures.

5) Dynamic graphs: In contrast, the adoption of dynamic graphs, which capture time-dependent interactions, is relatively limited in the included literature. Most studies focus on analyzing static relationships rather than temporal variations, leaving an opportunity for future research and development in this area.

6) Graph representation: The inclusion of graph representation is prevalent across the literature, indicating its significance in organizing and structuring data for efficient anomaly detection. Graph representations facilitate the identification of abnormal patterns by capturing the relationships and dependencies among entities in a structured manner.

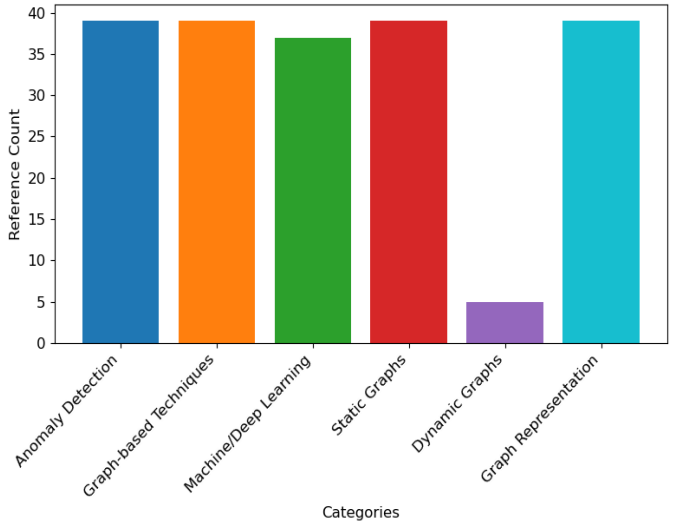

Fig. 4. Distribution of included studies based on given parameters.

B. Publication Trends in Graph-Based Anomaly Detection

The analysis of year-wise publication trends in graph-based anomaly detection, with a focus on Graph Convolutional Networks (GCN), among the included studies since 2019 reveals an interesting pattern as shown in Fig. 5. There has been a steady growth in the number of publications on this topic over the years, indicating the increasing importance and popularity of graph-based anomaly detection techniques. Specifically, since 2019, there has been a surge in research papers incorporating GCNs as a key component in detecting anomalies within graph structures. By the end of 2023, it is expected to surpass the number of publications in the year 2022. This trend suggests that researchers have recognized the power and effectiveness of GCNs in modeling complex relationships and capturing anomalous patterns within graphs. The utilization of GCNs reflects the continuous effort to leverage advanced machine/deep learning techniques to enhance anomaly detection performance in graph-based scenarios. This trend highlights the ongoing interest and active research in the field, with a focus on advancing graph-based anomaly detection methods using GCNs as a key tool.

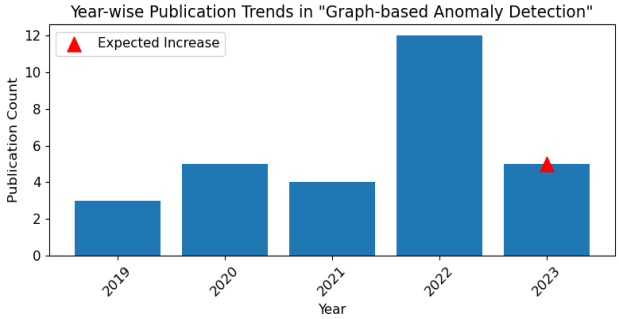

Fig. 5. Year-wise publication trends in graph-based anomaly detection.

VIII. Discussion

A. Key Insights and Observations

Graph-based anomaly detection has seen significant advancements in recent years. Machine learning, particularly deep learning, has emerged as a major approach in graph-based anomaly detection, enabling accurate detection by leveraging neural networks to capture complex relationships and patterns [1] [4]. Graph convolutional networks (GCNs) have been developed to effectively model graph structures and detect anomalies [9]. Graph representations play a crucial role in graph-based anomaly detection, and different approaches utilize various representation techniques [12]. These techniques include adjacency matrices, node features, edge features, or a combination of these [11]. By leveraging these representations, graph-based anomaly detection algorithms can effectively model normal behavior and detect deviations [27]. Graph-based anomaly detection encompasses various techniques, such as centrality-based methods, clustering-based methods, spectral methods, and local anomaly detection methods [32] [27]. Centrality-based methods identify nodes with high centrality measures as potential anomalies [31]. Clustering-based methods group nodes based on similarity and identify anomalies as nodes that do not fit into any cluster [27]. Spectral methods utilize the graph Laplacian matrix to identify anomalous patterns in the eigenvector space [32]. Local anomaly detection methods analyze local patterns and identify anomalies based on their deviation from local structures [11]. While graph-based anomaly detection has shown promise, dynamic graphs pose challenges [27]. Dynamic graphs involve evolving structures, requiring techniques that can handle the temporal dimension and capture evolving patterns [41] [43]. Developing algorithms that can effectively adapt to changing graph structures and identify anomalies in a dynamic setting remains a challenge [27].

Graph-based anomaly detection has witnessed significant advancements through machine/deep learning techniques and the utilization of various graph representations. Different techniques, such as centrality-based, clustering-based,

spectral, and local anomaly detection methods, contribute to the detection of anomalies. However, the challenges posed by dynamic graphs necessitate the development of innovative approaches to handle evolving structures and capture temporal patterns. Further research in this field will contribute to the advancement of graph-based anomaly detection techniques and their application in real-world scenarios.

B. Challenges and Limitations of Graph-Based Approaches

The challenges and limitations of graph-based approaches in anomaly detection include scalability issues, the requirement of domain expertise for manual feature engineering, handling imbalanced datasets, addressing the dynamic nature of graphs, heterogeneity and ensuring interpretability of the models. Overcoming these challenges will enhance the effectiveness and applicability of graph-based anomaly detection techniques in various real-world scenarios.

1) Scalability: One of the challenges in graph-based anomaly detection is the scalability issue when dealing with large-scale graphs [39]. As the size of the graph increases, the computational complexity of graph algorithms grows significantly, making it challenging to detect anomalies efficiently. Efficient algorithms and techniques are required to handle large-scale graphs and maintain real-time anomaly detection.

2) Domain expertise: Another challenge is the requirement of domain expertise and manual feature engineering [1]. Graph-based approaches often rely on feature extraction and selection, which demand expert knowledge and a deep understanding of the underlying graph structure. Manual feature engineering can be time-consuming and may not capture all relevant information, limiting the accuracy of anomaly detection.

3) Imbalanced datasets: Furthermore, graph-based approaches face challenges in handling imbalanced datasets [27]. Anomalies are typically rare events, resulting in imbalanced classes where the number of normal instances outweighs the number of anomalies. Imbalanced datasets can lead to biased models and reduced performance in detecting anomalies. Techniques such as data augmentation, oversampling, or adjusting the anomaly detection threshold are required to address this issue.

4) Dynamic graphs: The dynamic nature of graphs poses another significant challenge [27]. Dynamic graphs involve changing network structures over time, making it essential to develop techniques that can adapt to evolving patterns [43]. Handling temporal dependencies, capturing time-varying behaviors, and maintaining real-time detection in dynamic graphs remain active areas of research [35] [36] [37] [38] [39].

5) Heterogeneity: Heterogeneous graphs pose additional challenges in graph-based anomaly detection [4]. Heterogeneous graphs consist of multiple types of nodes and edges, representing diverse entities and relationships within a system or network. The presence of different node and edge types introduces complexity in modeling and analyzing the graph structure. Heterogeneous graphs often involve diverse data types, such as textual data, numerical attributes, or temporal information associated with different node types. The effective fusion and utilization of these heterogeneous data sources for anomaly detection require careful consideration and feature engineering techniques [37] [38] [39].

6) Interpretability: The interpretability of graph-based approaches is another limitation [9]. Deep learning models, such as graph convolutional networks (GCNs), often act as black boxes, making it challenging to understand the factors contributing to anomaly detection. Interpretability is crucial for building trust in the models and gaining insights into the detected anomalies.

C. Potential Advancements and Future Research Directions

1) Integration of deep learning: The integration of deep learning models has emerged as a promising approach in graph-based anomaly detection, enabling more effective and accurate detection of anomalies in complex graph structures. Several studies in the included literature have explored the integration of deep learning models in this context.

The researchers in [27] highlighted the effectiveness of deep learning models in graph-based anomaly detection. They emphasized that deep learning models, such as Graph Convolutional Networks (GCNs), can capture intricate relationships and patterns in graphs, leading to improved anomaly detection performance. The work carried out in [5] specifically mentioned the use of GCNs in anomaly detection. They highlighted the ability of GCNs to aggregate information from neighboring nodes, enabling the model to capture local graph structures and identify anomalous patterns. The study by [4] also discussed the integration of deep learning models in graph-based anomaly detection. They highlighted the potential of deep learning models, such as autoencoders (AEs) and recurrent neural networks (RNNs), in capturing complex patterns and anomalies in graphs. Moreover, [9] proposed a deep learning-based method for anomaly detection in graphs. They introduced a deep autoencoder model that leverages the expressive power of deep learning to learn robust representations of graph data and detect anomalies based on reconstruction errors. These studies collectively demonstrate the growing interest in leveraging deep learning models, particularly GCNs and autoencoders, for graph-based anomaly detection. The integration of deep learning models provides the capability to effectively capture and analyze complex graph structures, enhancing the detection performance and enabling the detection of subtle anomalies that may be challenging for traditional methods. By harnessing the power of deep learning, these approaches offer the potential to improve the accuracy and scalability of anomaly detection in various domains, including cybersecurity, social networks, biological networks, transportation networks, and other applications where graph-based data is prevalent.

The integration of deep learning models in graph-based anomaly detection represents an exciting research direction that holds promise for future advancements in the field.

2) Dynamic graph analysis: Let $G = (V,E,T)$ be a dynamic graph, where V represents the set of vertices, E represents the set of edges, and T represents the set of timestamps. We aim to detect anomalies in this dynamic graph.

For each timestamp $t \in T$ we denote the graph at time t as $G_t = (V_t, E_t)$, where V_t is the set of vertices at time t and E_t is the set of edges at time t. We assume that the graph evolves over time, and the vertex and edge sets can change at different timestamps. The anomaly detection problem in dynamic graphs can be formulated as finding a function $f : G \rightarrow \{0,1\}$, where $f(G) = 1$ indicates an anomaly in the graph and, $f(G) = 1$ indicates a normal graph. The temporal aspect of the network must be considered, as nodes and edges can appear, disappear, or change over time. Fig. 6 represents a dynamic network with 500 nodes, where each node appears at a different time point. The x and y coordinates of the nodes correspond to their respective node IDs. The color of each node represents its timestamp, with earlier nodes being displayed in cooler colors (e.g., yellow) and later nodes in warmer colors (e.g., red). The graph starts with the first node appearing at time point 0 and gradually increases to the last node appearing at time point 499. The edges between nodes connect consecutive nodes, forming a linear structure. The colorbar on the right side of the plot indicates the mapping between the timestamp values and the corresponding colors. The goal is to design a suitable algorithm or model that can accurately detect anomalies in the dynamic graph based on the evolving vertex [43] and edge sets at different timestamps.

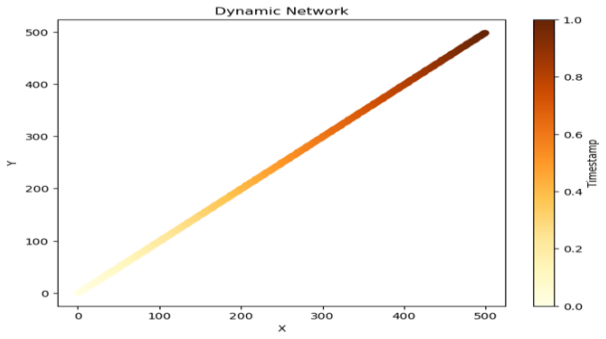

Fig. 6. Graphical representation of a dynamic network where each node appears at a different time point.

The existing research primarily focuses on the detection of anomalies in simple graphs. However, real-world networks are significantly more intricate and exhibit diverse characteristics [24]. These include heterogeneous graphs with multiple node types [38] [39], spatio-temporal graphs that evolve with time [35], and hypergraphs with non-pairwise relations [36]. Detecting and predicting anomalies in such complex graphs pose significant technical challenges [4]. For instance, the dynamic nature of nodes and links in real-world networks means that anomalous entities or relationships can sometimes exhibit normal behaviors similar to other entities in static networks. As a result, the accuracy of anomaly detection methods diminishes [4]. Consequently, key challenges persist in effectively modeling the temporal characteristics of dynamic networks and updating real-time graph embeddings. Additionally, in the context of heterogeneous graph anomaly detection, the incorporation of both attribute and structure information pertaining to various types of nodes and edges into the graph learning model represents an open research problem [11] [27] [37].

Hence, there remains ample scope for further exploration of anomaly detection and prediction on complex graphs as an important avenue for future research highlighting the importance of dynamic graph analysis in understanding and detecting anomalies in evolving systems.

IX. Summary

This systematic literature review focuses on anomaly detection in network data, with a particular emphasis on graph-based approaches, specifically Graph Convolutional Networks (GCNs). The paper discusses the fundamentals of GCNs, including graph representation, graph convolutional operations, and the structure of the graph convolutional layer. The paper also explores the use of GCNs in anomaly detection, discussing the applications of the graph convolutional layer, hierarchical representation learning, and the overall process of anomaly detection using GCNs. To address Research Question 1, a comprehensive review of the relevant literature is presented, comparing various GCN-based approaches. The findings and analysis section summarizes the reviewed studies, highlighting the significance of graph-based techniques, machine/deep learning, static graphs, dynamic graphs, and graph representation in anomaly detection. Further to address Research Question 2, the paper proceeds with a discussion on key insights, challenges, and limitations of graph-based approaches, such as scalability, domain expertise, imbalanced datasets, dynamic graphs, heterogeneity, and interpretability. Finally, to address Research Question 3, potential advancements and future research directions, including the integration of deep learning models and dynamic graph analysis, are identified.

X. Conclusion

This review has provided a comprehensive overview and analysis of anomaly detection in network data, with a focus on graph-based approaches and GCNs. The review of literature highlighted the significance of graph-based techniques, machine/deep learning, and various aspects of graph representation in anomaly detection. The findings suggest that GCNs have shown promising results in detecting anomalies and can effectively capture the complex relationships and patterns present in network data. However, several challenges and limitations, such as scalability, domain expertise, imbalanced datasets, dynamic graphs, heterogeneity, and interpretability, need to be addressed to enhance the practicality and applicability of graph-based approaches. Furthermore, the integration of deep learning models and dynamic graph analysis emerges as potential areas for future research. By leveraging the advancements in deep learning and exploring the temporal dynamics of networks, further improvements can be made in anomaly detection techniques. Overall, this paper provides valuable insights and directions for researchers and practitioners working in the field of anomaly detection, offering a foundation for future studies and advancements in this important area of research.

***Abstract*—Conversation among people is a profuse form of interaction that also carries emotional information. Speech input has been the subject of numerous studies over the last ten years, and it is now crucial for human-computer connection, as well as for medical care, privacy, and stimulation. This research aims to evaluate if the suggested framework can aid in speech emotion recognition (SER) activities and determine if Convolutional Neural Network (CNN) systems are efficient for SER activities using transfer learning models on spectrogram. In this investigation, the authors present a brand-new attention-based CNN framework and evaluate its efficacy against several well-known CNN architectures from earlier research. The effectiveness of the suggested system is assessed using the SAVEE dataset, an open-access resource for emotive speech, compared to famous CNN models like VGG16, InceptionV3, ResNet50, InceptionResNetV2, and Xception. The authors used stacked 10-fold cross-validation on SAVEE for all of our trials. Amongst these CNN structures, the suggested model had the greatest accuracy (87.14%), followed by VGG16 (83.19%) and InceptionResNetV2 (82.22%). Compared to contemporary techniques, the test results and evaluation show our proposed approach to have steady and impressive results.**

***Keywords*—Convolutional neural network; emotions; speech; transfer learning models; spectrogram**

I. INTRODUCTION

Automatic recognition and identification of emotions from speech signals in speech emotion recognition (SER) using machine learning is challenging [1]. SER is a quick and usual method of communication and exchanging information among humans and computers and has many real-world applications in the domain of Human-computer interaction (HCI). Feelings expressed via speech must be accurately identified and appropriately handled to provide more natural and HCI. However, building an effective SER is a complex and arduous effort due to utterance levels and abstract emotions [2]. Moreover, determining a methodologically felicitous algorithm is crucial in realizing and achieving a performance superior to the established benchmarks. The preparation and entry of sound data, obtaining features, and identifying emotions are only a few of the basic steps covered by standard SER approaches. In the quickest-growing study area currently, emotion detection in speech signals, scientists have created techniques to identify sentiments in speech signals inherently [3]. As soon as they are suggested, the concept of SER will be widely applied in the domains of schooling and medical care [4].

Although multimodal techniques can more effectively accomplish algorithmic methods for emotion identification [5], audio has been a useful medium for this job owing to the variety of data given by a person's voice [6]. Choosing a reliable approach for obtaining prominent and distinguishing characteristics from spoken words to describe the feelings of an individual speaking based on their auditory elements has become a key problem for feature mining experts. For SER, low-level handmade characteristics, including vitality, zero-crossing, length, linear classifier factor, Mel-frequency MFCC, and non-linear attributes like tiger power activator, were extensively studied during the previous ten years. Most investigations now use as a Mel-scale filtering of the financial institution voice spectrogram source characteristic when employing ML approaches for SER. CNNs often utilize spectrograms, a 2-D model representing speech sounds, to gather notable and distinct characteristics for implementation in SER [7] alongside other computational purposes [3, 8, 9]. Most two-dimensional CNNs are created specifically for optical evaluations [10, 11], and investigators have been motivated to investigate two-dimensional CNNs in the discipline of SER by their effectiveness. The CNN model may obtain excellent, important data to identify feelings in messages using spectrograms as appropriate descriptions of verbal data.

The potential of ML techniques in SER includes the systematic retrieval of emotional qualities from the unprocessed utterance and comprehending the correlations among those features. It has proven to be more effective than traditional methods. For instance, the researchers in [12] presented a combination of models constructed using long short-term memory (LSTM) and CNNs to implement temporal participation. The length of the talk hadn't been planned or

resolved, regardless of the speaker's depiction. Since feelings can fluctuate throughout a prolonged conversation, missing crucial details if spoken data has been split could influence the outcome. Leveraging continuous SER, [13] created a CNN framework with two downsampling/upsampling architectures and variable stratum compression coefficients. A system's efficiency might be impacted by fluctuating variables, leading to an overfitting issue. Consequently, the degree of complexity and feature count must be reduced to address and mitigate the issues. Recent developments in AI are also demonstrated by SER modelling with the attention system [2], transfer learning [7], as well as deep neural systems [14, 15]. They mainly referred to exceptional models for speech characteristics. The core components of SER include characteristics extraction and choosing, notwithstanding the improvement of the CNN mentioned above models. Speech sentiment may be inferred from several speech cues.

Current research develops the model using a complete methodology in light of its significance and application. As a result, it lacks a second predictor to do the categorization. Additionally, extract the emotions in communication using the attention component as a CNN layer. Additionally, because our representation uses the fourth pooling stage of the VGG-16 approach, it needs fewer components. In particular, this pooling stage collects priceless intriguing speech data, facilitating quick emotion identification. The following are the primary benefits provided by our suggested approach:

- One of the best strategies for SER that our findings suggest is a unique CNN model that combines the VGG-16 with the attention unit.
- By combining the attention and convolution modules on VGG-16, the recommended approach may identify areas of utterance that are more prone to degrade at each level.
- Since the suggested CNN approach may be taught completely, an additional filter for development and evaluation is not necessary.
- The benchmark SAVEE datasets are used to assess our model.
- The proposed technique has been assessed both qualitatively and quantitatively. The assessment's findings show that our approach beats cutting-edge techniques.

The remainder of the research paper is structured in the following fashion: Several comparable investigations are included in Section II. The suggested model is presented in Section III. The results of the study are reviewed and examined in Section IV. Section V presents our conclusion.

II. Related Work

In the modern day, the study of computational signal processing is still in its infancy. Many academics have established a variety of approaches in this field for SER during the last ten years. The two primary parts of the SER work are often separated into choosing characteristics and grouping. It is difficult to find a prejudiced choice of characteristics and grouping approach that accurately detects the speaker's feelings in this area [16]. ML algorithms are being quickly employed for SER because of the rise in information and expense processing [17, 18, 19, 20], and numerous investigators are using these techniques for reliable depiction of features in various domains [21]. Huang et al. [8] introduced a CNN-inspired strategy for SER due to its outstanding success in detecting images. In a comparable vein, [22] employed CNN to acquire excellent prejudiced characteristics based on spoken wave spectrograms and identify individuals' emotions. The Gaussian mixture method has been implemented by certain investigators [23] to determine the feelings of the speaker using reliable information.

Today, the majority of scholars derive excellent differentiation characteristics from speech recordings using two-dimensional CNNs. To discover concealed data, SER researchers are now capturing spectrograms, graphing messages concerning duration, and sending the results to CNNs [7, 24]. Additionally, researchers may use transfer learning procedures for SER by sending audio spectrograms across already trained CNN networks such as VGG [25]. To identify the feelings of the individual speaking through the SER framework, the CNNs approach can deduce excellent prejudiced characteristics from communication signals using spectrograms [26]. Likewise, to how LSTM-RNNs are continually exploited in the SER structure, hidden time-related data in messages is primarily learned using these networks [27]. ML methodologies now significantly contribute to the growth of SER curiosity.

The latest research by [28] revealed a, throughout its entirety, LSTM-DNN driven framework for SER that automatically extracts expression using unprocessed information instead of creating features manually. The combined strategy of CNN-LSTM is described in [29] for obtaining the most prominent characteristics derived from unprocessed spoken word data employing CNN and provided to the LSTM system for collecting the orderly data reminiscent of [30]. Ma et al. [31] established a framework for the model to handle varying audio lengths for SER. In this technique, CNN represented the verbal spectrogram characteristics, while RNNs processed the varying length phrases. Zhang et al. [32] introduced a method for SER using the already trained Alex-Net system for characteristics encoding and the conventional support vector machine (SVM) for feelings categorization.

To increase the identification efficiency of spoken messages, several techniques in the discipline of SER use CNN simulations with various forms of data [33]. Corresponding to this, other investigators developed an independent predictor [34] for identification. They employed the previously trained algorithm for obtaining fundamental characteristics using speech spectrograms that improve costs associated with the system data processing. In the current investigation, the authors present a brand-new attention-based CNN model that integrates the attention component alongside VGG-16 and evaluates its efficacy against a number of well-known CNN approaches from previous investigations. The following section provides a thorough description of the suggested framework with illustrations.

III. PROPOSED MODEL

The attention component and the well-known already trained CNN framework (VGG-16) are the foundation for our suggested approach. Considering two distinct explanations, the authors recommend the VGG-16 architecture. Firstly, it uses its reduced kernel shape, making it ideal for SER having fewer layers than its alternative equivalent VGG-19 approach, to gather the characteristics at the lowest level. Furthermore, it offers improved feature mining capabilities for SER identification. Among the transfer learning strategies is the tweaking strategy that authors employ. Authors employ the already trained size of ImageNet [35] in conjunction alongside the VGG-16 framework to perform the fine-tuning procedure. Since there aren't enough speeches available for learning, avoiding the overfitting issue is possible. Fig. 1 displays the suggested model's comprehensive component layout.

A. Pre-processing

An abundance of accurately tagged information is of utmost importance because SER is an identification challenge. It is crucial to select a collection of data that members of the identical group already tag. In contrast, the collection's producers, since multiple individuals, may interpret the identical words as expressing different feelings. To replicate the desired consistency, authors experimented with simulated records wherein specific performers or individuals deliver aloud a series of lines. In this study, researchers employ the SAVEE [36] dataset, which comprises precisely classified and noise-free audio specimens. There are 480 English speeches in the SAVEE database. The seven distinct emotions—neutral, angry, sad, happy, fear, disgust, and surprise—are represented by 15 phrases. Except for neutral, which contains 120 speeches, every emotion has 60 instances. Among the data collection, 60 illustrations for every feeling had been captured. Additionally, 420 speeches were recorded for the experiment's assessment. 30% of the data collection had been employed for testing, while 70% had been leveraged for training.

1) Augmentation: For each CNN framework, the dataset dimensions are a key determining element. A lack of input hampers the ability of CNN algorithms to effectively project inputs to concrete labels. A significant issue that insufficient data might cause is high variation in the assessment data forecasts. Authors employ augmentation to generate numerous training examples using the sparse audio recordings in the SAVEE dataset to get around this issue. The method implemented in this time-shifting as in Eq. (1).

$$\delta_{t_{new}} = \delta[t_{old} \pm \mu] \quad (1)$$

where, μ is the quantity of instances shifted, and δt_{old} is the audio stream. Originally recorded sound is captured at 44100 Hz in the current composition, and shifting is accomplished by s instances moving to the opposite direction.

2) Feature extraction: Selecting powerful characteristics within the voice input is crucial to achieving outstanding functionality for the proposed framework. The Mel spectrogram is a perfect feature because authors leverage CNN techniques for learning the data we provide. Fourier Transforms on recordings are used to create spectrograms, done independently to each of the smaller time portions of the audio input. Consequently, authors are presented with a frequency vs. time chart where the hue of the spectrogram represents the harmonic's intensity. Individuals, on the other hand, interpret frequencies exponentially instead of linear. This issue is resolved by the Mel magnitude, which converts a tone's perceptual pitch to its actual pitch.

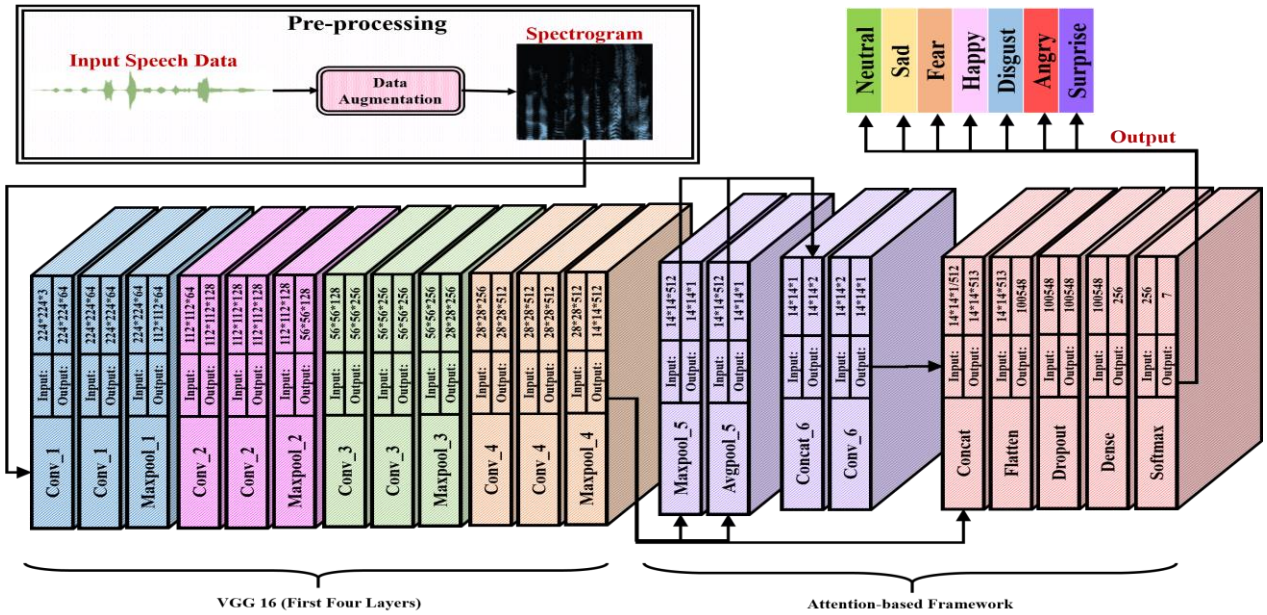

Fig. 1. The proposed architecture.

B. Attention-based Framework

Authors adopt the attention idea put forward by Woo et al. [37] for the proposed framework. The source tensor, which corresponds to the fourth pooling section of the VGG-16 framework utilized by the proposed technique, is subjected to maximum and average pooling operations. Then, employing the Sigmoid operation, these two resulting tensors are fused to conduct a convolution with a filtration value (ρ) of seven*seven. Fig. 1 displays the attention unit's layout. Eq. (2) defines the conjugated consequent tensor $(\partial_\mu(\beta))$.

$$\partial_\mu(\beta) = \theta(\rho[\beta_\mu^{avg}, \beta_\mu^{max}]) \quad (2)$$

where, the two-dimensional tensors obtained by average pooling and maximum pooling operations on the source tensor β are denoted by β_μ^{avg} and β_μ^{max}, respectively.

The fourth pooling section of the VGG-16 approach is employed in our approach. The scale-invariant component captures the intriguing hints of the picture. The midlevel area, or fourth pooling, better suitable for spectrogram, is where the intriguing hints are recovered. However, since spectrogram pictures are neither broader nor particular, the characteristics from other levels are inappropriate for spectrogram. As a result, the authors start by giving the attention component from the output of the fourth pooling layer. The production of the corresponding module is combined with the actual fourth pooling layer. Authors employ completely linked layers for expressing the concatenated characteristics obtained from the attention and convolution phase as a one-dimensional characteristic. In the proposed approach, the dense layer is set at 256, and the dropout is fixed at 0.5. The softmax layer groups the characteristics taken from the previous layers. The amount of groups in the softmax layer determines the measurement of the amount. The softmax layer produces the multinomial variation in likelihood ratings depending on the accomplished grouping. Eq. (3) defines the outcome of this distribution.

$$\varphi(x = z|y) = {e^{y_i}}/{\sum_n e^{y_n}} \quad (3)$$

where, y and z indicate the likelihoods that the softmax layer has been calculated and, correspondingly, one of the data categories employed by the suggested technique.

IV. Experiment and Results

A. State-of-the-art CNN Models

Five distinct CNN frameworks, including VGG16, InceptionV3, ResNet50, InceptionResNetV2, and Xception, have been employed in the present investigation. Among those most renowned and well-liked CNN designs is VGGnet. The distinctive VGGnet architecture consists of 138–144 million variables, approximately nineteen convolutional layers, Three*three convolutional filtering, five max–pooling stages, three completely linked layers, and a classification level as the final level [38]. By increasing its depth and breadth, Inceptionv3 is used to improve the processing capacity [39]. There are forty-eight layers in the design. The recommended framework is iterated with max-pooling to decrease the number of variables. ResNet is a standard feed-forward system with a residual link, in addition. The $(\gamma - 1)$ th results of the preceding level, also known as $(\gamma_t - 1)$, would be used to generate the residual layer outcome. The result of various procedures, including the convolution with various filtering widths and batch normalization accompanied by an activation operation on $(\gamma_t - 1)$, is referenced as $\sigma(\gamma_t - 1)$. Eq. (4) [38] can be employed to determine the residual section's ultimate result, γ_t.

$$\gamma_t = \sigma(\gamma_t - 1) + \gamma_t - 1$$

Each of the various fundamental residual blocks makes up the residual system. However, the tasks performed in the residual block fluctuate due to the various topologies of residual systems. A residual system with fifty levels is referred to as ResNet50. The InceptionResNetV2 is an amalgamation of 164-layer inception architectures featuring a residual link. To avoid any associated deterioration issues, the system uses multiple-sized CNNs that undergo training on various pictures [38]. "Extreme inception" is the abbreviation for the CNN structure known as Xception. The Xception design is a linear pile of residually connected separable by depth levels. Its 36 convolutional levels serve as the system's extraction of characteristics foundation [40].

B. K-Fold Cross-Validation

A popular method for determining the genuine forecasting errors of networks and fine-tuning the system's characteristics [41] to avoid generalization mistakes is cross-validation. Given the inconsistency in data collection, numerous models commonly encounter the overfitting problem. This outstanding approach is widely employed to address this issue [42]. The training information needs to be divided into K sections, each including an n/k specimen, wherein n is the initial sample amount, to begin the K-fold cross-validation operation. As a result, k-1 portions are employed in learning, whereas the residual portions are exploited in validation [43, 44]. The grid-search technique in our suggested method incorporates this significant strategy. The present research additionally employed the holdout approach, particularly a 3-split holdout, which is a way of partitioning the samples into several parts and engaging one part to learn the mathematical framework alongside additional parts for validating and testing the predictions. Additionally, the 10-fold cross-validation is used for several CNN networks; the study will go into more depth about the outcomes later [45-48].

C. Results

The performance of the proposed model and various CNN models is presented in Table I.

TABLE I. Performance of Various CNN Models

	Accuracy	***Precision***	***Recall***	***F1-score***
VGG16	83.19	90.68	90.97	90.82
InceptionV3	81.34	90.63	88.8	89.71
ResNet50	80.74	88.58	90.13	89.34
InceptionResNetV2	82.22	90.31	90.17	90.24
Xception	80.99	89.22	89.78	89.5
Proposed Model	87.14	92.85	93.42	93.13

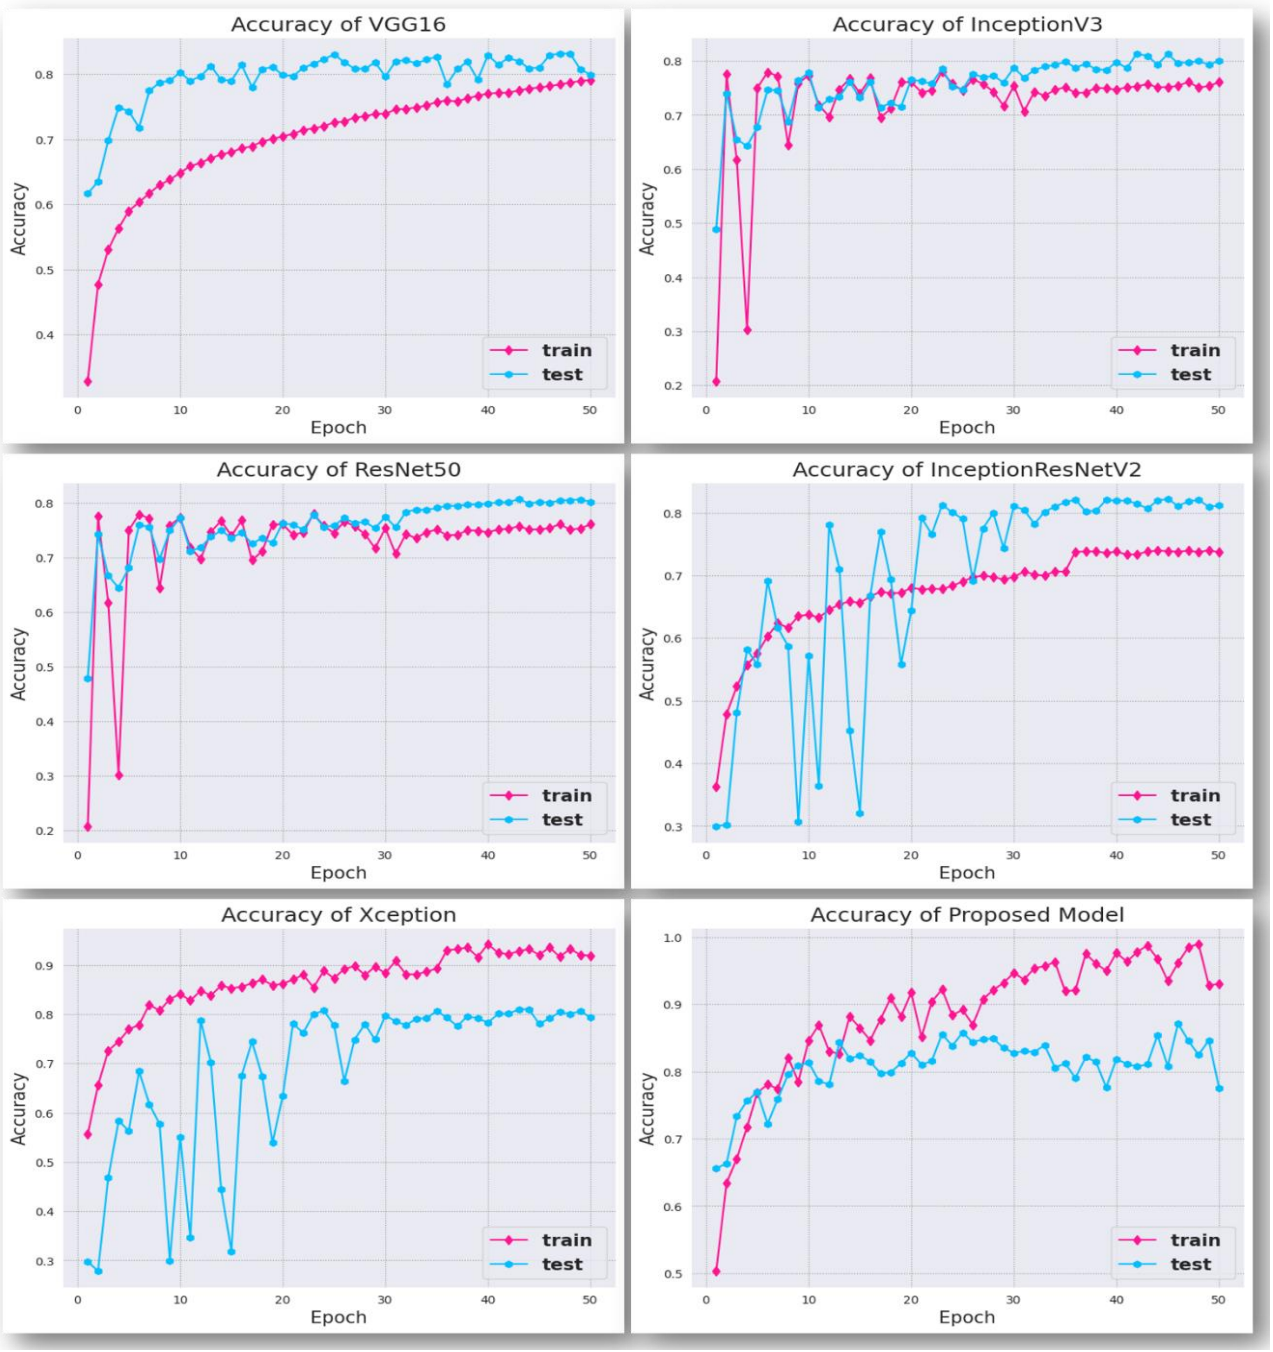

Fig. 2. Accuracy graph of various CNN models.

The proposed model achieved the highest performance with 87.14% accuracy, 92.85% precision, 93.42% recall and 93.13% f1-score. The second-best performance is demonstrated by VGG16 (83.19% accuracy, 90.68% precision, 90.97% recall and 90.24% f1-score) followed by InceptionResNetV2 (82.22% accuracy, 90.31% precision, 90.17% recall and 93.13% f1-score) and then InceptionV3 (81.34% accuracy, 90.63% precision, 88.8% recall and 89.71% f1-score).

ResNet50 observes the last performance among the underlying models with 80.74% accuracy, 88.58% precision, 90.13% recall and 89.34% f1-score. The accuracy graph, loss graph and confusion matrix for the various models are depicted in Fig. 2, Fig. 3 and Fig. 4.

The accuracy grows significantly in the initial few epochs, as seen in the Fig. 2, showing that the system is acquiring knowledge quickly. Following that, the trajectory becomes flatter, implying that there aren't sufficient epochs necessary for refining the simulation anymore. Overfitting occurs when the initial data precision improves, but the test accuracy deteriorates. It means that the framework has begun to remember the data. Inception V3 and ResNet 50 have been observed to have the minimum overfitting issue [49, 50].

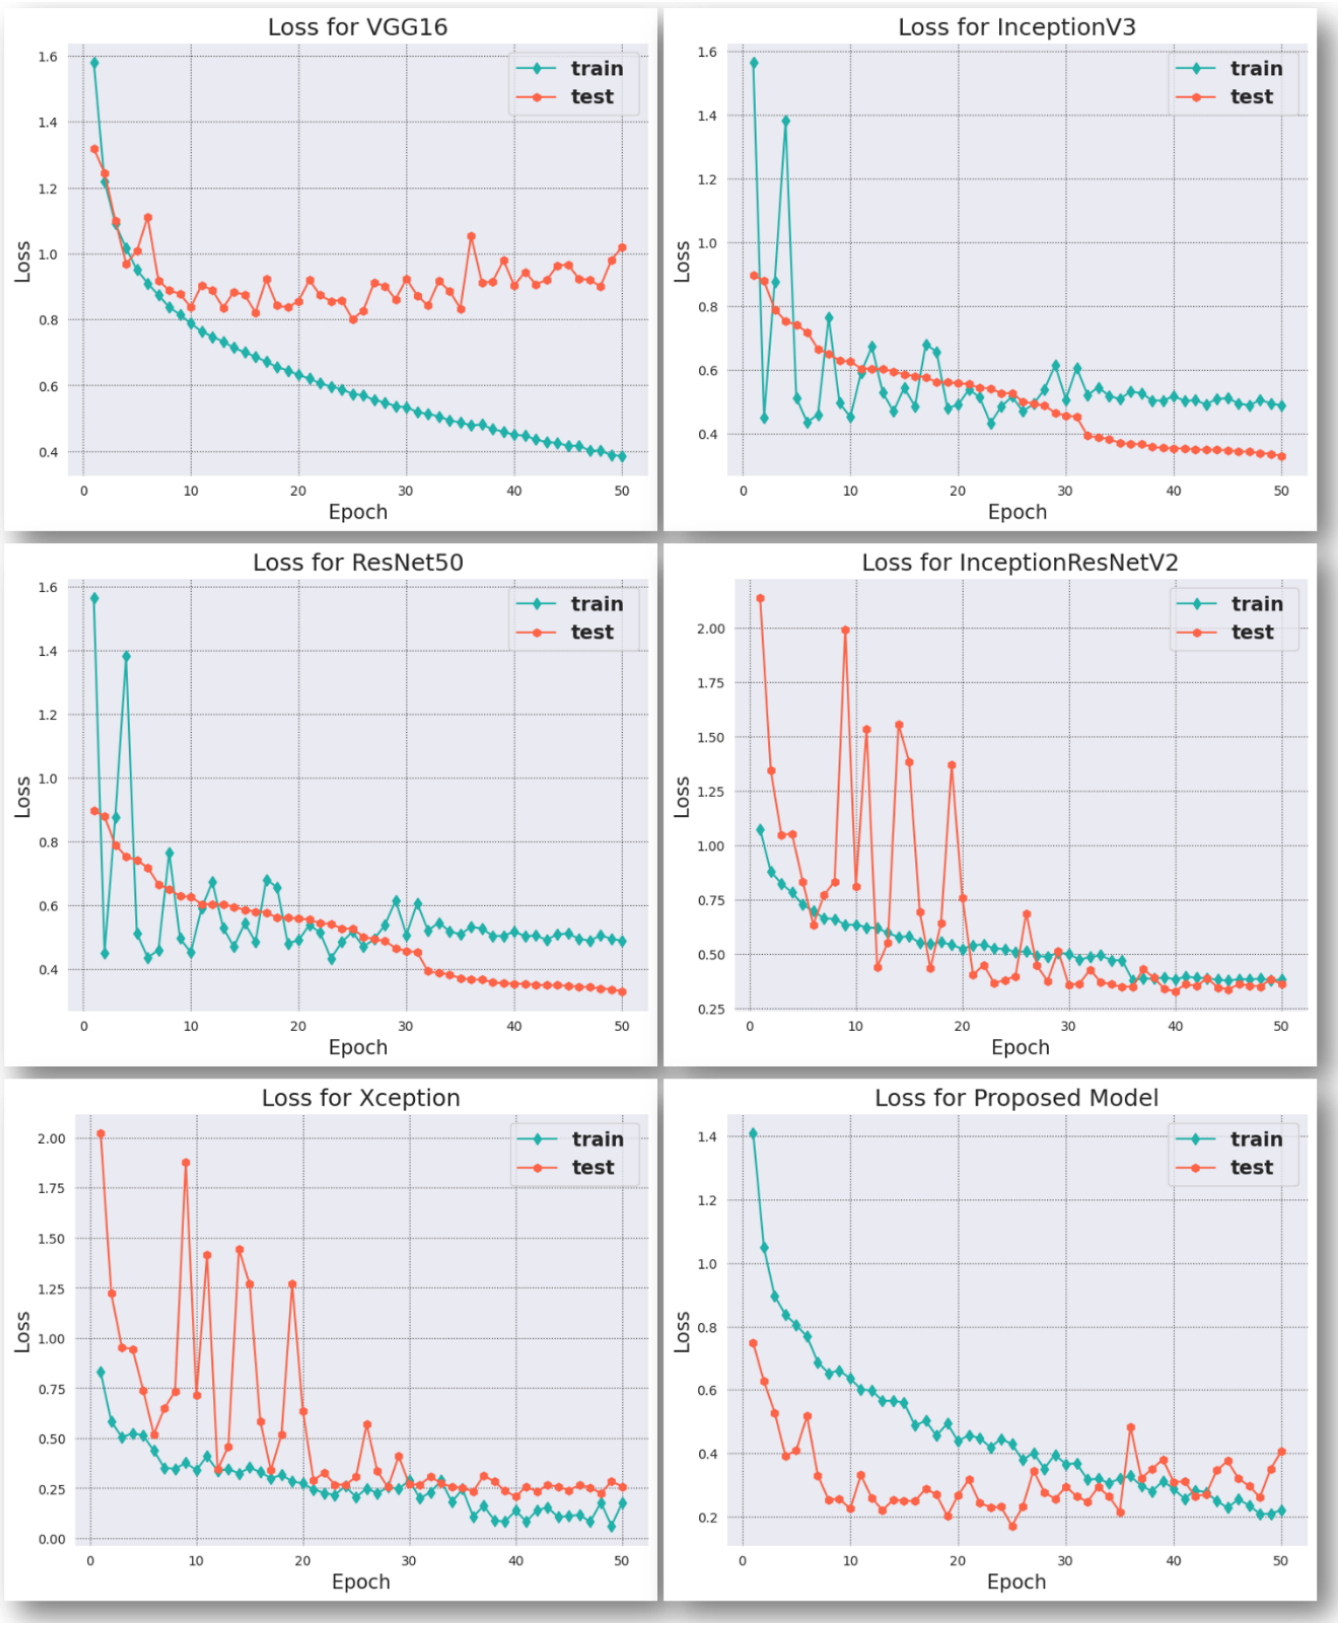

Fig. 3. Loss graph of various CNN models.

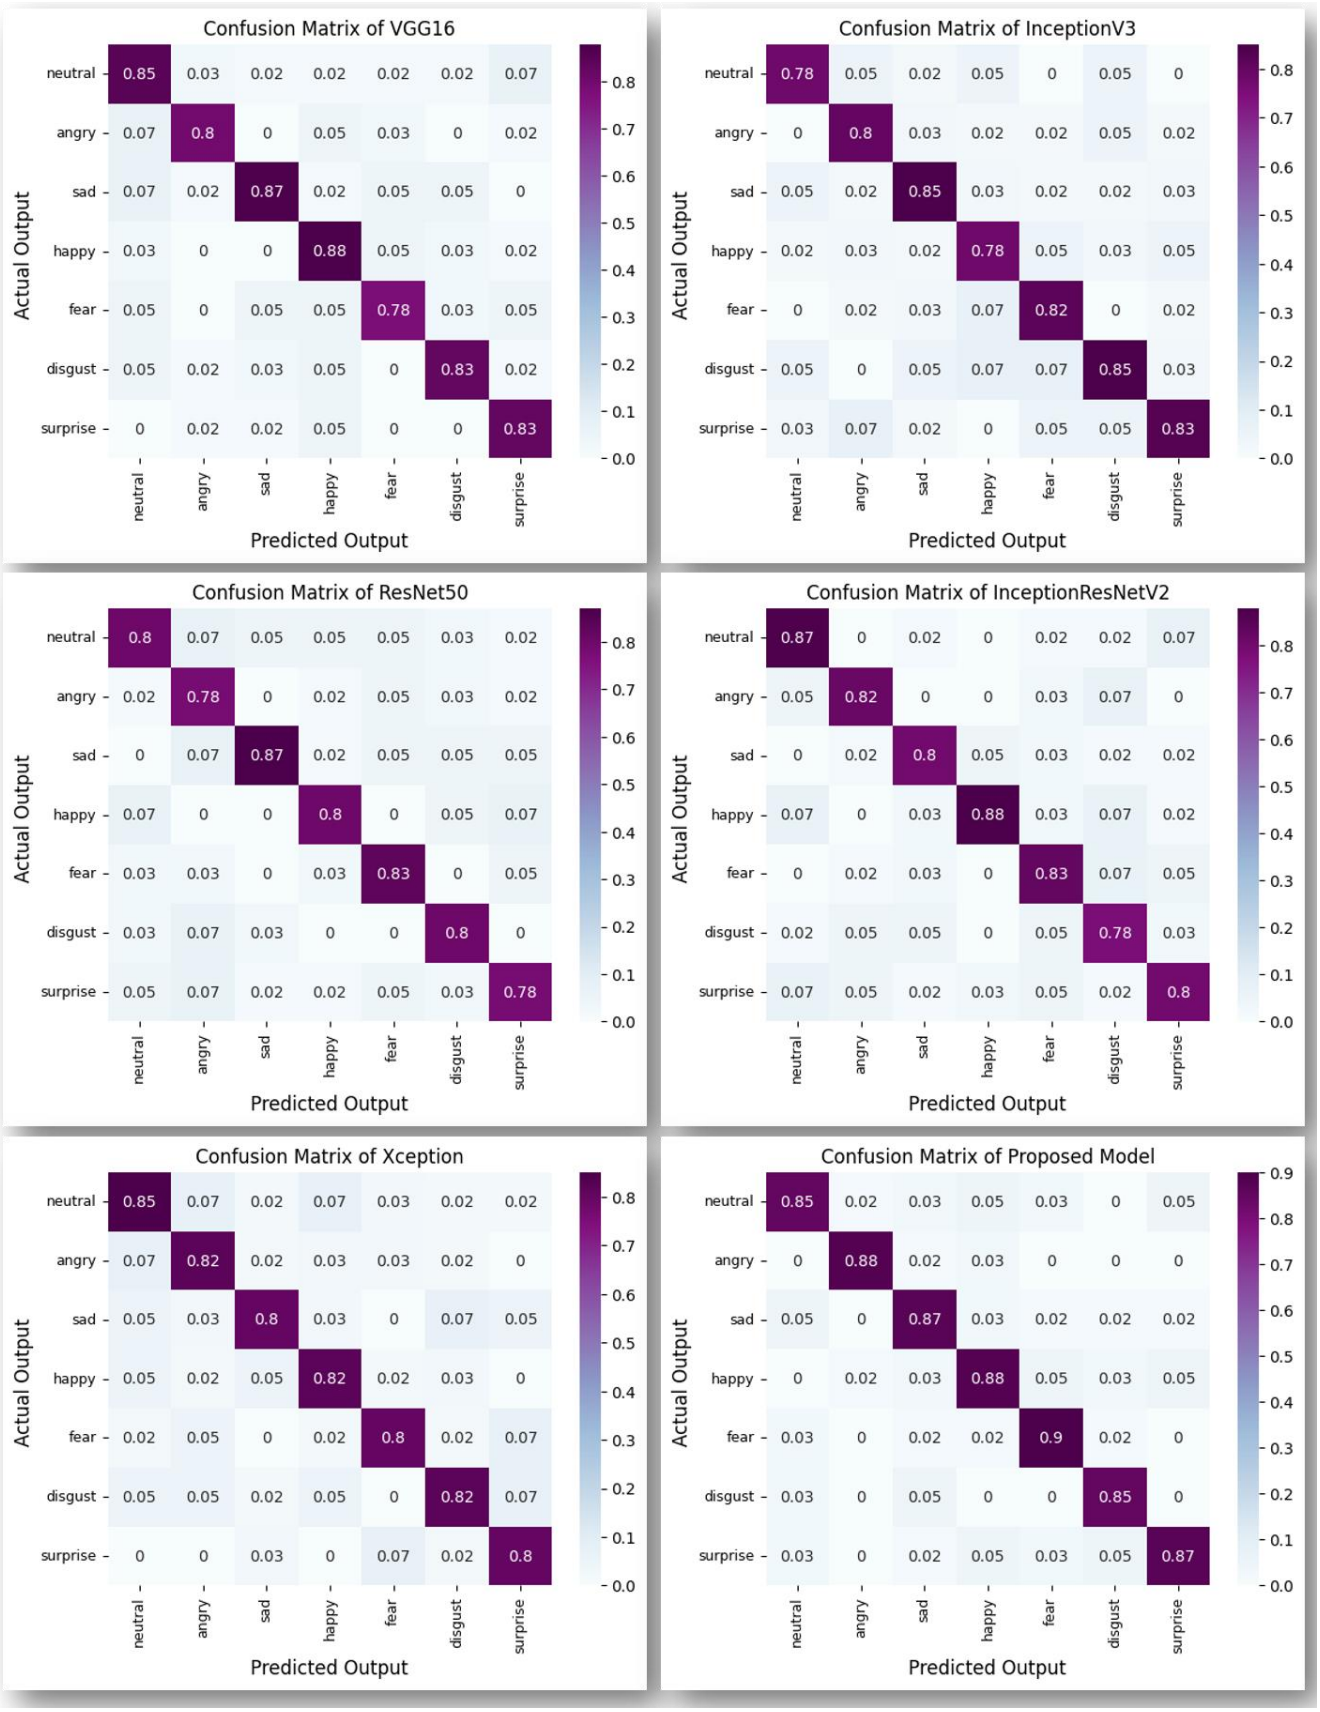

Fig. 4. Confusion matrix of different CNN models.

The loss on the learning set falls significantly during the initial few epochs, as seen in the Fig. 3. The loss in the test dataset is not declining at a comparable pace as in the preliminary set, but maintains nearly constant throughout numerous epochs. This indicates that the proposed framework generalizes effectively to new inputs.

The confusion matrix shows if the framework is "confused" in distinguishing among the various classes. It resembles a two-dimensional matrix, illustrated in the Fig. 4. The proposed model is observed to provide best results in comparison to the other prevailing models in the existing literature.

In future, authors aim to extend this research to incorporate the ensemble of various models to be fed to the attention module and compare it with existing research.

V. CONCLUSION

A key challenge to improving the model's accuracy compared to industry standards is creating a rigorous approach to gather relevant speech characteristics. Acquiring and evaluating voice elements for emotion recognition in spoken language may be challenging. The key challenges in designing a SER framework are extracting valuable characteristics and properly classifying those traits. However, developing contemporary ML techniques reduces the difficulty associated with these complicated activities. As a result, authors developed a novel SER model using attention-based CNN units, which acquire significant characteristics simultaneously with those required to group feelings. The SAVEE dataset, an open-access resource for emotional speech, is used to compare the performance of the proposed system against well-known CNN models such as VGG16, InceptionV3, ResNet50, InceptionResNetV2, and Xception. For all our experiments, the authors employed stacked 10-fold cross-validation on SAVEE. The recommended model exhibited the highest accuracy (87.14%) among these CNN architectures, followed by VGG16 (83.19%) and InceptionResNetV2 (82.22%). The test findings and assessment reveal that our suggested strategy has consistent and excellent outcomes compared to modern methods.

***Abstract*—In recent years, the escalating challenges of noise pollution in urban environments have necessitated the development of more sophisticated sound detection and classification systems. This research introduces a novel approach employing a Convolutional Long Short-Term Memory (ConvLSTM) network tailored for real-time impulsive sound detection in metropolitan landscapes. Impulsive sounds, characterized by sudden onsets and short durations—such as honking, abrupt shouts, or breaking glass—are inherently sporadic but can significantly impact urban soundscapes and the well-being of city dwellers. Traditional sound detection mechanisms often falter in identifying these ephemeral noises amidst the cacophony of urban life. The ConvLSTM network proposed in this study amalgamates the spatial feature learning capabilities of Convolutional Neural Networks (CNN) with the temporal sequence retention attributes of LSTM, culminating in an architecture that excels in both sound detection and classification tasks. The model was trained and evaluated on a comprehensive dataset sourced from various urban settings and demonstrated commendable proficiency in discerning impulsive sounds with minimal false positives. Furthermore, the system's real-time processing capabilities ensure timely interventions, paving the way for smarter noise management in cities. This research not only propels the frontier of impulsive sound detection but also underscores the potential of ConvLSTM in addressing multifaceted urban challenges.**

Keywords*—Deep learning; CNN; LSTM; hybrid model; ANN; impulsive sound

I. Introduction

The burgeoning growth and urbanization of cities around the globe has, in recent decades, ushered in a plethora of environmental and societal challenges [1]. Among these challenges, noise pollution stands out as a particularly pervasive issue, affecting both the physical [2] and psychological health [3] of urban residents. While the continuous hum of traffic or the distant murmur of a crowded plaza might be classified as the usual sounds of urban life [4], impulsive sounds—those characterized by sudden onsets and fleeting durations—present a unique set of challenges. Whether it's the abrupt honk of a car, a sudden shout, or the shatter of glass, these noises can be more than just momentary disturbances; they can disrupt sleep, exacerbate stress, and even influence long-term health outcomes.

Historically, noise monitoring in urban spaces has relied predominantly on traditional sound detection methodologies [5]. However, these conventional systems often lack the precision and agility needed to discern between the myriad of auditory signals that coexist in a bustling urban environment [6]. Specifically, the ability to distinguish impulsive sounds from the ambient noise milieu and subsequently classify them in real-time has remained a significant gap in urban noise management systems [7]. This lacuna is further widened when considering the increasing heterogeneity of urban sounds as cities continue to evolve and densify.

Enter the era of deep learning and its transformative impact across various domains. Recent advancements in neural networks, especially Convolutional Neural Networks (CNNs) [8], have demonstrated remarkable success in image and sound processing tasks. CNNs, designed to automatically and adaptively learn spatial hierarchies from data, have fundamentally altered the landscape of sound analysis in controlled environments. However, the temporally fleeting nature of impulsive sounds in dynamic urban environments presents challenges that go beyond the scope of traditional CNNs. It necessitates the incorporation of temporal sequence learning, an attribute inherent to Long Short-Term Memory (LSTM) networks.

LSTM networks, a subtype of recurrent neural networks, excel at tasks that require the understanding of long-term dependencies, making them particularly suited for sequence prediction problems, like those seen in speech and time-series data [9]. The integration of CNN's spatial feature learning with LSTM's prowess in temporal sequence retention could potentially hold the key to a robust solution for impulsive sound detection and classification in urban locales. This potential amalgamation gave birth to the Convolutional LSTM (ConvLSTM) network—a hybrid model aiming to harness the strengths of both parent architectures.

This research pivots around the design, implementation, and evaluation of a ConvLSTM network tailored explicitly for

the detection and classification of impulsive sounds in real-time urban settings. Recognizing the profound implications of efficient noise management—ranging from urban planning and policy-making to the well-being and satisfaction of city residents—this study endeavors to bridge the existing technological gap. Through the marriage of convolutional and recurrent mechanisms, we embark on an exploration into a new frontier of urban sound management, positing a solution that promises both accuracy and timeliness in addressing the cacophony of modern urban life.

II. Related Works

The quest to discern and classify impulsive sounds within urban environments is embedded in a rich tapestry of research efforts, encompassing fields from acoustic engineering to artificial intelligence. This section delves into the pertinent literature, highlighting seminal works, and tracing the evolution of methodologies applied to this challenge.

A. Urban Sound Detection and Classification

One of the earliest works in urban sound classification was presented by [10], who utilized basic spectral features coupled with Support Vector Machines (SVM) to classify a limited set of urban sounds. Their model, though pioneering, had a limited scope in differentiating between closely related sounds. A more comprehensive approach was introduced by [11], which focused on extracting Mel-Frequency Cepstral Coefficients (MFCC) from urban soundscapes. Their work laid the foundation for many subsequent endeavors by demonstrating the potential of MFCC in capturing the nuances of urban noises.

B. Convolutional Neural Networks in Sound Analysis

The revolution brought about by deep learning in image processing soon trickled into the realm of acoustic analysis. Authors in the study [12] were among the first to employ CNNs for environmental sound classification. His model, though primarily geared towards stationary sounds, showcased the profound potential of CNNs in capturing intricate sound patterns. Further advancements by [13] extended the use of CNNs, leveraging transfer learning from pre-trained image-based networks to sound data, highlighting the shared hierarchical structures between the two domains.

C. LSTM and Sequence Modeling in Acoustics

Long Short-Term Memory (LSTM) networks, a subtype of recurrent neural networks (RNNs), have emerged as particularly influential in the realm of acoustic analysis. Their inherent capability to capture and model long-term dependencies within sequences makes them exceptionally suited for time-based sound data. Researchers in [14] effectively harnessed LSTMs for voice activity detection, shedding light on their potential in discerning complex temporal patterns. Furthermore, [15] built upon this by integrating LSTMs with attention mechanisms, aiming to identify anomalous sounds in industrial settings. These studies collectively underscore the pivotal role of LSTMs in advancing the frontier of sequence modeling within the acoustics domain.

D. ConvLSTM in Image and Video Processing

Before its foray into acoustic analysis, ConvLSTM made waves in the domain of video processing. Researchers in [16] introduced ConvLSTM as an extension to the traditional LSTM, integrating convolution operations into the recurrent updates. Their groundbreaking work in precipitation forecasting exhibited ConvLSTM's potential in spatiotemporal sequence forecasting. This novel architecture caught the attention of many, with [17] later applying it to video classification tasks, proving its versatility across multiple temporal data types.

E. Hybrid Models in Sound Detection

The intersection of diverse neural network architectures has given rise to hybrid models, which aim to leverage the unique strengths of each constituent network for enhanced performance in sound detection tasks. Recognizing the potential of such amalgamations, [18] introduced a Convolutional Recurrent Neural Network (CRNN) specifically tailored for detecting anomalous sounds within varied environments. By seamlessly integrating the spatial feature extraction capabilities of Convolutional Neural Networks (CNNs) [19] with the temporal sequence modeling prowess of Recurrent Neural Networks (RNNs) [20], their research set a new benchmark in the field. This innovative approach highlights the intrinsic benefits of harnessing both spatial and temporal dimensions in sound analysis. Hybrid models, as delineated by such pioneering works, elucidate the way forward, promising enhanced accuracy and adaptability in the complex domain of sound detection.

F. Real-Time Sound Processing

The necessity for real-time sound processing, particularly in urban contexts, is paramount. Early systems, as chronicled by [21], relied heavily on handcrafted features and simplistic classifiers. However, with the proliferation of deep learning, architectures evolved to address real-time demands. Authors in [22] presented a sound event detection system employing a stacked CNN-LSTM architecture capable of real-time sound localization and classification, illuminating the pathway for subsequent real-time models.

G. Challenges in Sound Detection Models

Navigating the complex domain of hybrid sound detection models introduces a myriad of challenges. Firstly, the integration of diverse architectures, such as CNNs and RNNs [23], presents computational burdens. The enhanced model complexity often results in increased training times, demanding more computational resources and potentially hindering real-time deployment. Additionally, the fusion of spatial and temporal data streams can lead to overfitting [24], especially when training on limited datasets [25], necessitating rigorous regularization techniques and data augmentation [26].

Another pertinent challenge is the adaptation to diverse acoustic environments [27]. Hybrid models, though versatile, may struggle with high variability in soundscapes, from fluctuating noise levels to the unique acoustic signatures of different urban settings [28]. Lastly, the interpretability of these hybrid models remains elusive. As the models grow in complexity, understanding their decision-making processes

becomes intricate, posing challenges for validation and further refinement. Addressing these challenges is crucial for the successful adoption and efficacy of hybrid models in real-world sound detection applications.

In summation, while the corpus of work surrounding urban sound detection is extensive, the specific challenge of real-time impulsive sound detection and classification in urban settings remained a largely unexplored niche. The incorporation of ConvLSTM in this context, as embarked upon in this research, represents a synthesis of past insights and current innovations, promising to further the field's understanding and capabilities.

III. Materials and Methods

This segment delineates the methodologies and resources employed throughout this investigation. It encompasses the dataset curated for discerning perilous urban acoustics, coupled with detailed insights into data assimilation, preparatory phases, and the construction of an intricate neural network model targeting the identification of hazardous urban noises. Fig. 1 provides a schematic representation of the devised framework, emphasizing real-time perilous urban acoustic detection. Subsequent subsections offer a comprehensive breakdown of the utilized resources and techniques, encapsulating the datasets engaged, the data assimilation paradigm, model conceptualization, challenges associated with impulsive acoustic detection, and a detailed exposition of the integrated CNN-LSTM architecture.

A. Data

At the study's inception, data acquisition was prioritized, recognizing the necessity of comprehensive information for robust research outcomes. An assortment of expansive datasets was engaged to scrutinize the sounds termed as "hazardous." The Environmental Sound Classification (ESC-50) dataset [29] emerged as the preferred choice for program evaluation. From its vast repertoire of 2,000 auditory samples, a curated subset of approximately 300 sounds was employed. The ESC-50's categorization encompassed:

- Faunal Acoustics (e.g., canines, felines, bovines, swine).
- Natural Phenomena (e.g., precipitation, oceanic waves, avian calls, electrical discharges).
- Human-Origin Sounds (e.g., neonatal distress, ambulatory noises, respiratory patterns).
- Domestic and Mundane Noises (e.g., door interactions, digital keystrokes, time alerts, vitreous fractures).
- Hazardous Acoustics (e.g., emergency vehicular alerts, rail transit, motor operations, timber-cutting equipment, aerial transport, pyrotechnics, detonations, canine alerts, ballistic discharges, and other precarious impulsive acoustics).

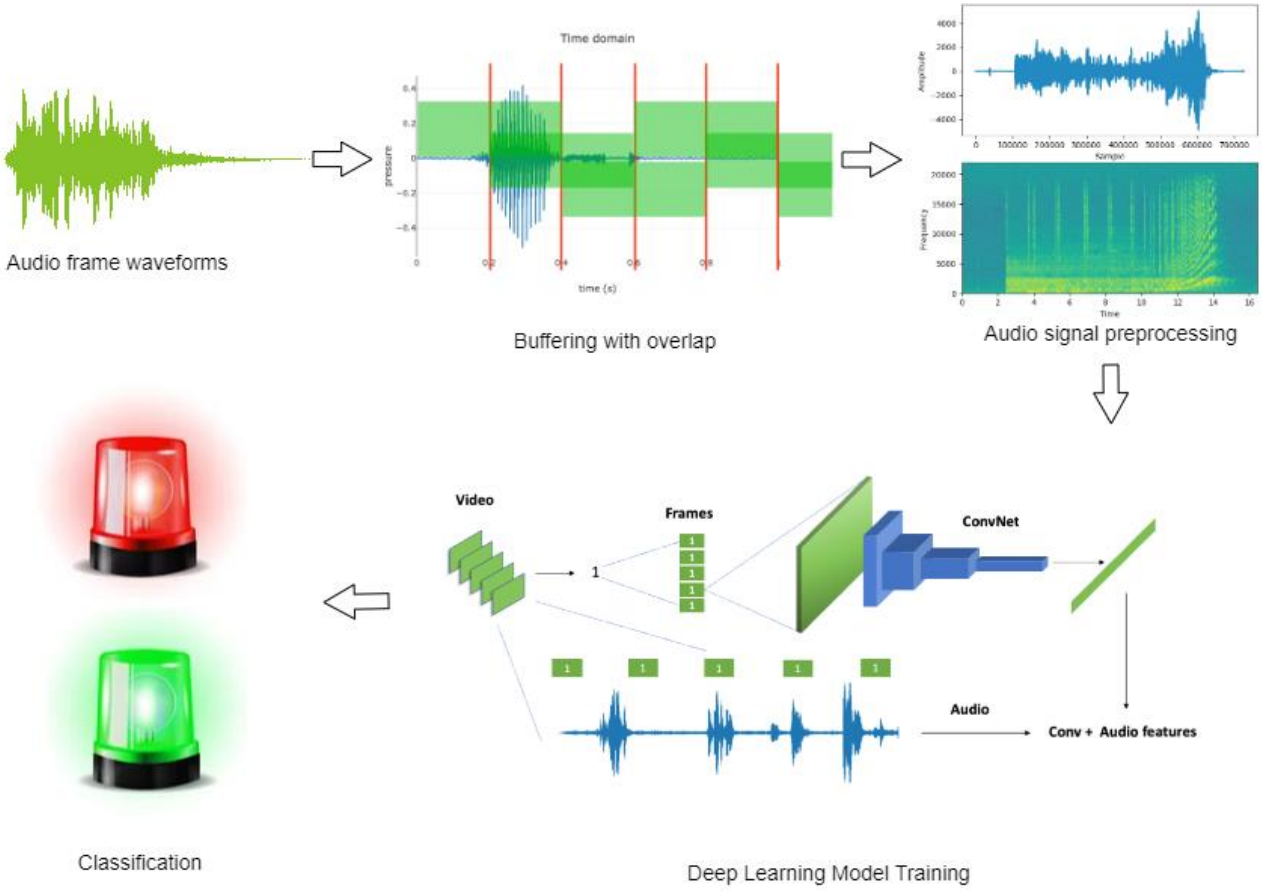

Fig. 1. Architecture of the proposed framework.

Despite the extensive nature of the ESC-50, this investigation was particularly centered on the hazardous acoustics subset, eschewing the remainder. A comparative analysis between the bespoke dataset's technical parameters and the ESC-50's original specifications can be referenced in Table I.

TABLE I. TECHNICAL PARAMETERS OF THE DEVELOPED DATASET

Characteristics	Accuracy
Overall size	661 MB
Size after preprocessing	45 MB
Number of files	2000
Number of files after preprocessing	301
Extension of files	.ogg

Within the observed region, incidents characterized by gunshots, vocal distress, and fragmented glass were identified as anomalous or "atypical." Consequently, the efficacy of the proposed framework was scrutinized, targeting its applicability in automated monitoring systems.

In pursuit of this objective, the research synthesized a dataset amalgamating diverse audio samples recorded across multifaceted environments within railway stations. This curated dataset encompassed 8,000 distinct perilous urban sound manifestations distributed across eight categorizations. The dataset's intention lies in facilitating the training and validation of both machine learning and advanced deep learning architectures in discerning and classifying hazardous urban acoustics.

Predominantly, the dataset resonated with ambient auditory elements, notably picks, gunshots, and glass rupture cues. To encapsulate the nuances of diverse operational environments, ambient acoustics were assimilated from both indoor and outdoor milieus.

For analytical rigor, the acoustic cues were partitioned into segments lasting one second—reflecting the typical duration of the identified events of significance. Each of these segments was further dissected into 200 MS frames, exhibiting a 50% overlap. To elucidate, each one-second segment was articulated into nine distinct frames.

Table II offers a meticulous breakdown of the dataset, elucidating the composition of signals, frames, and segmented intervals. This tabulated exposition illuminates the heterogeneity of perilous urban acoustics, with an emphasis on their respective spectrograms. The table furnishes insights into the spectrographic analysis of varied impulsive acoustics, encompassing phenomena like vehicular glass rupture, canine alerts, emergency vehicular signals, infantile distress, security alarms, and various fire warning systems. This tabulation underscores the salience of the curated dataset and the pioneering CNN-LSTM deep learning paradigm.

B. Model Overview

Subsequent to initial preparations, the focus shifted towards logic programming. Central to this phase was the objective of formulating methodologies for comprehensive audio detection. The intricacies of discerning potentially alarming acoustic events can be bifurcated into two specific sub-endeavors:

TABLE II. SAMPLES OF IMPULSIVE SOUNDS IN THE DEVELOPED DATASET

Sound	Time (sec)	Spectrograms
Automobile glass shattering	3.84	Dog barking	22.15	
Police siren	24.19	Ambulance siren	15.41	
Constant wail from police siren	56.87	
Single gunshot	3.84	Explosion	7.78	
Baby crying	6.66	Burglar alarm	11.13	Fire alarm beeping	1.41	
Fire alarm bell	1.59	Smoke alarm	0.99	Fire alarm yelp	2.3	

- Firstly, within the continuous audio data stream, there is a need to detect and isolate discrete pulse signals, ensuring their distinction from ambient auditory noise.
- Secondly, once extracted, the signal must then be classified, ascertaining its alignment with one of the multiple predefined acoustic events.

C. Detection of Impulsive Sound Events

The quantification of power for a series of consecutive, non-overlapping audio signal blocks serves as a cornerstone for various methodologies [9]. The computational approach to ascertain the power of the kth signal block, comprising N samples, is articulated by Eq. (1):

$$e(k) = \frac{1}{N}\sum_{n=0}^{N-1} x^2(n+kN) \qquad k = 0,1,... \tag{1}$$

Consider, for instance, an auditory manifestation of a gunshot, registered at approximately 4.6 seconds. For blocks consisting of N = 4,000 entries, corresponding to each block's duration, the power value span equates to roughly 90 milliseconds. The identification of blocks autonomously, especially in the context of transient pulse noises, can be executed via several distinct strategies, contingent upon the chosen approach:

- Grounded in the standard deviation of data that's been calibrated in terms of power metrics;
- Through the application of the median value from a median filter operating on the power units;
- By setting adaptive thresholds pertinent to the power units.

A deeper analysis reveals that this methodology predominantly leans on the standard deviation of power units' normalized values. Further examinations have deduced that normalized power block values situated within the interval [0, 1] stand as a pivotal element in this analytical schema.

$$e_{norm}(j) = \frac{e_{win}(j) - \min_j\left(e_{win}(j)\right)}{\max_j\left(e_{win}(j) - \min_j(e_{win}(j))\right)} \tag{2}$$

Following the initial processes, the focus transitioned to evaluating the standard deviation, commonly referred to as variance, for a specified set of data points:

$$\mathrm{var}(k) = \frac{1}{L-1}\sum_{j=0}^{L-2}\left[e_{norm}(j,k) = \bar{e}_{norm}(k)\right]^2 \tag{3}$$

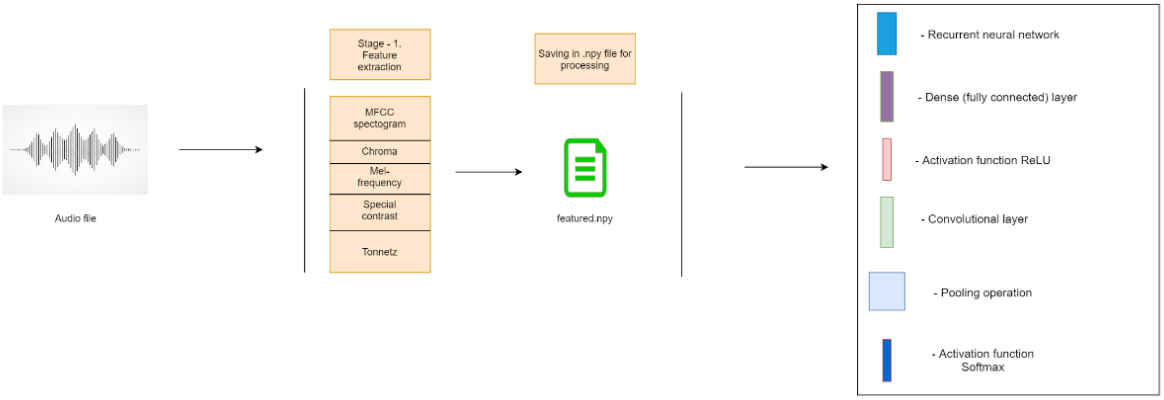
In scenarios characterized by the presence of ambient noise, block powers generally exhibit a uniform distribution within the interval [0,1] (as illustrated on the left). Upon recalibrating the power value for an audio segment to fit within this defined range, any significant deviation above the established power levels of background units triggers the automatic detection of a pulse signal. Gradual alterations in signals can be discerned by observing the average value of normalized power metrics. Notably, this methodology displays resilience in the face of fluctuations in ambient noise intensity.

D. Proposed Model

In the present research, a synergistic architecture has been postulated, integrating Convolutional Neural Networks (CNN) with Recurrent Neural Networks (RNN). In this structure, the RNN does not function as a recursive layer within the CNN. Instead, it operates independently, employing a Rectified Linear Unit (ReLU) activation for information processing. The RNN dimension is set at 128. A detailed representation of this integrated architecture can be viewed in Fig. 2.

E. Feature Extraction

In this investigation, the process of feature extraction from auditory signals spanned approximately 90 minutes, given that the dataset under scrutiny amounted to 6.6 GB. This specific size was selected intentionally, with the research aiming to assess methodologies on a comparatively modest dataset. In subsequent phases, the established techniques will be applied to data in a singular pass. Following the comprehensive analysis of the auditory files, a resultant set of 8,674 sounds, equating to a cumulative duration of 5,439 seconds or 90.65 minutes, was obtained. A closer examination of the feature extraction component can be understood by referring to the coding segment, and the entire process is graphically represented in Fig. 3.



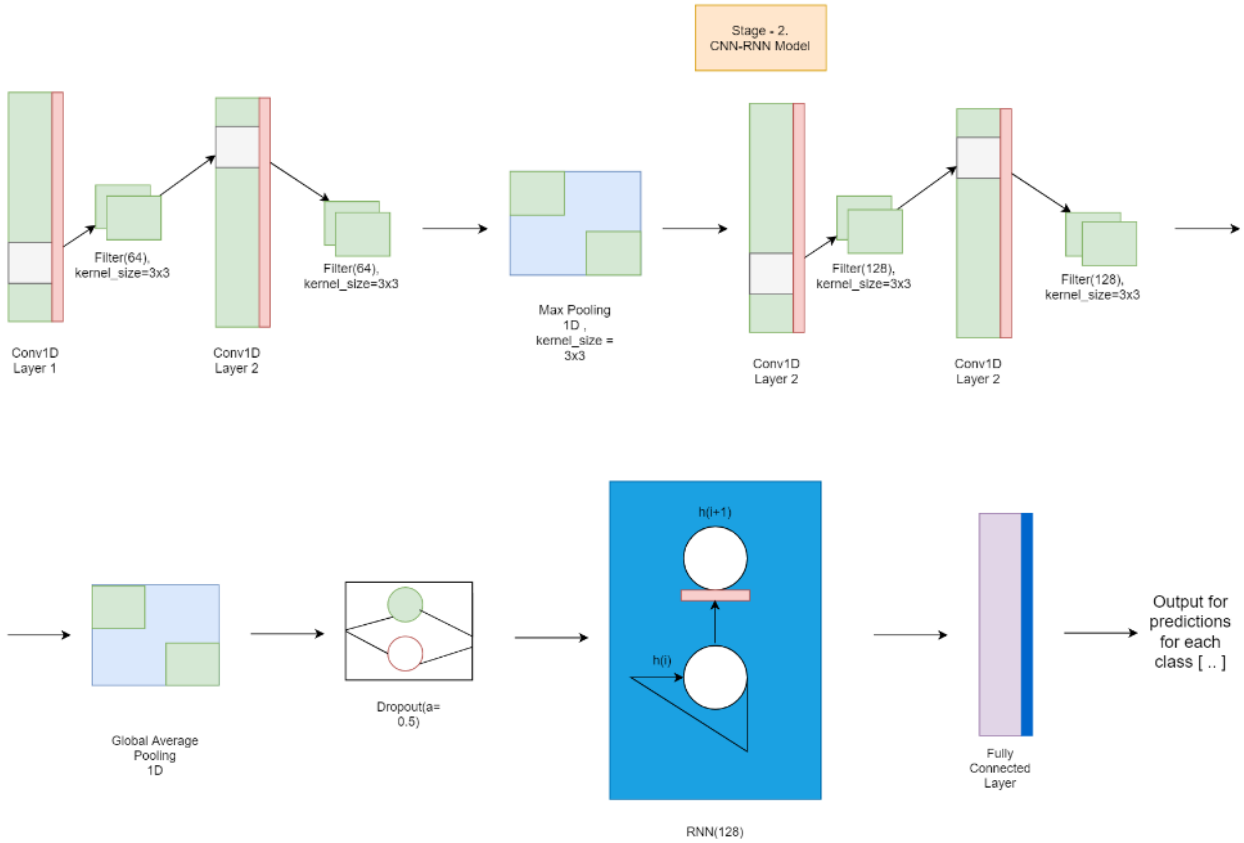


Fig. 2. Architecture of the proposed model.

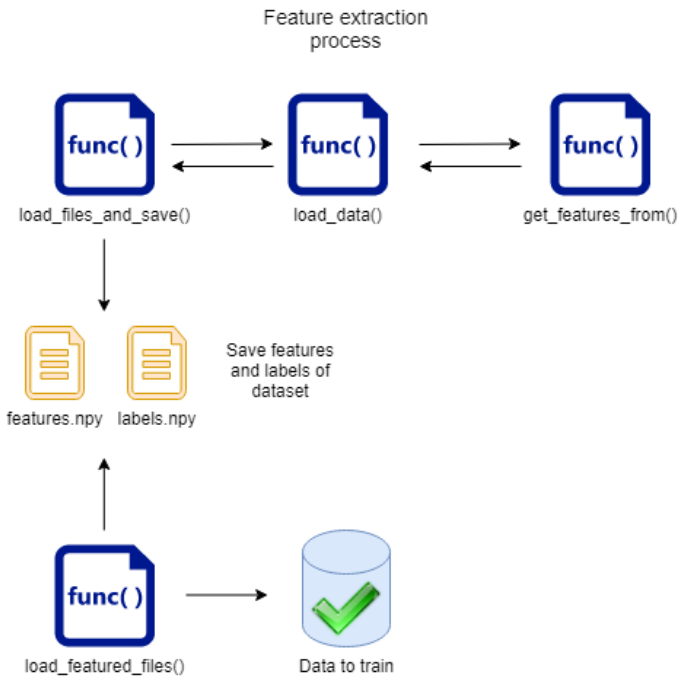

Fig. 3. The proposed framework.

Within the scope of this research, four distinct functions were delineated. Among them, three were explicitly designated for the extraction of features and subsequent data preservation. To elaborate:

1) The load_files_and_save() function invoked load_data(). This latter function systematically iterated over the dataset to acquire individual sound samples.

2) Following this, get_features_from() was summoned for each sound sample to extract its pertinent features.

3) Post-extraction, these attributes, along with their corresponding labels, were committed to persistent storage in two separate .npy formatted files.

Subsequent to the storage phase, data retrieval was facilitated by the load_featured_files() function. This prepared the dataset for the training phase, utilizing the integrated RNN-CNN model previously delineated in Fig. 2. This model's architecture encompassed two convolutional layers: one derived from a global maximum pooling mechanism and the other from a global average pooling paradigm.

IV. Experimental Results

This segment elucidates the empirical outcomes derived from employing the synergized CNN-LSTM model for the identification of hazardous urban auditory events. Initially, the

metrics tailored for appraising the efficacy of the aforementioned deep learning model are delineated. This is succeeded by a presentation of the results from both training and testing phases, encompassing model accuracy, associated losses, the distinct confusion matrices, and AUC-ROC curve impulsive sound classification.

A. Evaluation Metrics

The efficacy of any machine learning or deep learning model, especially in contexts like hazardous urban sound detection, necessitates a rigorous and comprehensive evaluation strategy. This section elucidates the primary metrics employed to assess the proposed CNN-LSTM model's performance:

Accuracy: This is the most fundamental metric, representing the ratio of correctly predicted instances to the total instances in the dataset [30]. It provides a broad understanding of the model's effectiveness, encapsulating its capacity to correctly identify both dangerous and non-dangerous sounds.

$$accuracy = \frac{TP + TN}{P + N} \tag{4}$$

Precision: Precision ascertains the proportion of true positive predictions in the pool of all positive predictions [31]. In the realm of urban sound detection, high precision denotes that the sounds flagged as 'dangerous' by the model are indeed perilous with minimal false alarms.

$$preision = \frac{TP}{TP + FP} \tag{5}$$

Recall (or Sensitivity): This metric quantifies the model's ability to correctly identify all potential hazards [32]. In essence, recall measures the fraction of actual dangerous sounds that were rightly detected by the model.

$$recall = \frac{TP}{TP + FN} \tag{6}$$

F-score: Harmonizing precision and recall, the F-score is the harmonic mean of these two metrics [33]. It assists in providing a balanced measure, especially when the class distribution is skewed. An optimal model would strive for a high F-score, indicating both robust precision and recall.

$$F1 = \frac{2 \times precision \times recall}{precision + recall} \tag{6}$$

Utilizing these metrics provides a holistic understanding of the model's capabilities, ensuring it is adept at identifying genuine threats while minimizing false alarms.

B. Results

This section offers a comprehensive assessment of the experimental results emanating from the dangerous urban sound detection exercises. The results of the CNN-LSTM model's endeavor at discerning impulsive sounds are visually illustrated in Fig. 4 and Fig. 5.

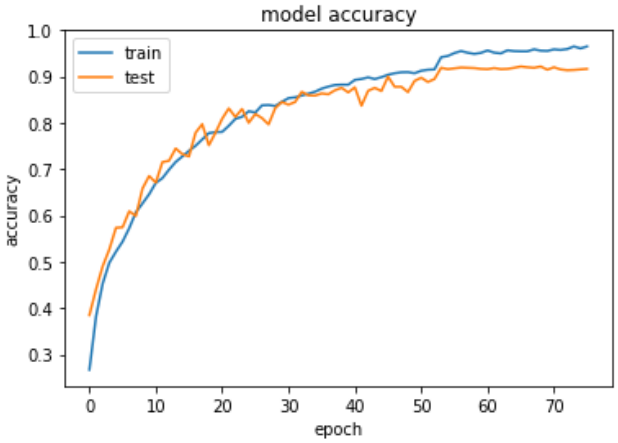

Fig. 4. Model training accuracy.

Fig. 4 specifically delineates the performance metrics during both training and testing phases for the inaugural dataset furnished by the research team. Notably, the CNN-LSTM model exhibited an impressive proficiency, registering an accuracy rate of 95% during its training phase. This was achieved over an approximate span of 80 epochs. Diving deeper into the model's architecture, it was observed to have approximately 87,822 parameters.

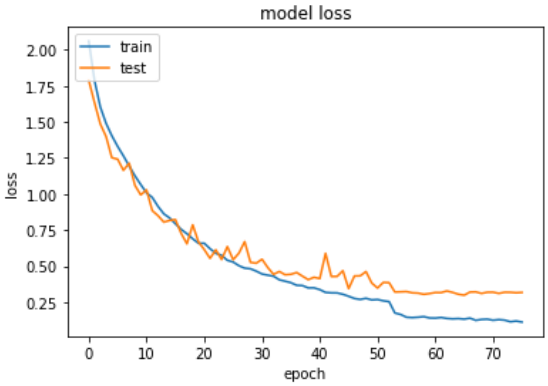

Fig. 5. Model training loss.

Furthermore, the duration of the training phase offers insight into the model's computational efficiency. The entire training process was completed in roughly 267 seconds, translating to slightly more than four minutes. This timeline underscores not only the model's accuracy but also its expedient processing capabilities.

In tandem, precision, recall, and F-score – though not explicitly detailed in the current dataset visualizations – remain paramount for comprehensive model assessment. These metrics, when considered in conjunction, ensure a holistic appreciation of the model's true capability, especially in real-world urban soundscapes.

In this section, we turn our focus to the findings from the second dataset, sourced from an open repository, and their implications as demonstrated in Fig. 6.

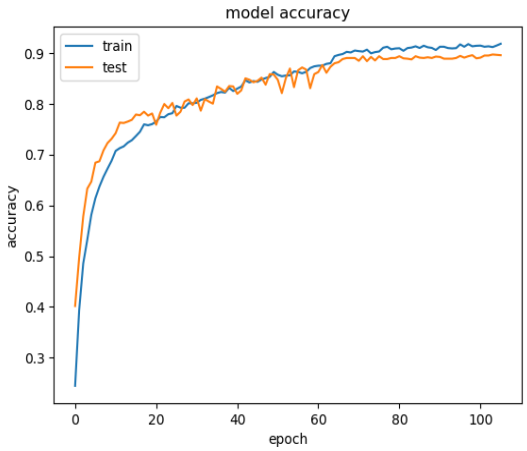

Fig. 6. Model test accuracy.

The CNN-LSTM model's performance on the second dataset is showcased in Fig. 7, providing invaluable insights into its adaptability and precision. Over a span of approximately 110 epochs, the model achieved an accuracy of 92%. This underscores its consistent performance, even when confronted with potentially disparate sound data from varied sources.

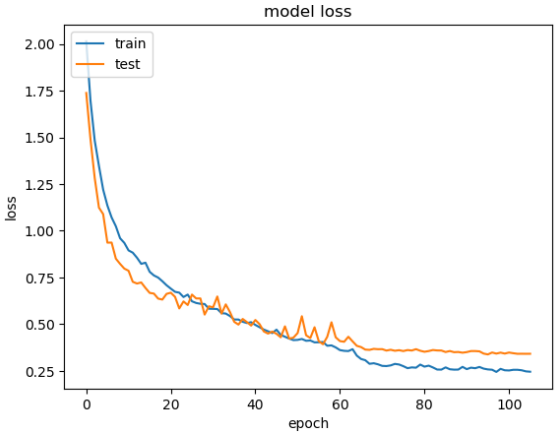

Fig. 7. Model test loss.

In the post-training phase, the model's performance was quantified using a confusion matrix, providing clarity on its precision across various classifications—specifically delineating true positives, true negatives, false positives, and false negatives, in the context of diverse urban acoustics. Fig. 8 presents a graphical representation of this matrix, elucidating the categorization efficacy for impulsive sounds. The implemented CNN model facilitated the differentiation of eight distinct hazardous urban auditory signals.

Fig. 9 depicts the AUC-ROC curve pertinent to the detection of perilous auditory events. The curve provides insights into the model's sensitivity to variations within the training dataset. The outcomes suggest that the integrated CNN-LSTM framework adeptly discerns hazardous acoustic events with commendable precision. Observations from the graph indicate a consistent performance, signifying the model's robust training tailored specifically for the identification of hazardous acoustical scenarios.

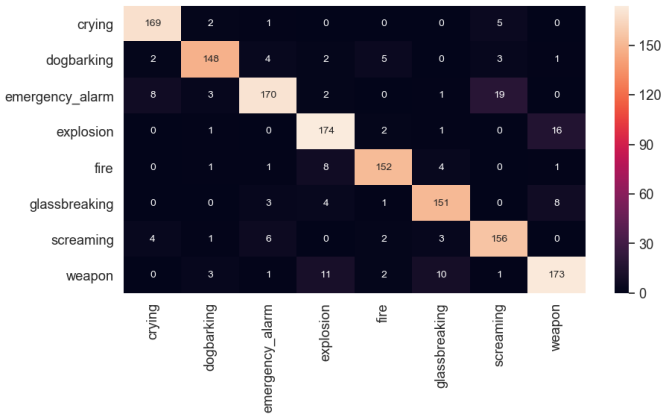

Fig. 8. Confusion matrix.

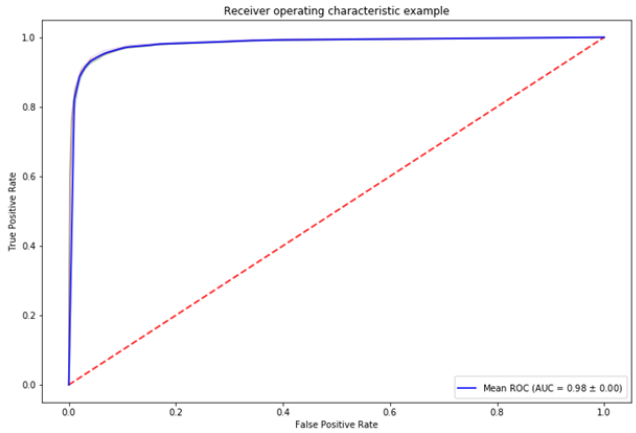

Fig. 9. ROC-AUC curve.

Consequently, the introduced deep neural network exhibits superior efficacy in consistently detecting hazardous urban sounds across all evaluation metrics. The success of the proposed methodology may be attributed to the utilization of the advanced RNN-CNN for weight and bias adjustments, coupled with an optimized training duration. The findings indicate that the presented deep neural network can be readily adapted to cater to both concise and extensive auditory inputs in contemporary applications.

V. Discussion

The task of detecting and classifying dangerous urban sounds using deep learning architectures has garnered considerable attention given the importance of public safety and efficient urban management. This study presented a novel Convolutional LSTM (CNN-LSTM) network specifically tailored for real-time impulsive sound detection and classification in urban settings. The outcome of this research offers significant insights and implications, which are discussed in this section.

A. Comparative Performance of the Proposed Model

The CNN-LSTM architecture, as revealed by the results, showcases a notable advancement over previously proposed models for urban sound detection. In comparison to standard CNN architectures, the introduction of RNN allows the model to effectively process temporal sequences in the auditory data,

proving its prowess in capturing the temporal dynamics inherent in sound samples [34]. Not only does this substantiate the architectural choices made in this research but it also suggests potential avenues for further refining and expanding the hybrid deep learning models in auditory signal processing.

B. Efficacy in Hazardous Sound Detection

A pivotal achievement of this study is the high classification accuracy for sounds that have immediate safety implications, such as gunshots, alarms, and screams [35]. Precision in detecting these sounds is crucial for real-time monitoring systems that aim to promptly respond to emergencies. The proposed model's ability to discern these sounds from a cacophony of urban noises, with significant accuracy, positions it as a strong candidate for deployment in urban surveillance systems.

C. Model Generalizability and Robustness

Another salient point worth discussing is the model's performance across diverse datasets [36]. Its consistent results, even with different datasets including open-source ones, indicate robustness and generalizability. The implications here are two-fold: First, the model appears to be resilient to overfitting [37], a frequent pitfall in deep learning paradigms. Second, its generalizability suggests that with minor modifications [38], the proposed architecture could potentially be employed in varied urban environments, extending beyond the specific settings of this study.

D. Computational Efficiency and Real-time Implementation

The study indicates that the model's training lasted a mere few minutes, emphasizing the computational efficiency of the CNN-LSTM architecture. This is crucial for scaling up the approach and integrating it into real-time surveillance systems, where rapid model training and updating are of essence. Given the emergent nature of urban sounds and the ever-evolving urban landscape, the ability to quickly train and retrain models can be a game-changer.

E. Challenges and Limitations

While the findings are promising, it is essential to acknowledge certain challenges. Ambient noises, characteristic of dynamic urban settings [39], can sometimes interfere with the accurate detection of impulsive sounds. Furthermore, while the model has been tested on selected datasets, its performance in other global urban contexts – each with its unique soundscapes – remains to be evaluated.

F. Future Research Directions

Several prospective avenues emerge from this study:

- Data Augmentation: Experimenting with more extensive and diverse datasets, inclusive of global urban soundscapes, could further test and improve the model's robustness.
- Model Refinements: While the CNN-LSTM architecture demonstrates efficacy, the integration of attention mechanisms might enhance its ability to focus on critical sound segments, thereby potentially improving accuracy.
- Transfer Learning: Given the computational efficiency of the proposed model, it would be intriguing to investigate the benefits of transfer learning, applying knowledge from pre-trained models to expedite the training process even further.
- Integration with Visual Surveillance: A holistic urban surveillance system could combine auditory cues from the CNN-LSTM model with visual data from CCTV cameras, enhancing the accuracy and response time of emergency systems.

In conclusion, the CNN-LSTM model's performance in detecting dangerous urban sounds signals a promising step forward in urban surveillance and safety systems. Its computational efficiency, robustness, and high accuracy across datasets underpin its potential for real-world applications. Nevertheless, like all research, it sets the stage for further inquiries, refinements, and innovations in this domain.

VI. Conclusion

The paramount importance of ensuring urban safety cannot be overstated, and the deployment of advanced technological measures is crucial in these endeavors. This research aimed to bridge the extant gaps in urban sound detection by proposing a novel Convolutional LSTM (CNN-LSTM) architecture tailored for real-time impulsive sound detection and classification. The results, as delineated in the study, highlight the efficacy of this hybrid model in discerning and classifying hazardous urban sounds amidst the complex soundscape of urban environments.

The model's comparative performance, evidenced by its high classification accuracy, demonstrates its potential utility for urban surveillance systems. Especially noteworthy is its ability to accurately detect sounds of immediate safety concern, such as alarms, screams, and gunshots. Moreover, the robustness and generalizability of the model, as indicated by its consistent performance across diverse datasets, fortify its position as a leading contender for wide-scale implementation in urban settings globally.

However, while the findings undoubtedly underscore the potential of the CNN-LSTM architecture, they also pave the way for future research. There remains a vast expanse of uncharted territory in this domain, especially concerning model refinements, transfer learning, and the integration of auditory and visual surveillance cues. Such advancements could further refine detection accuracy and foster comprehensive urban safety measures.

In sum, this study serves as a testament to the untapped potential of deep learning paradigms in enhancing urban security. The proposed CNN-LSTM model, with its impressive results, sets a foundational precedent for further innovations and refinements. As urban centers continue to grow and evolve, it is our sincere hope that the fruits of this research contribute to safer, more secure, and harmonious urban living experiences for all.

Breast Cancer Detection System using Deep Learning Based on Fusion Features and Statistical Operations

Suleyman A. AlShowarah
Faculty of Information Technology, Mutah University, Karak, Jordan

***Abstract*—Breast cancer is considered as the second cause of death for women. The earlier is diagnosed, the easier the patients can be recovered. The need for studies to detect this kind of cancer easily and accurately came from the growing rate of infected patents by breast cancer exponentially. This study is conducted to investigate the use of deep-learning model for breast cancer detecting using the technique VGG-19 and ultrasound images. Two layers of VGG19 structure were used: (i.e. fc6 and fc7. Based on these two layers (fc6 and fc7), new datasets were created, which are named as statistical operations. These datasets will be employed as input for the following Machine Learning classifiers: K-Nearest Neighbors, Random Forest, Naïve Bayes and Decision Tree. Data augmentation was considered to increase the dataset size for better learning of CNN. Random Forest achieved high accuracy (88.63), precision (0.88), recall (0.88) and F-Measure (0.88). The results of the classification accuracy in the three scenarios are slightly similar; this proves that the breast cancer can be detected even if the size of data in the training dataset was minimal.**

Keywords*—Breast cancer detection; breast cancer classification; deep learning; vgg-19; breast tumor*

I. INTRODUCTION

Cancer is considered as an uncontrolled growth of cells in human body. Breast cancer is one type of cancers, which considered as the second cause of death for women. It is known for patients and doctors, the earlier the cancer is diagnosed and detected, the easier the patients can be recovered. Because of the growing rate of infected by breast cancer exponentially [1]; there is need for studies to detect this kind of cancer easily and accurately. It is considered as a motivation for such study in that the diagnosed people in this kind of cancers is growing day by day. For example, in the US [2], most women are diagnosed with breast cancer compared to any other type of cancer, except for skin cancer. This cancer affects one in three of new female annually. In a year 2023, the estimated diagnosed women in US with invasive breast cancer to be 297,790, and with non-invasive breast cancer will be 55,720 [2]. Although these statistical numbers reflect what is obtainable in most advanced economies, and it was illustrated by studies that about 58% of deaths occur because of this cancer in less advanced countries. The high death rate from breast cancer is because of the lack of early detection, as more than 33% are for population aged 30-49 and 81% for 30-59 years old are diagnosed for this cancer [3], [4], [5].

In order for early detection and saving lives of breast cancer, a mammography was developed by scientists with some limitations of its functions. Despite of that, some of studies showed a reduction in death rate of about 40% after a mammogram screening [6, 7]. About 15 of the 1,000 women seen with mammography are recommended for a biopsy, and about 13 women of these biopsies show a false positive results (not present) [8]. A major limitation of mammographic screening was highlighted by C.K. et al. [9]: breast cancers of prognostic significance are not diagnosed.

Several of strategies were implemented to enhance the performance of screening mammography: including double checking and screening at annual intervals [10], apply two views for each breast [11], and make a comparison with previous mammograms [12]. The serious features can be detected by radiologists for each scan such as architectural distortions, micro-calcifications, and asymmetries as cancer biomarkers or cancer risk. Detecting these serious features manually leads to additional costs and will let the radiologists pay more efforts for mammography [13]. One of systems emerged in the 1990s named as Computer-aided detection (CAD), this is to detect and then classify breast cancers in mammograms automatically. But still the performance of such these traditional systems has not improve screening process significantly, this is mainly due to their lack specificity [14,15]. Specificity relates to how abnormalities can be discriminated by algorithms when screening, which differs from how it is diagnosis; it employs causal inference as to the origin of the abnormality. However, detecting anomalies in screening mammographs is important in the diagnosis.

Recently, the researchers in [16] reported that novel algorithms based on CNN can be used to improve the performance of screening mammography and also to increase the efficiency of mammography professionals. In this matter, some of researchers developed different CNNs-based algorithms for automated mammographic analysis purposes [17].

This study aims to detect and classify the images of breast cancer using deep-learning, which can be employed as system used to help doctors and radiologists in their diagnosis automatically. To achieve this aim, it will be conducted based on CNN using VGG-19. The pre-trained technique VGG-19 is used to achieve high accuracy by finding distinctive details features of image [18] [19]. The two layers of the VGG19 structure were used (i.e. layer 6; which called fc6, and layer 7; which called fc7), and each contains 4096 features. Also, more feature vectors were created from (fc6 and fc7), which named

as statistical operations. Statistical operations are used to generate more datasets using Average (Avg), Minimum (Min), Maximum (Max), and fusion between fc6 and fc7. All aforementioned datasets will be used as input for the processes of classification using different algorithms (i.e. K-Nearest Neighbors (KNN), Random Forest (RF), Naïve Bayes (NB) and Decision Tree (DT)).

The results illustrated that Random Forest algorithm achieved high accuracy (88.63), precision (0.88), recall (0.88) and F-Measure (0.88) for fc7 of second scenario. The results were slightly similar; this approves that these features can provide a better accuracy when used in detection studies. Also, the results of the classification accuracy in the three scenarios are slightly similar; this proves that the breast cancer can be detected even if the number of images in the training dataset were minimal.

The motivation of conducting this study is represented by:

1) The literature need for researches of detecting breast cancer using CNN with new model like VGG-19 based on the two layers: fc6 and fc7.

2) To the best of my knowledge, I could not find any research in the literature performed based on statistical operations for detecting breast cancer using VGG-19.

3) Based on features that were extracted by VGG-19, it can be a contribution for this study by providing the literature with a differentiation between the results of different aforementioned classifiers and with different three scenarios.

This research is designed into five sections. The overview of related studies in literature is introduced in Section II. Section III discusses the methodology for the proposed model and the experiment design. Then, the experimental results and discussion are discussed in Section IV. Finally, Section V presents the conclusion.

II. Literature Review

Several of studies showed several of automated, and computer vision approaches to classify breast cancer- based images [20, 21]. Some of them have focused on segmentation process, and then features were extracted from images [22]. While in some other studies followed the pre-processing steps for better feature extraction, this is to improve the contrast in the images and then to detect the infected part of image [23]. For example, the most important and the first of the pre-processing steps in the mammogram analysis are applying the segmentation for the infected region, which allows focusing on region of interest in the images. The researchers in [24] applied the technique called texture filter in the segmentation of the breast region.

Lastly, in this matter, there was a study conducted by de Vos, et al. [25] who implemented DL for extraction features for region of interest from cancer images. In their study, they used three techniques of convolutional neural network (ConvNet) to detect and to extract features from a 3D image, which are: the presence of the anatomical structure of interest in the following: 1) axial, 2) coronal, 3) sagittal slices. The method of their localization was compared to the manual method using the distances between the centroids and the walls with an automatically and manually defined reference frame. Many other researches have adapted a pure deep learning based on its layers for extraction features [26–30], and also using one of most interesting methods such a high pass isotropic filter [31].

Image cropping aims to enhance image quality by removing distracting content/also adding aesthetics, which are mainly categorized-based on that. Different methods are available to achieve such this task. Often, these methods can apply techniques like: machine learning, deep learning, segmentation, saliency-based, and sparse coding. For example, the study conducted by Mishra et al. [32] used ML radiology using classification pipeline. They segmented the region of interest, and then extracted the useful features. Their study was performed on the dataset: (BUSI), and the results showed improving in classification accuracy. While the study conducted by Byra [33] used DL for the classifying the cancer parts from images. The transfer learning (TL) was used and then deep representation scaling (DRS) layers were added between the blocks of pre-trained CNNs to enhance the provided information. In order to analyze these parts classification, the enhancement was only for the parameters of the deep representation scaling layers during training, this is to enhance the pre-trained CNNs, which was much better compared to other techniques.

Some of researchers in [34] developed algorithm: Dilated Semantic Segmentation Network (Di-CNN) and then they used it to detect and classify the breast cancer. The pre-trained DenseNet201 deep model was used in their work and then trained using TL that was used for feature extraction. In addition, they applied a 24-layer CNN and fusion features in their work. The results of the fusion process have improved the classification accuracy in the detection process.

Ahmed et al. [35] used patch selection to classify breast tissue based images using TL. The features were extracted using CNN to discriminate patches, which are an input for an Efficient-Net architecture that is considered as an architecture of CNN and employed for scaling technique that scales all dimensions of: width, depth, and resolution based on a compound coefficient; these input were trained on the dataset: ImageNet. The classifier support vector machine was used for classifying features that were extracted from the Efficient-Net. The results showed that the suggested model achieved better results compared to the standard methods.

The use of DL has outperformed most recent methods. A good example of this, it is the study in [35], which built based on the geometric properties of the edge features to extract the abnormal patches structures in the expected regions. For example, the researchers in [36] conducted a study and the features were extracted from the image using CNN (DenseNet); which are then provided in fully connected layers (FC) for classifying the benign and cancerous cells of breast cancer image. However, the researchers in [37] presented deep learning methods for detecting and classifying models. Deep learning can be used perfectly for computer vision problems, especially image optimization and interpretation. This has led to a wave of pioneering applications of medical imaging, and

available databases of image have presented the growth of DL algorithms aimed to detect cancer images.

Other researchers in [38] conducted a study to extract the most important and useful information using DL including convolution layers for breast cancer detection. They showed that the features extracted by DL models are better in term of accuracy than traditional and manual methods. DL methods showed that it has ability to detect pathological forms of cancer that were previously thought to be difficult to diagnose using conventional and manual methods. The researchers in [39] presented DL-based techniques for detection breast cancer images. In their work, a dataset was published containing canine mammary tumor (CMT). Also, (VGG-16) was used to investigate the performance of hybrid frameworks using different algorithms on CMT and other datasets of breast cancer.

The works that have been done in the literature on DL using CNN among others, have provided an insight to the researchers on how an automatic representation method without supervised descriptors in extracting, i.e. independent of any human intervention that could influence these representations [40].

In fact, Deep CNNs usually have too large number of parameters, so that it is not reasonably trained without a very large dataset. Moreover, medical datasets are usually not large enough to adequately train a deep CNN model from scratch. Thus, transfer learning in deep learning was explored to be used in the medical imaging to solve such problem. So, the transfer learning transfers knowledge between large source and small target domains [41], which can be done by using pre-training a CNN model with the source of images, then re-training parts of the model with the target images. In [42], the researchers used CNN AlexNet to detect the images of breast cancer from dataset named: BreakHis [43]. Their results showed that the classification accuracy is 79.85%.

While the researchers Han et al. in [44] have proposed a framework for breast cancer multi-classification using class structure-based deep CNN model on the dataset named: BreakHis. The results showed 93.2% of classification accuracy.

The researchers Nuh et al. in [45] have conducted a study to discriminate between samples infected and non-infected breast cancers images based on CNN using different spatial patches. The results showed for window sizes: 5x5 and 7x7 are 86.91% and 86.17% respectively.

The researchers in [46] have presented a CNN classifier for the visual analysis of area of cancer in images of malignant breast cancer. The results showed a higher performance for their proposed classifier compared to random forest classifier: 84.23% classification accuracy. It was approved by results of Hafemann et al. [47] that used a CNN; It showed better results compared to traditional approach that always needs huge efforts and effective expert in the field of knowledge [48].

III. Methodologies

This section presents the dataset design, and the experimental setup model.

A. Database Design

The Dataset of Breast Ultrasound Images (Dataset BUSI) is used in this research and can be obtained online [49]. The dataset consists of 780 images with size 500×500 pixels; including the segmentation masks that refers to 600 patients. The dataset consists of three classes: normal, malignant, and benign. The whole dataset was divided into training and test dataset. However, this is not enough as dataset to train data using the model of deep learning; therefore, a data augmentation step is achieved to increase the dataset size for better learning of CNN. These implemented steps are achieved multiple times until the size of dataset of each class has reached 5872.

B. Experimental Setup Model

The experiment of this study was designed based on three scenarios: 1) 50% for training and 50% for testing, 2) 70% for training and 30% for testing, and 3) 80% for training and 20% for testing. So, for each scenario - the experimental setup for the proposed model is displayed in Fig. 1 and consists of set of steps, as follows:

Step 1: The MATLAB is used for automatically extracting feature form images based on Pre-trained VGG-19. The outputs are two datasets for fc6 and fc7. Each of fc6 and fc7 contains 4096 features. These datasets will be used in the step 3.

Step 2: Creating a new dataset from step 1 by performing the statistical operations (i.e. Avg, Min, Max, and fusion of fc6 and fc7). These datasets will be used also in step 3.

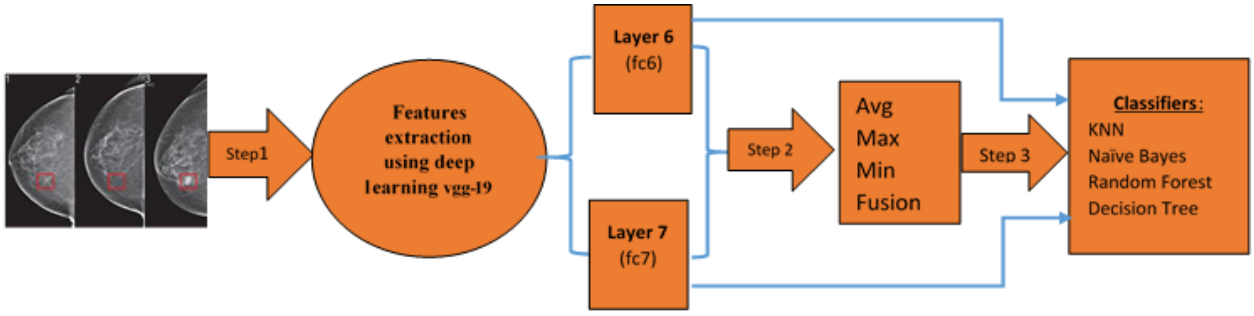

Fig. 1. Proposed experimental setup model.

The explanation for the statistical operations is in the following: 1) Max: It is the largest value of fc6 and fc7. 2) Min: It is minimum value of fc6 and fc7. 3) Avg: It is the average for (fc6 and fc7). 4) Fusion between fc6 and fc7: It is used to combine the first group of fc6: (4096) next to the second group of fc7: (4096), and thus that will create dataset, which contains 8192 features.

Step 3: The aforementioned classifiers will be applied on the datasets that obtained from step 1 and step 2 to provide the results represented by Accuracy, Recall, F-measure, Precision, and duration time.

IV. Experimental Results and Discussions

The study is designed for three scenarios. In each scenario, the results of the evaluation of performance for the breast cancer images is represented by: Accuracy (Acc), Recall, F-measure, Precision (Pre) and duration training time for each classifier. The evaluation of performance is applied on the following four classifiers; KNN, NB, RF, and DT. The results of each scenario are illustrated in the following subsections.

A. First Scenario

This scenario was designed based on the percentage of 50% for training and 50% for testing. Its aim is to investigate the influence of 50% of the data size in the training dataset on the classification accuracy. In this scenario, three results are obtained. First, results for original fc6 and original fc7 datasets. Second, results for the statistical operations. Finally, results for fusion feature between (original fc6 and original fc7) dataset.

1) Results for original fc6 and original fc7 datasets separately: Table I and Table II show the results of the Fully Connected: fc6 feature vector dataset and fc7 feature vector dataset which were obtained from CNN outputs based on using different classifiers.

The results showed that Random Forest outperforms other algorithms in classifying breast cancer if it is malignant or benign for fc6 and fc7 which are (88.24) and (88.35) of classification accuracy respectively. However, the training time required to conduct the experiment shows that DT required more time (i.e. 16.03) compared to others, but KNN required little time (i.e. 0s). The reason for that, because there is no training model; the comparison occurs directly between the test row with other training rows (examples), and this explains the slow in time for testing, especially if there is large size of data (examples) for the training [52-53]. This results match with the results in [50] in term of that RF outperforms other classifiers used in their study. Their study compared Random Forest with Support Vector Machine, DT, Multilayer Perceptron, and KNN.

To the best of my knowledge, there was no the same study achieved to detect breast cancer based on the same proposed model in using deep learning with these four classifiers together (i.e. KNN, NB, RF, and DT), and also using statistical operations (i.e. Avg, Max, Min, and Fusion of fc6 and fc7), or using the three scenarios.

2) Results for the statitsical operations: The results of three datasets that created for statistical operations (i.e. Avg, Max, and Min) are presented in this section.

Tables III to V show results of the three statistical operations, whereas Random Forest algorithm outperforms other algorithms in classifying breast cancer if it is malignant or benign for Avg, Max, and Min, which are (88.28), (87.87), and (88.07) respectively. Despite of the Random Forest have showed an acceptable classification accuracy that outperformed other classifiers, it showed also an acceptable training time. While the training time required to conduct the experiment, the classifier Decision Tree required more time (i.e. 14.38s) compared to others, but KNN required little time (i.e. 0s), this is for the same reason mentioned in Section A of First Scenario. This results match with the results in [50] as mentioned in Section A of First scenario in the field of conducting study on RF, but not in using the statistical operation or three scenarios.

3) Results for fusion feature between (orginal fc6 and orginal fc7) dataset: This dataset is created by fusion of fc6 (4096 feature) and fc7 (4096 feature). The total feature will be 8192. The results in Table VI showed that Random Forest algorithm (88.38) outperformed other algorithms in classifying breast cancer if it is benign or malignant. The second-high accuracy is for KNN (86.78). While the training time for the classifiers, DT required large time (28.79s), but KNNs required less time (0s) when compared to other classifiers.

The summary of first scenario is that the results for all datasets used in first scenario are slightly similar to each other; especially for RF and KNN. This means all the features used in the study can have the same influence on the classification accuracy.

B. Second Scenario

This scenario was designed based on the percentage of 70% for training and 30% for testing. Its aim is to investigate the influence of 70% data size in the training dataset on the classification accuracy. In this scenario, three results are obtained. First, results for original fc6 and original fc7 datasets. Second, results for the statistical operations. Finally, results for fusion feature between (original fc6 and original fc7) dataset.

1) Results for original fc6 and original fc7 datasets separately: Table I and Table II show the results of the Fully Connected: fc6 feature vector dataset and fc7 feature vector dataset which were obtained from CNN outputs based on using different classifiers.

The results showed that Random Forest outperformed other algorithms in classifying breast cancer if it is benign or malignant for fc6 and fc7, which are (88.24) and (88.63) of classification accuracy respectively. While the training time for the classifier Decision Tree required more time (i.e. 31.09s) for fc7 compared to others. But KNN required little time (i.e. 0s), this is for the same reason mentioned in Section A of First Scenario. This results match with the results in [50] as mentioned in Section A of First scenario in the field of

conducting study on RF, but not in using the statistical operation or three scenarios.

2) Results for the statitsical operations: The results of three datasets that created for statistical operations (i.e. Avg, Max, and Min) are presented in this section.

Tables from III to V show results of the three datasets (avg, max, and min). The classifier Random Forest outperformed other algorithms in classifying breast cancer for Avg, Max, and Min, which are (88.51), (87.95), and (88.36) respectively. Despite of the RF have showed an acceptable classification accuracy that outperformed all other classifiers, and the training time was also an acceptable compared with others. While the training time for the classifier Decision Tree required more time (i.e. 81.13s) compared to others. But KNN required little time (i.e. 0s), as this explained earlier in Section A of First Scenario. This results match with the results in [50] as mentioned in Section A of First scenario in the field of conducting study on RF, but not in using the statistical operation or three scenarios.

TABLE VII. COMPARISON BETWEEN PROPOSED MODEL VS. MOST RELATED WORKS

Authors' References	Description of method/ technique	Dataset Size	Performance metric/s (value/s)
[54]	It consists of two stages: 2D detection and 3D aggregation. In 2D, the magnitude and orientation field map generated using Gabor filters. Then, features extracted using Faster-RCNN to determine the spatial pattern of AD. In 3D, the fusion strategy for regions is used for 2D into 3D. They used Soft classifier.	265 DBT image. They were collected from 68 patients	Mean True positive fraction (MTPF) of 50 +_ 0.04 ACC=90%
[55]	They used VGG-16 with progressive fine-tuning to evaluate its performance on AD detection. Then, the results were compared with a custom CNN architecture that were trained from scratch.	280 image	AUC=0.89
[56]	Breast masses detected system was developed based on texture description, spectral clustering, and support victor machine (SVM). ROIs were segmented using spectral clustering relaying on texture. Then, the optimal features were submited to SVM. They used SVM classifier.	-	Accuracy 90%
[51]	Different of CNN models are used for feature extraction: VGG16, InceptionV3, and ResNet50. Data were enlarged up to 400X to increase the accuracy. They used Softmax classifier.	7,909 images (Number of patients 82: 24 benign patients and 58 malignant patients).	98.26%.
The proposed model	The following are used in this study: - CNN (VGG-19 technique): features extracted from two layers: (fc6+fc7). - Fusion for two layers: (fc6+fc7) - Apply classifiers on: Fc6, fc7, statistical operations (avg, max, min, and fusion). - Three scenarios in the training dataset. - Used the following classifiers: K-Nearest Neighbors, Random Forest, Naïve Bayes, and Decision Tree.	5872	Accuracy (88.63%)

3) Results for fusion feature between (original fc6 and original fc7) dataset: This dataset is created by fusion of fc6 (4096 feature) and fc7 (4096 feature). The total feature will be 8192. The results in Table VI showed that there was not big difference between them, but Random Forest algorithm achieved higher accuracy compared to other algorithms in classifying breast cancer if it is benign or malignant for (88.61) of accuracy. The second-high accuracy is for KNN (86). While for the training time for classifiers; Decision Tree required more time (73.95s), but KNNs required little time (0s) compared to other.

The summary of second scenario is that results for all datasets used in the second scenario are slightly similar to each other; especially for RF and KNN. This means that all the features used in the study can have the same influence on the classification accuracy

C. Third Scenario

This scenario was built based on the percentage of 80% for training and 20% for test data set. Its aim is to investigate the influence of 80% data size in the training dataset on the classification accuracy. In this scenario, three results are obtained. First, results for original fc6 and original fc7 datasets.

Second, results for the statistical operations. Finally, results for fusion feature between (original fc6 and original fc7) dataset.

1) Results for orginal fc6 and orginal fc7 datasets separatly: Table I and Table II show the results of the Fully Connected: fc6 feature vector dataset and fc7 feature vector dataset which were obtained from CNN outputs based on using different classifiers.

The results showed that Random Forest outperforms other algorithms in classifying breast cancer if it is benign or malignant for fc6 and fc7, which are (88.10) and (88.35) of classification accuracy. While the training time for the classifier Decision Tree required more time (i.e. 57.63s) for fc7 compared to others, but KNN required little time (i.e. 0s. This results match with the results in [50], as discussed in Section A of First and Second Scenarios.

2) Results for the statitsical operations: The results of three datasets that created for statistical operations (i.e. Avg, Max, and Min) are presented in this section.

The results of statistical operations are presented in Tables from III to V. The results show the Random Forest algorithm outperformed other algorithms in classifying breast cancer for Avg, Max, and Min, which are (88.35), (88.20), and (87.88) respectively. In addition to these results of having acceptable accuracy for the Random Forest, the confusion matrix; F-measure, recall, and precision are scored high values among all other classifiers.

The training time for RF was also in an acceptable compared with others. While the training time for the classifier Decision Tree required more time (i.e. 51.01s) compared to others, but KNN required little time (i.e. 0.02s. This results match with the results in [50] in the field of classification accuracy results for RF, as they did not conduct their study in using the statistical operation or three scenarios.

3) Results for fusion feature between (original fc6 and original fc7) dataset: This dataset is created by fusion of fc6 (4096 feature) and fc7 (4096 feature). The total feature will be 8192. The results in Table VI showed that there were not big difference between the values of accuracy. Therefore, Random Forest algorithm outperformed other algorithms in classifying breast cancer if it is malignant or benign in fusion dataset that achieved (88.25) of accuracy. The second-high accuracy is for KNN (86.63). While the training time for the classifiers Decision Tree required large time (91.39s), and KNNs required less time (0s) compared to other classifiers.

The summary results for the three scenarios show that the classifier Forest showed better classification accuracy compared to other classifiers. In general, the required time to achieve was high for the case; fusion dataset in the third scenario, this is because the size of data is huge in the training, which was 80% and required a lot of time. In term of investigating the influence of the three scenarios on the classification accuracy, the results have approved that the detection for breast cancer can be achieved with almost similar classification accuracy even if the training dataset was minimal.

Table VII shows the comparison between our proposed model with most similar studies conducted for breast cancer detection. The proposed model can be considered as one of the interesting study, for number of reasons, mentioned below.

Some others of previous studies were performed on small dataset compared to proposal model.

Some others of previous studies were performed on large data size in training dataset (examples) compared to proposal model which contained a few images (examples). Three scenarios were considered in the proposal model. It was approved by our proposal model that using few number of images in the training dataset usually leads to low classification accuracy compared to use large number of images.

Some of previous data enlarge the data up to 400 times categories to increase the data size such as in [51]. This may influence on the training dataset that then would effect on the accuracy. In our proposed model, there were no enlarge in the training datasets.

To the best of my knowledge, we have not come across to any research performed based on statistical operations nor using three scenarios to detect breast cancer for the classification accuracy purposes, which considered a new method in this field.

V. Conclusion

The aim of this study is to investigate the use of deep learning model for breast cancer detecting using VGG-19 that used for extracting features from ultrasound images. Two layers of VGG19 structure were used: (i.e. fc6 and fc7); each of layer contains 4096 features. Also, more feature vectors were created from (fc6 and fc7), which called statistical operations. Different statistical operations are used to generate more datasets such: average, minimum, maximum and fusion of both fc6 and fc7. These datasets will be employed as input for the following ML classifiers: KNN, Random Forest, Naïve Bayes and Decision Tree. Data augmentation was considered to increase the dataset size for better learning of CNN.

Based on the results; Random Forest achieved high accuracy (88.63), precision (0.88), recall (0.88) and F-Measure (0.88) for fc7 of second scenario. The results were slightly similar; this approves that these features can provide a better accuracy when used in detection studies. Also, the results of the classification accuracy in the three scenarios are slightly similar, this approves that the breast cancer can be detected even if the size of data in the training dataset was minimal.

In the future work, it is recommending to conduct more investigation to improve the classification accuracy results and reduce training time using different algorithms.

Detecting Threats from Live Videos using Deep Learning Algorithms

Rawan Aamir Mushabab AlShehri[1], Abdul Khader Jilani Saudagar[2]
Information Systems Department, College of Computer and Information Sciences,
Imam Mohammad Ibn Saud Islamic University (IMSIU), Riyadh, Saudi Arabia

***Abstract*—Threat detection is an important area of research, particularly in security and surveillance applications. The research is focused on developing a threat detection system using DL techniques. The system aims to detect potential threats in real-time video streams, enabling early identification and timely response to potential security risks. The study uses two state-of-the-art DL models, MobileNet and YOLOv5, to train the object detection system. The TensorFlow object detection API is employed for training and evaluating the models. The results of the study indicate that MobileNet outperforms YOLOv5 in terms of detection accuracy, speed, and overall performance. The justification for selecting MobileNet over YOLOv5 is based on several factors. First, MobileNet has a lightweight architecture, making it suitable for real-time applications where processing speed is critical. Second, it is efficient in terms of memory usage, enabling it to operate effectively on low-resource devices. Third, MobileNet provides high accuracy in detecting objects of different sizes and shapes. The study evaluated the performance of the threat detection system using various evaluation metrics, including mean average recall (mAR), mean average precision (mAP) and Intersection over union (IoU). The results show that the system achieved high accuracy in detecting threats, with an overall mAP (mean average precision) of 0.9125, mAR (mean average recall) of 0.9565 and Intersection over union (IoU) of 0.9045. In this study, researchers present a highly efficient and successful method for identifying threats through the utilization of deep learning methods. The research demonstrates the superiority of MobileNet over YOLOv5 in terms of performance, and the results obtained validate the effectiveness of the proposed system in detecting potential threats in real-time video streams.**

I. INTRODUCTION

Nowadays, technologies are experiencing unprecedented growth and advancement, particularly in the field of Data Sciences (DS). DS encompasses a wide range of disciplines, including Artificial Intelligence (AI), Machine Learning (ML), and Deep Learning (DL). AI involves the external creation of intelligence for various systems, enabling them to make decisions based on insights derived from available data. ML empowers machines to process data and generate knowledge and intelligence by integrating applied statistics and optimization theory. DL is a subfield of ML that specifically concentrates on constructing, training, and deploying extensive and intricate neural networks [1]. By leveraging data in parallel, these neural networks carry out their operations with the aim of accomplishing their assigned tasks. To develop an intelligent system for object detection, it is necessary to identify and categorize moving objects. Object detection entails the ability of computers and software systems to identify the presence and location of various objects within an image, such as vehicles, animals, humans, and more. Deep convolutional neural networks have gained significant prominence in tasks like image classification, object classification, localization, and object detection [2]. DL technologies have been increasingly applied in image classification, target tracking, object detection, image segmentation. These technologies have helped in different social life events and cases. The focus in this research is to use these technologies to raise safety and security. Considering the escalating global crime and terrorism rates, the demand for automated video surveillance has surged. The combination of surveillance and detection has become critically significant. While human detection and tracking are desirable, the unpredictable nature of human movement presents significant challenges in effectively tracking and categorizing suspicious activities. The focus of this research is to identify and detect potentially threatening objects captured by Close Circuit Television Cameras (CCTV) [3]. This idea comes out of the great need for detecting threatening objects to help evaluate situations or prevent any further crimes. Finally, the idea behind this research is extracted and built based on the previous studies in the field of DL techniques. Also, among the search between the previous studies, there was no use of the MobileNet model in the field of recognizing and detecting objects in videos especially threatening objects.

A. Object Detecting Technique

Object detection is a computer vision technique that empowers software systems to identify, locate, and track objects within images or videos. One of its notable features is the ability to classify objects (such as people, tables, chairs, etc.) and precisely determine their coordinates within the image. This is achieved by drawing a bounding box around the object, although the accuracy of the bounding box may vary. The effectiveness of the detection algorithm is measured by its capacity to accurately locate objects within the image. An example of object detection is facing detection.

Object detection algorithms can either be pre-trained or trained from scratch, with pre-trained weights from existing models often utilized and fine-tuned to suit specific requirements or use cases. Object detection is a crucial area of research in computer vision and finds widespread applications in various fields, including surveillance, robotics, autonomous vehicles, and image and video search engines. The objective of object detection is to enable machines to comprehend and

interpret the visual world in a similar manner to humans. Deep learning techniques, such as convolutional neural networks (CNNs), are commonly employed in object detection algorithms to analyze images or videos and identify objects within them. These algorithms are trained on large datasets comprising labeled images, where the object's location and class are annotated. The training process involves adjusting the weights and biases of the neural network to minimize the error between predicted and actual object locations and classes. Once trained, object detection algorithms can be applied to detect objects in new images or videos. The algorithm typically outputs a set of bounding boxes corresponding to the detected objects, accompanied by their class labels and confidence scores. Post-processing techniques can be further employed to refine the bounding boxes and enhance the accuracy of the object detection process.

In recent years, there has been significant progress in object detection, driven by advances in DL and the availability of large datasets. State-of-the-art object detection algorithms can achieve high accuracy and real-time performance on a wide range of object types and scenarios. In addition to the traditional object detection methods, there are also several advanced techniques that have emerged in recent years. Below are a few examples:

1) One-shot object detection: Traditional object detection algorithms require a large amount of labeled data during the training phase. One-shot object detection, on the other hand, is a technique that can detect objects with only one or a few examples of each object class during training.

2) Instance segmentation: Instance segmentation is an extension of object detection that not only detects the objects in an image but also segments each object instance from the background. This technique is useful in scenarios where precise object boundariesare necessary, such as in medical imaging or autonomous driving.

3) 3D object detection: While traditional object detection works on 2D images, 3D object detection can detect objects in 3D space. This is important for applications such as robotics and autonomous vehicles, where the detection of objects in 3D is necessary for navigation and obstacle avoidance.

4) Few-shot object detection: Similar to one-shot object detection, few-shot object detection is a technique that can detect objects with only a few examples of each object class during training. However, few-shot object detection is more challenging than one-shot object detection as it requires the algorithm to generalize to unseen object classes.

B. Object Detecting from Image and Video

Object detection is an important and prominent area of research that combines deep learning (DL), computer vision, and image processing. Its primary objective is to identify specific semantic objects, such as people or animals, in digital images and videos. Within the field of object detection, there are well-established areas of study, such as pedestrian detection and face detection. However, object detection has broader applications in various DL fields, including image restoration and video surveillance [4]. To differentiate between different objects, object detection employs a multi-label classifier, although it does not determine the specific identity of each object. This is where Image Localization comes into play, as it precisely determines the object's location within the image by providing a bounding box around it. Image Localization technology has practical applications in image retrieval, with facial detection being a widely used example. Additionally, it can assist in pedestrian detection at traffic lights to enhance traffic flow and aid visually impaired individuals. It also facilitates Sign Language Detection (SLD) to support communication with the deaf and mute community. The process of object detection involves providing an image or video frame, using algorithm-based models to search for targeted objects, and assigning specific categories to each identified target [5]. Object detection algorithms commonly employ machine learning (ML) and DL techniques to achieve meaningful results. Furthermore, the ultimate goal of object detection models is to emulate the rapid comprehension and recognition of objects by the human brain when observing images or videos. Training DL algorithms and models to match the intelligence of the human brain using computer technology is a challenging yet crucial task, particularly in the context of detecting potentially threatening objects.

C. Problem Statement

The research focuses on the detection and recognition of objects using ML and DL techniques, which is a prominent area of study for DL enthusiasts. The aim is to enable machines to learn autonomously by simulating the functioning of neurons in the human brain. While previous works have explored object detection for various social issues, there is a lack of research specifically addressing the detection of threatening objects in videos and evaluating the MobileNet model for this purpose. This research aims to enhance community safety and security by improving the detection of threatening objects, as incidents and accidents often result from inadequate security measures or delayed responses to immediate threats. The research seeks to answer two main questions: is there an efficient way to detect threats from live videos using DL algorithms, and how accurate and efficient is the MobileNet model in detecting objects in live videos? The objectives of the study are to detect threats in live videos to prevent the criminal use of threatening objects and to assess the efficiency and accuracy of the MobileNet model in detecting threatening objects. The research utilizes DL techniques to identify and detect threats in live video clips or surveillance videos. The idea for this research originated from the urgent need for video analysis on the internet, and it builds upon a review of previous studies in DL and its techniques. The researchers identified a gap in utilizing the MobileNet model for identifying and detecting potential shapes and threats in videos. The MobileNet model will be employed in this research to detect threatening objects, and the results will be analyzed in terms of accuracy and quality.

II. LITERATURE REVIEW

The DL fields are full and rich by the research in this domain. The related work to this contribution was different in the model that they used, or they study the same model to different dataset, or they wanted to detect images instead of

video. There are very limited kinds of literature that have adopted detecting threats by using DL or ML algorithms. This section presents most of the notable research worked on DL, ML, and object detection.

A. Object Detection Algorithms

Object Detection is a very trending domain among researchers. It was thoroughly studied from the beginning of 2010 until the current time [6]. That shows how much this domain is important and rich. Fig. 1 shows the number of publications with the keywords of "Object Detection" during the past 10 years.

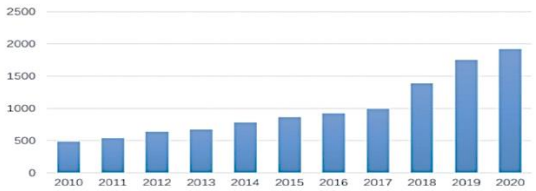

Fig. 1. The growing numbers of publications in object detection algorithms.

Object detection plays a crucial role in computer vision applications, enabling the automatic identification and localization of objects within images or videos. The researcher Shaukat Hayat. el at [7], studied a DL framework for object recognition purposes. The proposed model was further tuned, and the recognition performance was improved. They use nine different object classes taken from wide varied image dataset caltech101 and deploy five layers CNN model. They compared the proposed model's performance with different classical bag-of-words (BOW) approaches trained on a novel. This algorithm achieved an accuracy level of 90.12% is much better than different classical BOW approaches. While Kanimozhi S. el at [8], tried to detect and track the object in the sports field to make the computer learn Deeply, which is none other than the application of DL. The proposed method increases the accuracy level in identifying real-time household objects. Aniruddha Srinivas Joshi, el at [9], adopted the idea of detecting face masks from video footage. A highly effective face detection model is applied for obtaining facial images and cues. A distinct facial classifier is built using DL to determine the presence of a face mask in the facial images detected. The proposed method has shown its good effectiveness in identifying facial masks by achieving high precision, recall, and accuracy. As for using ML algorithms to detect threats included in the social media post, Shatha Alajlan. el at [10] has published research in that domain. She utilized the CNN model on the TensorFlow platform to classify Instagram content (images and Arabic comments) for threat detection. The results of this research showed that the accuracy of the developed model is 96% for image classification and 99% for comment classification.

1) Using object detection algorithms: Muhammad Shakeel. el at [11] have developed a passenger security screening system that employs DL techniques to detect potential security threats by rotating the image of a person's body. However, this method has limitations in identifying the specific type of threat and precisely locating its position within the body. Shaoqing Ren. el at [12] have conducted a study on object classification and detection performance, achieving a remarkable 5-7 frame rate per second and 73.2% mean average precision (mAP). Their approach involves categorizing objects and identifying their precise location, allowing for the development of an efficient security screening algorithm that accurately detects threats at specific locations using an enhanced faster R-CNN model. A comprehensive analysis of cargo X-ray image analysis automation was carried out by Jaccard, Nicolas et al. [13]. The review emphasized the importance of employing image pre-processing techniques, including image quality enhancement, manipulation, material discrimination, and segmentation. These techniques play a crucial role in improving the accuracy of automated image understanding algorithms and rectifying errors that may arise during image acquisition.

Moreover, Jaccard's paper proposes an automated threat detection method to further improve the accuracy in the analysis of cargo X-ray images. Nicolas Jaccard el at. [13] have developed a CNN model specifically designed for detecting threats in X-ray images. Their model was trained using an augmented dataset that included real threat images, resulting in a high detection rate of 90% and a low false alarm rate of only 0.8%. The effectiveness of image manipulation and quality improvement techniques in enhancing the proposed solution is highlighted in their study. In their study, Akcay, Samet et al. [14] investigated the potential of convolutional neural networks (CNNs) for object classification in X-ray baggage images. Their research focused on utilizing CNNs to improve the accuracy of object classification in this domain.

On the other hand, Riffo, Vladimir and Flores Sebastian [15], proposed an innovative automated approach for object detection in X-ray images, specifically for baggage screening purposes. Their solution involved the utilization of an adapted implicit shape model (ASIM), an enhanced version of the implicit shape model introduced in the research conducted by Leibe, Bastian et al. [16]. The ASIM approach employed SIFT descriptors to describe objects using multiple X-ray images from different perspectives. The visual vocabulary of object parts was then used to characterize the object, and targets were detected by searching for similar visual words and spatial distributions. Although the object detector incorporated pose estimation and Q-learning computer vision techniques, it may not be ideal for region-based threat detection.

Furthermore, Nurhopipah, Ade et al. [17] conducted a study that delved into various aspects of motion detection, face detection, data training, and face identification. Their research aimed to explore the complexities associated with these areas in the context of threat detection. Their utilization of the Accumulative Differences Images (ADI) approach for motion segmentation proved successful, with motion detection reaching a high success rate of 92.655%. The Haar cascade classifier was employed for face detection, with a success rate of 76%, and face identification reached 60%. Meanwhile, Busarin Eamthanakul. el at [18] implemented the background subtraction method and median filter to compute data and analyze traffic conditions. Their system was able to detect the

number of objects or cars on the road, providing useful data for traffic management.

Nipunjita Bordoloi. el at [19] developed a security system that effectively tracks object movement and detects anomaly motion in real-time. Background subtraction was utilized to track objects, and the system achieved success in detecting suspicious activity. Alavudeen Basha. el at [20] also delved into suspicious activity detection, using a CNN-DBNN algorithm to detect human activity. The technique of foundation subtraction was used for human detection, with larger bounding boxes to enclose individuals. A Discriminative Deep Belief Network (DDBN) was implemented for activity classification, with an impressive accuracy rate of 90%. The research in computer vision systems continues to advance, providing new and innovative ways to detect and analyze data.

2) Using mobilenet model: MobileNet models offer an efficient solution for on-device intelligence across various recognition tasks. Developed specifically for TensorFlow, MobileNets are a family of computer vision models designed with a mobile-first approach. These models prioritize accuracy while considering the limited resources available for on-device or embedded applications. MobileNets fall under the category of lightweight deep convolutional neural networks, significantly smaller in size and faster in performance compared to many other popular models. Their small footprint, low latency, and low power consumption make them well-suited to meet the resource constraints of diverse use cases. MobileNet models can be leveraged for classification, detection, embeddings, and segmentation tasks, providing a versatile framework for on-device intelligent applications.

3) The Gap on the Literatures: This research aims to complete what other researchers have done by using DL algorithms and the MobileNet model to detect objects in images and videos. All the studied and reviewed literature were specifying different domain of study or different type of purposes. However, this research focus on Using the MobileNet model to detect the threatening objects on videos. According to previous studies, various researchers have reported high AP values for this model's ability to detect different classes such as cars, persons, and chairs. Some research findings suggest that the AP reaches as high as 99.76%, while others claim to achieve a slightly lower value of 97.76% [21]. Researchers want to approve if the same percentage would be detected with the same purpose they aim to study. This action has not been previously investigated by researchers in the field of object detection by using DL algorithms.

III. Methodology

This research aims to investigate the effectiveness of the MobileNet model in detecting threatening objects. Object detections a crucial task in computer vision, and it has numerous applications in various domains, such as security, surveillance, and autonomous driving. The research is focused on detecting threatening objects in public places, and the results could have significant implications for improving public safety as its none of the research objectives. The research approach adopted is a qualitative exploratory approach, which is a suitable method for gaining an in-depth understanding of a phenomenon.

A. Research Design

A research design serves as a structured framework or strategy for collecting, measuring, and analyzing data with the purpose of addressing specific research inquiries [22]. Fig. 2 shows the research scenario that the researcher follows to answer the research question and fulfill its objectives.

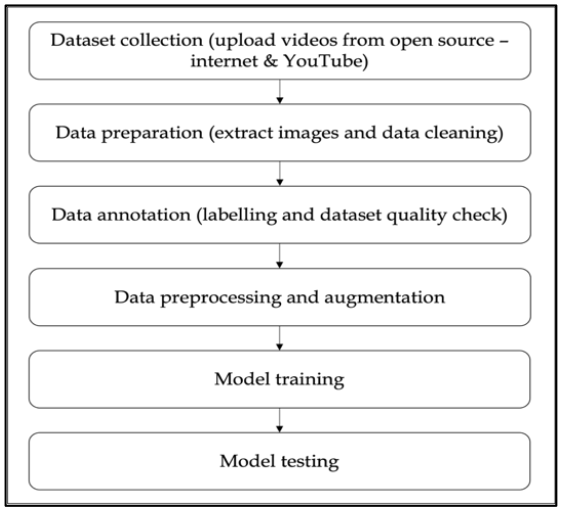

Fig. 2. Research scenario.

B. Data Collection

The dataset used in this study was curated for the purposes of the study. It was generated and collected by the researcher from various sources. It consists of five classes of objects that are considered potentially dangerous or threatening, including: fire, guns, knives, arrows, and swords. These objects were chosen due to their prevalence in public safety incidents and their potential to cause harm. To obtain the data, various sources were utilized, including YouTube videos that contained CCTV footage, educational videos for learning fighting skills, and demo videos. The videos were processed by extracting frames at a rate of 1 frame per second (1 fps) to capture the necessary images for the dataset. The use of CCTV footage is particularly useful as it allows for the collection of authentic data from public places where security cameras are commonly used. To annotate the dataset, the RoboFlow tool was utilized, which is a popular image annotation tool used for object detection tasks. Annotations provide additional information about the images, indicating the location and class of the object within the image. These annotations are essential for training ML models to accurately detect objects. To increase the diversity of the dataset, augmentations such as rotation and contrast difference were applied to the images. These augmentations help to create variations of the images, which can improve the performance of ML models by exposing them to a wider range of data. The purpose behind curing such dataset is essential for training ML models to accurately detect these objects within the five mentioned classes and improve public safety.

C. Data Preparation

Object detection from images is a fundamental task in DL that requires a significant amount of labeled data for training. The MobileNet SSD model is a popular DL model for object detection, but it requires a large, labeled dataset for effective training. In this study, a sufficient amount of data was obtained by collecting threatening videos and CCTV footage from online resources such as YouTube. The videos collected for this study mainly contained real-life activities, such as ATM robberies and police operations, to ensure that the dataset reflects real-world scenarios. Additionally, training and rehearsal-based videos were included to increase the number of images for each object in the dataset. This was an important step because having a larger dataset with a balanced distribution of classes can improve the performance of the model. To create the labeled dataset, frames were extracted from the videos at a rate of 30 frames per second (30 FPS) using the RoboFlow tool. Each frame was manually labeled for the presence of five different objects, including guns, knives, swords, arrows, and fire. Manual labeling is a crucial step in creating a high-quality labeled dataset because it ensures that the labels are accurate and consistent. The use of real-life video footage and manual labeling ensures that the dataset is of high quality and accurately reflects the threatening objects. This can improve the accuracy and reliability of the model when detecting threatening objects in real-world scenarios.

1) Data cleaning: After extracting all the images from videos uninformative and vague frames are discarded for data cleaning and maintaining data quality. Only frames with clear object visibility are remained after cleaning that are labelled manually for five object classes. Data classes are sampled in such a way that create a balanced number of images per object in training, validation, and testing.

D. Data Annotation

In this phase, the researcher used the RoboFlow annotation tool that enabled drawing bounding boxes around the objects of interest. RoboFlow enables the uploading of videos and extraction of images with varying FPS rates. Each image is labeled for its particular class name and bounding box. The RoboFlow tool allows saving the bounding box values in different formats, as required by the model. In this case, the labeling is saved as a CSV file to comply with the MobileNet SSD file format. The minimum and maximum values for the bounding box x and y sides are saved to draw the bounding box rectangle. The RoboFlow interface for image labeling is depicted in the Fig. 3. When labeling the images using the RoboFlow tool, a bounding box is drawn around the object of interest in the image. The bounding box is represented by a rectangular box with four values: the x-coordinate and y-coordinate of the top-left corner of the box, and the width and height of the box. To save the bounding box values in the CSV file, the RoboFlow tool records the minimum and maximum values for the x and y coordinates of the top-left corner of the box, as well as the width and height of the box. These values are saved in separate columns in the CSV file, along with the class name of the object in the image. For example, there is an image containing a gun, and the bounding box around the gun has a top-left corner coordinate of (100, 150), a width of 50 pixels, and a height of 100 pixels. The RoboFlow tool would save the following values in the CSV file for this object as follow:

- Class Name: Gun
- Minimum x-coordinate: 100
- Maximum x-coordinate: 150
- Minimum y-coordinate: 150
- Maximum y-coordinate: 250

To start the annotation step, the researcher opened each image using the chosen annotation tool. For every image, the researcher carefully drew bounding boxes around the instances of the objects that aimed to be detected. For each bounding box, the researcher assigned the correct class label from the five mentioned classes which are: fire, gun, knives, arrows, or swords. This step was done manually to ensure accurate placements and labels, as these annotations would serve as the ground truth for the models training phase. With the annotated dataset in hand, the next step was to integrate it with the respective training frameworks. The researcher utilized the annotations they had created to train the object detection models.

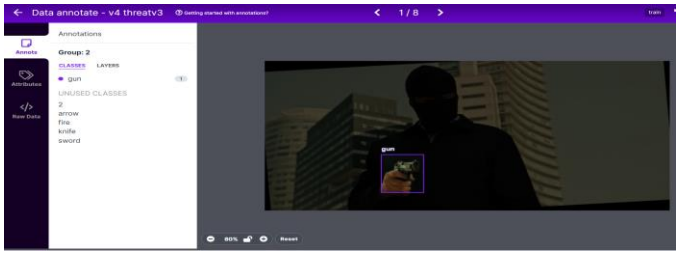

Fig. 3. RoboFlow interface.

1) Dataset quality check: Ensuring data quality is a critical step before building models for object detection. Poor data quality can lead to inaccurate and unreliable models. Below the used methods taken to ensure data quality in object detection:

- Annotation Quality Control
- Data Cleaning and Preprocessing
- Balanced Class Distribution
- Data Augmentation
- Validation and Anomaly Detection
- Consistent Image Quality
- Real-World Scenario Simulation
- Review Annotations for Ambiguity
- Class Label Consistency
- Cross-Validation
- Continuous Monitoring
- Use External Data Sparingly

- Expert Review
- Feedback Loop

Once reached the confident in the quality of the annotations, we proceeded to export the annotated dataset from RoboFlow. The platform typically provided options to export the data in formats that were compatible with various deep learning frameworks. Given this scenario, the researchers ensured that the exported format aligned with the chosen model architecture, whether it was YOLO or MobileNet SSD.

E. Data preparation and Augmentation

Data preprocessing is applied in order to make it suitable for effective model training. Images are resized to one scale 416x416 for MobileNet SSD model. Data preprocessing enhances data quality and decreases training time. Images are scaled, cropped, and resized to make them in same format before model training. Data augmentation is also applied to increase veracity of data so model can learn better with more data as addressed before. Images are rotated, blurred, and adjusted contrast and orientation for data augmentation purposes.

F. Data Limitations and Issues

DL models require a large amount of data to train effectively, and the more data feed into the model, the better its performance would be. In this study, the researchers have around 2000 images for each object after augmentations. However, the number of images per sample is relatively low, and the diversity of real scenarios is limited, which are some of the limitations of this dataset. To improve the performance of the model, more data can be collected from real-time scenarios. Furthermore, due to privacy concerns and issues, many establishments and markets are hesitant to share their camera recordings. Therefore, more collaboration and support are needed to collect a diverse range of datasets to improve the model's performance and deliverables.

G. Model Building

This research focus on two DL models. The YOLOv5 (You Only Look Once version five) model, which has undergone thorough scrutiny by researchers, stands out as the initial model that has gained recognition for its effectiveness in object detection. This model showcases highly promising accuracy outcomes based on two key metrics: mAP (mean average precision) and FPS (frames per second). In a study conducted by S. Murthy et al. [23], the application of YOLOv5 was investigated, and it demonstrated superior speed and a 95% accuracy rate compared to other object detection algorithms examined in the comparative analysis. Additionally, it achieved an average precision ranging between 67 and 70, along with a frames per second rate ranging between 65 and 124. A thorough comparison of the YOLO model versions in the below sections. In reference to the Debojit Biswas et al. work that has been done [24] MobileNet SSD model achieved 92.97% average detection accuracy in the experiment. Sanjay Kumar et al. confirm in his work that the SSD on MobileNet has the highest mAP among the models targeted for real-time processing [25]. That was promising to start the investigation upon this case.

1) YOLOv1: First object detection network that combines the problem of identifying class labels and determining bounding boxes for a set amount of classes, making it a one-stage detector (rather than two-stage detectors which first detects the regions of interest, and then classify that region as a specific class based on given input during training). This is possible by fully connecting the two important steps of bounding box prediction and classification of labels to an end-to-end differentiable network [26].

2) YOLOv2: From it's iteration of version one of YOLO, works have been done too dramatically improve the performance of the accuracy through the addition of BatchNorm, improved resolutions, and the use of anchor boxes [27].

3) YOLOv3: Improvements made from the previous model included the use of more connections in its backbone network layers as well as adding a new network that aids in the model's ability to identify smaller objects better (with the use of feature pyramid network (FPN) that allows the model to learn objects of different sizes simultaneously). Added an objectness score for the model's bounding box predictions, which helps determine the bounding box to take for all the bounding boxes overlapping a specific ground truth object within an image [26][27].

4) YOLOv4: Additional improvements were introduced into the YOLO series in YOLOv4 through the introduction of:

- Feature Aggregation which combines the features extracted from previous layers
- Bag of Freebies - several methodologies and functions added to improve its performance without affecting the model's inference during production. The main additions are related to data augmentation such as rotation, flip, crop, hue, saturation, mosaic, MixUp, Blur, etc.
- Self-Adversarial Training which allows the model to find the region of the image that its network relies most on and subsequently editing the image to remove this reliance to enable generalisation of the model.
- CIoU loss as the loss function which not only observes the overlap of bounding boxes with the ground truth (which is already done for IoU), but also how close the box was to the ground truth box in terms of the pixel distances within the image, which is an additional part of the loss function that is trained so that it enables the network to pull the predicted bounding box closer to the ground truth box.
- Using Mish activation as the activation function instead of ReLU which improves the performance of the model due to its ability to push the features created by the model towards its optimal [27][28].

5) YOLOv5: YOLOv5 represents the most recent iteration of the YOLO (You Only Look Once) series of object detection models, originally introduced in 2016. Developed by Ultralytics, a reputable computer vision research company,

YOLOv5 offers notable advancements in both accuracy and speed when compared to its predecessors. It attains state-of-the-art performance across multiple benchmark datasets while preserving real-time inference speeds on modern GPUs. This algorithm employs a single convolutional neural network (CNN) to predict object classes and bounding boxes by dividing the input image into a grid and making predictions based on each grid cell. This approach enables faster inference times and improved accuracy compared to region-based CNNs used in other object detection models. YOLOv5 has gained significant traction within the computer vision community and finds applications in various domains, including autonomous vehicles, robotics, security, and more [26]. YOLOv5 contains three layers as an object detection model: Backbone as the feature extractor, the Neck which combines and mixes different features extracted from the Backbone, and the Head which takes the outputs from the Neck and predicts bounding boxes and classification. The Backbone that mentioned in Fig. 4 was CSPDarknet. CSPDarknet is a neural network that contains a set of convolutional layers which are useful for consolidating images and extracting useful features which can be learnt from the model. As shown in Fig. 4, the Backbone consists of a set of BottleNeckCSP (Cross Stage Partial) blocks and a Spatial Pyramid Pooling (SPP) block. The bottleneck part of BottleNeckCSP helps reduce the number of feature maps, which in turn reduces the model size and computation. The cross stage partial part of BottleNeckCSP also aids in reducing the model size and computation required by reducing the amount of gradient information during optimization within the network while maintaining good accuracy for the model. It does this by splitting the base layer into two parts (one as the base layer, the other is partitioned into multiple blocks) and merging them back together again through a cross-stage hierarchy strategy. The SPP block performs pooling of the features from the previous CSP block to generate fixed-length outputs. This avoids the need to do any cropping, warping or preprocessing at the start of the input to the neck and is done through pooling which is an information aggregation function [30].

After the Backbone, the feature mixing and combining model used was Path Aggregation Network (PANet). PANet is a network architecture with a bottoms-up approach, where there is a feature hierarchy which aggregates and passes the information of multiple convolutional layers at different stages, enhancing the signals between lower layers and upper layers. Linking different feature levels together to allow the model to accurately detect both larger and small objects when performing object detection.

As shown in Fig. 4, there are several concatenation blocks which combine the lower and higher-level features together to be fed into the final head layers. The final layer is a set of 1x1 convolutional layers that takes in the input of the Neck (PANet) to pass into the regression that detects the bounding boxes and classifies them, and these are then used for training and inference/prediction [28]. During training, YOLOv5 will see the images inputted from the training dataset, use the Backbone (CSPDarknet) to extract out relevant features, thereafter, utilizing the PANet to concatenate lower and higher-level features together, and these are finally passed to output the bounding boxes and classes for different region of the image as predictions. This will be trained using the training dataset and can be used for inference after enough training is done for the model [29].

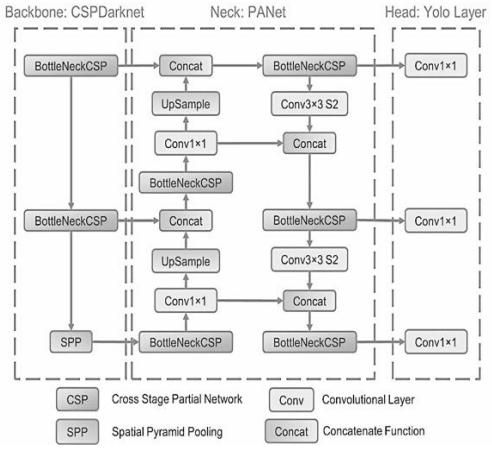

Fig. 4. YOLOv5 model architecture.

6) MobileNet Single Shot MultiBox Detector (SSD): The MobileNet Single Shot MultiBox Detector (SSD) is an object detection algorithm that combines the Single Shot Detector (SSD) framework with the MobileNet architecture. This algorithm was developed by Wei Liu et al. in 2016 [31]. MobileNet is specifically designed for mobile and embedded devices, offering a lightweight convolutional neural network architecture that utilizes depth-wise separable convolutions. These convolutions help reduce computational requirements while maintaining high accuracy. On the other hand, the SSD framework is a popular approach for object detection that utilizes a single convolutional neural network to predict object classes and bounding boxes [31]. MobileNet SSD enables real-time object detection on devices with limited computational resources, such as mobile devices and robotics. It is particularly beneficial for applications that require real-time object detection, including autonomous vehicles and surveillance. Despite its efficiency, MobileNet SSD achieves high accuracy on benchmark datasets like PASCAL VOC and COCO, all while maintaining fast inference times. As a result, it has gained significant adoption within the computer vision community and finds applications in various domains such as security, surveillance, and robotics [15][24]. MobileNet SSD comprises two key layers: a backbone model used to extract relevant features (in this case, VGG-16 was employed as the feature extractor), and the detector head, which outputs crucial information for object detection.

The VGG-16 model, proposed by researchers at the University of Oxford in 2014, serves as the backbone for many computer vision tasks. It is a convolutional neural network architecture comprising 16 layers, including 13 convolutional layers, 5 max pooling layers, and 3 fully connected layers. The

primary purpose of the convolutional layers is to extract meaningful features from the input image, enabling the model to capture relevant patterns and structures. On the other hand, the pooling layers play a crucial role in reducing the spatial dimensionality of the extracted features. By down sampling the feature maps, these pooling layers enhance computational efficiency during subsequent processing stages. Together, the combination of convolutional and pooling layers in the VGG-16 architecture enables effective feature extraction and representation for a wide range of computer vision applications. Finally, the fully connected layers learn to classify the extracted features into their corresponding categories. The detector head consists of several convolutional blocks that link to the detection block, as well as a post-processing step called Non-Maximum Suppression (NMS) as shown in Fig. 5. The purpose of the convolutional blocks that are linked at different levels to the detection head is to extract features at multiple levels, which enables the model to detect both small and large objects by extracting features for them. Subsequently, the NMS block will take the bounding boxes that are outputted from the model and pick out the bounding box that is closest to the ground truth bounding box using Intersection-over-Union (IoU) as the metric. NMS is only used during training. As an overview for the methodology of MobileNet SSD, the model will be fed the images from the training dataset, which goes through a feature extraction process in VGG-16 as the backbone. These feature extractors are then further convoluted, and features at different levels of convolutions are passed to the detection head for bounding box and classification prediction. For training, there is an additional process of NMS which choose the most prominent bounding box for each ground truth box. The pretrained SSD MobileNet v1 FPN with dimension of 640x640 were used for detecting the objects. it is an object detection model based on a single-shot detection (SSD) architecture with a feature pyramid network (FPN) and uses the MobileNet V1 neural network as a base feature extractor. This model is designed to detect objects in images of size 640x640 pixels. The SSD architecture is a popular object detection approach that predicts object categories and bounding boxes in a single forward pass through the neural network. The SSD MobileNet v1 FPN 640x640 model consists of a base network, feature pyramid network, and detection network.

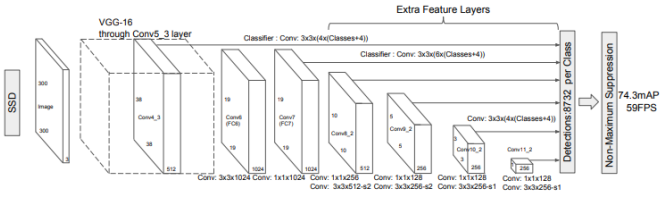

Fig. 5. MobileNet Single Shot Multi box Detector (SSD).

- Base Network: The base network of the model is the MobileNet V1 neural network. It is a lightweight deep neural network architecture that uses depth wise separable convolutions to reduce the number of parameters and improve computational efficiency. The MobileNet V1 architecture consists of a sequence of depth wise separable convolutional layers followed by standard convolutional layers, which are used to extract feature maps from the input image.
- Feature Pyramid Network: The feature pyramid network (FPN) is used to combine feature maps from different levels of the MobileNet V1 base network. The FPN is a top-down architecture that aggregates high-resolution feature maps from the lower levels of the base network with lower-resolution feature maps from the higher levels of the network. This creates a pyramid of feature maps with rich semantic information at multiple scales, which is useful for detecting objects of varying sizes in the input image.
- Detection Network: The detection network is used to predict the bounding boxes and object categories in the input image. The detection network consists of a set of convolutional layers that process the feature maps generated by the FPN. These layers are used to predict the locations and class scores of the objects in the input image. The SSD MobileNet V1 FPN 640x640 model uses a set of default anchor boxes at different scales and aspect ratios to generate object proposals. These proposals are then refined by the detection network to improve the accuracy of the final object detection results.

The SSD MobileNet V1 FPN 640x640 is a powerful object detection model that combines the strengths of the MobileNet v1 architecture, the feature pyramid network, and the single shot detection approach to achieve high accuracy and computational efficiency.

a) Parameters of the MobileNet SSD Model

The parameters for this model are as follows:

- Backbone architecture: This model uses a MobileNet V1 architecture as the backbone. MobileNet is a lightweight convolutional neural network architecture designed for mobile devices, which makes it suitable for real-time object detection on low-power devices.
- Feature Pyramid Network (FPN): This model uses a Feature Pyramid Network (FPN) to generate a multi-scale feature map. FPN is a technique used to extract features from images at different scales, which helps improve the accuracy of object detection.
- Input size: The input size for this model is 640x640 pixels. This means that the model can detect objects in images up to 640x640 pixels in size.
- Batch size: The batch size is the number of images that are processed simultaneously. The batch size of 8 was used for training the model.
- Learning rate: The learning rate is a hyperparameter that controls how much the model adjusts its parameters during training.
- Number of classes: The number of classes is the number of object categories that the model can detect. In this case it was five classes.

- Anchor boxes: Anchor boxes are a set of predefined bounding boxes of different sizes and aspect ratios that the model uses to detect objects.
- NMS threshold: The Non-Maximum Suppression (NMS) threshold is a parameter that controls how much overlapping bounding boxes are merged into a single detection. The default NMS threshold for this model is 0.6, but it can be changed depending on the specific use case.

b) Model Architecture

The details of model architecture with parameter setting for threat detection is given as:

- Number of classes: This specifies the number of classes or object categories that the model will detect. In this case, the model is trained to detect five classes.
- Image resizer: This defines how the input image is resized to fit the input size of the model. Here, a fixed shape resizer is used with a height and width of 640 pixels.
- Feature extractor: This defines the feature extraction backbone of the model. In this case, the SSD MobileNet V1 FPN Keras architecture is used. The depth multiplier is set to 1.0, and the minimum depth of the network is set to 16. The conv hyperparams section specifies the hyperparameters used for the convolutional layers of the feature extractor, including the L2 regularization weight, random normal weight initializer, and batch normalization parameters.
- Override base feature extractor hyperparams: This indicates that the hyperparameters specified in this pipeline config file will be used to override the default hyperparameters of the base feature extractor.
- FPN: This specifies the Feature Pyramid Network used for multi-scale feature extraction. The minimum and maximum levels of the feature pyramid are set to 3 and 7, respectively.
- Box Coder: In object detection, the box coder is used to encode and decode the predicted boxes, which is necessary because the predicted boxes are in a relative format and need to be converted back to the absolute coordinates of the image. The box coder section specifies the method used to encode and decode boxes. In this particular case, the box coder is using the faster R-CNN box coder method, which encodes boxes using their center coordinates, width, and height. The y scale and x scale values specify the scaling factors for the center coordinates, while the height scale and width scale values specify the scaling factors for the height and width. These scaling factors are used to normalize the box coordinates to a similar range.
- Matcher: The matcher section specifies the method used to match predicted boxes to ground truth boxes. In this case, the argmax matcher method is used, which matches predicted boxes to ground truth boxes based on their maximum intersection-over-union (IoU) overlap. The matched threshold value specifies the minimum IoU overlap required for a predicted box to be considered a match, while the unmatched threshold value specifies the maximum IoU overlap allowed for a predicted box to be considered unmatched.
- Similarity Calculator: It specifies the method used to calculate the similarity between predicted boxes and ground truth boxes. In this case, the IoU similarity method is used, which calculates the IoU overlap between two boxes.
- Box Predictor: In the SSD MobileNet V1 FPN 640x640 model, the box predictor is responsible for predicting the bounding boxes for the detected objects. The weight shared convolutional box predictor is used as the box predictor, which shares weights between the class prediction and box prediction layers. This helps to reduce the number of parameters in the model. The depth parameter specifies the number of filters in each convolutional layer of the box predictor. In this model, it is set to 256.
- Number of layers before Predictor: this parameter specifies the number of convolutional layers before the predictor layers. In this model, four convolutional layers are used before the predictor.
- Kernel Size: It specifies the size of the convolutional kernel used in the predictor layers. In this model, a kernel size of 3 is used.
- Class prediction Bias init: It initializes the bias for the class prediction layer. In this model, it is initialized to -4.599999904632568.
- Convolutional Hyperparameters: It specifies the hyperparameters for the convolutional layers in the box predictor. It includes the regularizer, initializer, activation function, and batch normalization parameters.
- L2 Regularizer: It applies L2 regularization to the convolutional layers to prevent overfitting. The weight value provided is 3.9999998989515007e-05.
- Random Normal Initializer: This parameter initializes the weights of the convolutional layers using a normal distribution with a mean of 0 and a standard deviation of 0.009999999776482582.
- Activation: The activation parameter specifies the activation function used in the convolutional layers. In this model, the RELU_6 activation function is used.
- Batch Normalization: It applies batch normalization to the convolutional layers to improve the training process. It includes the decay rate, scale, and epsilon values. In this model, the decay rate is set to 0.996999979019165, the scale is set to true, and the epsilon is set to 0.0010000000474974513.
- Anchor boxes: In object detection, anchor boxes are pre-defined bounding boxes of various sizes and aspect ratios that are used to identify objects in an image.

- Anchor Generator: It specifies how these anchor boxes should be generated. In the SSD MobileNet V1 FPN 640x640 model, the anchor generator uses the multiscale anchor generator which generates anchors at multiple scales and aspect ratios. The values provided in the multiscale anchor generator section is the following:

o Min level and max level: These specify the minimum and maximum levels of feature maps in the FPN.

In this case, the feature maps are generated at levels 3 to 7.

- Anchor Scale: This specifies the base size of the anchor boxes. The size of the anchor boxes is proportional to the square root of the area of the feature map.
- Aspect Ratios: These specify the aspect ratios of the anchor boxes. In this case, three aspect ratios are used: 1.0, 2.0, and 0.5.
- Scales per Octave: This specifies the number of scales to be used per octave. In this case, two scales are used per octave.
- Score Threshold: minimum confidence score for detections to be considered. Value is 9.99999993922529e-09.
- IoU Threshold: intersection over union (IoU) threshold used for non-maximum suppression. Value is 0.6000000238418579.
- Max Detections per Class: maximum number of detections to keep per class after non-maximum suppression. Value is 100.
- Maximum total Detections: maximum number of detections to keep over all classes after non-maximum suppression. Value is 100.
- Use Static Shapes: whether to use static shapes for the output tensor shapes. Value is false.
- Score Converter: method for converting scores. Value is SIGMOID.
- Normalize loss by number of Matches: whether to normalize the total loss by the number of matched ground truth boxes. Value is true.
- Localization Loss: weighted_smooth_l1: the localization loss function. No values provided, uses default parameters.
- Freeze Batch norm: whether to freeze the batch normalization parameters during training. Value is false.
- Batch Size: The number of images that are fed into the network at once during training. In this case, the batch size is set to 8.
- Data Augmentation Options: A list of data augmentation options to apply to the input images during training. In this case, two types of data augmentation are used: random horizontal flips and random crops.
- Sync Replicas: A Boolean variable that controls whether to use synchronous gradient updates during training. When set to true, the gradients are computed and averaged across all replicas before the weights are updated. This can lead to better convergence but requires more memory and communication.
- Optimizer: Specifies the optimizer used during training. In this case, the momentum optimizer is used with a cosine learning rate schedule.
- Learning Rate: The learning rate schedule used during training. The learning rate is decreased according to a cosine schedule that decreases the learning rate from a base value of 0.04 to a final value of 0 over 25,000 steps. The learning rate is also gradually increased from a warmup value of 0.0133 over 2,000 steps.
- Momentum Optimizer Value: The momentum value used by the optimizer. In this case, the momentum is set to 0.9.
- Use Moving Average: A Boolean variable that controls whether to use a moving average of the model weights during training. When set to false, the raw weights are used. When set to true, the moving average of the weights is used instead, which can improve the robustness of the model.

7) Python: Model implementation, training and evaluation is done in python programing using several libraries as listed below:

- PyTorch: PyTorch is a python library, a deep learning framework for building and training neural networks, widely used for research and production in machine learning programming language and the Torch library. Torch is an open-source ML library used for creating deep neural networks and is written in the Lua scripting language. It's one of the preferred platforms for deep learning research. Outcome of PyTorch is a model file that can be loaded in mobile device and can be used for prediction. The researchers used PyTorch for MobileNet and yolov5 implementation, training, and evaluation.
- TensorFlow: An open-source machine learning framework for developing and deploying machine learning models, including deep learning models. Both yolov5 and MobileNet SSD models can be implemented in PyTorch and TensorFlow these are just two standard libraries for implementing neural networks. Researchers tried TensorFlow for implementation, but PyTorch was more user friendly, so PyTorch was adopted.
- OpenCV: An open-source computer vision library offering tools for image and video processing, including object detection and analysis processing. OpenCV supports a wide variety of programming languages like Python, C++, Java, etc. It can process images and

videos to identify objects, faces, or even the handwriting of a human. Researchers have used OpenCV for reading images and applying preprocessing steps like scaling and normalization of images.

- RoboFlow: A platform for managing, annotating, and preprocessing data for computer vision projects, assisting in training machine learning models.
- Matplotlib**:** A Python plotting library used for creating static, interactive, and animated visualizations in data analysis and model output visualization. Matplotlib is also used for evaluation and analysis of results like building confusion metrics after prediction is done through this library. Outcome of matplot lib is plots and charts generated as images that can be used for visualization of training loss and accuracy with each epoch.
- Seaborn: A statistical data visualization library built on top of Matplotlib, designed to generate informative and attractive statistical graphics. Seaborn is also used for plotting various analysis charts of training loss and accuracy values.

H. Model Evaluation

1) Model evaluation metrics: Mean Average Precision (MAP) is the universal standard metric used to compare performance between object detection models created by different authors [32]. This metric is specifically derived from Average Precision (AP). Since classification is performed during object detection for different bounding boxes along with the provision of the ground truths, the fundamentals of the confusion matrix apply. The matrix enables computations to be made with accuracy, precision, and recall. It consists of the True Positive (TP), True Negative (TN), False Positive (FP) and False Negative (FN) values [32]. In the context of object detection:

- True Positive: Detection made correctly by the model.
- True Negative: Background region correctly detected by the model (where there are no objects)
- False Positive: Wrongly detected regions made by the model.
- False Negative: Regions where the ground truths are missed by model.

Intersection-over-Union (IoU) is the next metric used to determine whether bounding boxes are TP, TN, FP or FN. IoU is defined as the area of overlap between the bounding box predictions and the ground truth, divided by the area of union between them [33]. An IoU of 1 means the bounding boxes predicted match exactly the ground truth boxes, whereas an IoU of 0 depicts no overlap between the two bounding boxes [34]. Fig. 6 shows the IoU equation.

A threshold is a hyperparameter predetermined to decide between TP, TN, FP or FN. For example, with a threshold of 0.5 for a ground truth bounding box, if the predicted bounding box has an IoU greater than 0.5 for that particular ground truth, it is considered a TP. Whereas an IoU lower than 0.5 means the predicted bounding box is a FP. Through the IoU, we are able to determine the confusion matrix (TP, TN, FP, FN) for every bounding box, and subsequently calculate the precision and recall.

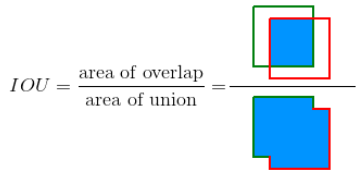

Fig. 6. Intersection over union equation.

- Precision: of the positive classes that are correctly detected, how many are actually positive? This follows the following Eq. (1) [33]:

$$\text{Precision} = TP / TP+FP \quad (1)$$

- Recall: of all positive classes, how much can we predict the class correctly? It is preferred that this measure is as high as possible. It follows the following Eq. (2) [33]:

$$\text{Recall} = TP / TP + FN \quad (2)$$

We also, calculate the accuracy that measure considers the correct classification out of all classes, where a high value of accuracy if preferred. This factor is explained in the following Eq. (4) [33]:

$$\text{Accuracy} = TP + TN / TP + FP + TN + FN \quad (3)$$

AP uses precision and recall creating an Area Under the Curve graph (AUC-PR) for the model. For every threshold, there is a different precision since the object detector will output a confidence score, which is then determined by the threshold on whether each bounding box is TP, TN, FP or FN. AP will take the precision and recall at every threshold, graph out a precision-recall plot, and thereafter take the area under the curve. The closer AUC is to 1, the better the model, and vice versa. It is better to have a high AUC as the model is good at predicting and distinguishing between classes it calculated based on the TPR (y-axis) versus the FPR (x-axis). AP is done separately for each class within the object detection model. Also, F1-measure that measure mainly computes the harmonic mean of precision and recall measuring them at the same time [33]. It has the below Eq. (4):

$$\text{F1-measure} = 2 \text{ x Recall x Precision / Recall + Precision} \quad (4)$$

To consolidate all these scores into one metric, mAP was introduced. mAP will take all the AP of each class (will have n number of scores for n number of classes) and take the mean of those AP to obtain one score. This score is the metric used to determine the overall performance of the object detection model.

2) Model validation: Model validation refers to the procedures and actions conducted to verify that a model is functioning as intended and aligns with its objectives and intended business applications. Typically, the validation

process involves the assessment performed by individuals who are not the model developers or owners, as their impartial perspective is valuable due to their non-technical background [31]. In the context of machine learning, validation may involve ML experts evaluating the labeling process to ensure its accuracy and reliability.

IV. Results and Discussion

This section aims particularly to answer the research questions which is: is there any efficient way to detect threats from live videos using DL algorithms? The other question was how accurate and efficient is using the MobileNet model to detect objects from live videos? The analysis has been conducted according to detailed steps that will be mentioned on the analysis Section 4.3. Comparison is done based on mean average precision (mAP) and frames per second (FPS) on the datasets collected as a part of research findings.

A. Data Preparation

1) Dataset collection: For the purpose of this study, a carefully curated dataset was created to support the research objectives. The dataset was generated and collected by the researcher from various sources, specifically chosen to include objects that are considered potentially dangerous or threatening. The dataset comprises five classes of objects: fire, guns, knives, arrows, and swords. These object classes were selected due to their relevance in public safety incidents and their potential to cause harm.

To obtain the necessary data, a range of sources was utilized. This included gathering footage from YouTube videos that contained CCTV recordings, educational videos demonstrating fighting skills, and demo videos. By extracting frames from these videos at a rate of 1 frame per second (1fps), the required images for the dataset were captured. The inclusion of CCTV footage is particularly valuable as it provides authentic data from public places where security cameras are commonly employed.

To annotate the dataset with the necessary information for object detection, the researcher employed the RoboFlow tool. RoboFlow is a widely used image annotation tool specifically designed for object detection tasks. Annotations provide crucial additional details about the images, such as the precise location and class of the object within each image. These annotations are vital for training machine learning models to accurately detect and classify objects. To enhance the diversity of the dataset and improve the performance of the machine learning models, various augmentations were applied to the images. Techniques such as rotation and contrast adjustment were employed to create variations of the original images.

By introducing these augmentations, the models were exposed to a wider range of data, enabling them to better handle different image conditions and variations. The careful curation of this dataset, encompassing the five specified object classes, serves as a crucial foundation for training machine learning models to accurately detect these objects and contribute to public safety improvements.

2) Data cleaning: In this research, the process of data cleaning and maintaining data quality played a crucial role in preparing the dataset for object detection models. After extracting images from videos, uninformative and vague frames were carefully discarded to ensure that only relevant and clear frames were included in the dataset. This step aimed to eliminate any noise or ambiguity that could hinder the performance of the models. The remaining frames with clear object visibility were then subjected to manual labeling for five object classes. Manual labeling involves human annotators carefully marking the objects of interest in each frame, providing accurate ground truth annotations. To ensure a balanced distribution of images per object class in the training, validation, and testing sets, the data classes were sampled strategically. This sampling process helps prevent bias towards specific object classes and ensures that the models are exposed to a diverse range of objects during training and evaluation. By performing data cleaning, manual labeling, and strategic sampling, the researchers improved the overall quality and representativeness of the dataset. This, in turn, enhances the reliability and generalizability of the object detection models, allowing them to effectively detect and classify objects in various real-world scenarios.

3) Data preprocessing: To ensure effective model training, data preprocessing techniques were applied to the dataset. One of the key preprocessing steps involved resizing the images to a standardized scale of 416x416 pixels, which is suitable for the MobileNet SSD model input. This resizing step helps to ensure consistency in the input size across all images, facilitating efficient model training. Data preprocessing serves to enhance the quality of the data and reduce training time. In addition to resizing, other preprocessing operations were applied to make the images compatible with the model requirements. These operations included scaling, cropping, and further resizing to bring all images into a consistent format prior to model training. By standardizing the images, the model can effectively process and analyze them. Data augmentation techniques were also employed to increase the diversity and veracity of the data, thereby enabling the model to learn better. Data augmentation involves applying various transformations to the images to create additional training samples. These transformations include rotation, blurring, and adjustments in contrast and orientation. By introducing such variations, the model becomes more robust and capable of handling different image conditions and variations that may be encountered in real-world scenarios. The combination of data preprocessing, including resizing and standardizing the images, along with data augmentation techniques, enhances the quality, variety, and quantity of the training data. This, in turn, contributes to the overall performance and generalization capabilities of the object detection model during training and subsequent inference tasks.

4) Data annotation: During this phase, the researcher utilized the RoboFlow annotation tool to facilitate the

annotation process for object detection. This tool allowed for the drawing of bounding boxes around the objects of interest in the images. By uploading videos into RoboFlow, images with varying frames per second (FPS) rates were extracted. Each image was then labeled with its corresponding class name and bounding box. For each image, bounding boxes were manually drawn around the instances of the objects to be detected. The researcher carefully assigned the correct class label from the predefined set of five classes: fire, gun, knives, arrows, or swords. This manual annotation process ensured accurate placement of the bounding boxes and correct labeling, as these annotations served as the ground truth for the subsequent model training phase. Once the dataset was annotated, the next step involved integrating it with the respective training frameworks. The annotations created by the researcher were utilized as the training data for the object detection models. These annotations, combined with the corresponding images, formed a labeled dataset that could be used to train the models and enable them to detect and classify objects accurately.

a) Data Quality Check

Below is the explanation of the used methods and steps taken to ensure data quality in object detection:

- Annotation Quality Control: Ensure accurate and consistent annotation of bounding boxes and class labels in the dataset. Annotators should follow clear guidelines and have a solid understanding of the objects of interest. This research has five object types (guns, swords, knives, arrows, and fire) in the dataset. Researchers have annotated each object carefully using RoboFlow. Bounding boxes were created with extreme care.
- Data Cleaning and Preprocessing: researchers removed duplicate images after annotations to build a good model. Also, we have eliminated corrupted images or annotations that might negatively impact training.
- Balanced Class Distribution: researchers ensured that the dataset has a balanced distribution of objects across classes to prevent bias towards dominant classes and improves the model's ability to detect all classes accurately. Normal videos are recorded at 30 fps, means 30 frames per second can be extracted and in this case, 1 frame/sec was extracted. There were some images that do not have any object, such images were deleted, and remaining images were annotated accurately. Exact number of samples before augmentation for all objects is provided in Table I below:
- Data Augmentation: researchers have applied data augmentation techniques such as random rotation between -15 degree to + 15 degree to increase the number of data samples.

TABLE I. CLASSES SAMPLES

Classes	Train	Test	Valid
Arrow	1286	186	360
Gun	1362	209	379
Sword	1370	221	394
Fire	1297	197	353
Knife	1312	198	369

- Validation and Anomaly Detection: researchers have eliminated images that have no object or object is not clearly visible, etc.
- Consistent Image Quality: researchers have ensured that images are of consistent quality and resolution. They have applied resizing for all images to be 416x416.
- Real-World Scenario Simulation: researchers have collected videos from demos, CCTV videos and social media to collect diverse and real-world scenarios to train a good model.
- Review Annotations for Ambiguity: researchers have reviewed annotations that are ambiguous or challenging for the model to detect, such as partially occluded objects or objects in cluttered scenes.
- Class Label Consistency: researchers have verified that class labels are consistent across annotations. With every annotation object name was specified with that annotation to make sure that each object has its correct name.
- Cross-Validation: Divide the dataset into training, validation, and test sets. Cross-validation can help assess how well the model generalizes by training on one subset and testing on another.
- Continuous Monitoring: Continuously monitor and update the dataset as needed. Over time, as the model's requirements change or new challenges arise, the dataset should evolve accordingly.
- Use External Data Sparingly: When using external data sources like stock images or online datasets, ensure that they are relevant and high-quality. External data should complement the dataset without introducing noise.
- Expert Review: researchers engaged experts' volunteers to review and validate the quality of the dataset, ensuring that the annotations and data align with the real-world scenarios.
- Feedback Loop: Establish a feedback loop with annotators to address questions, provide clarification on guidelines, and continually improve annotation quality.

5) Model evaluation

a) Results of Performance Metrics Comparison

In Table II researchers indicate the difference across different aspects. These results are achieved after training both models on same dataset. A dataset is divided into three parts which are: training, validation, and testing. For each class 70%, 20% and 10% images are used for train, valid test, respectively.

- Train set is provided to the model during training so model can learn pattern from this data.
- Validation set is used to evaluate model during training, this is unseen for model but during training results are analyzed through this unseen data. If model is not learning correctly then we tune the parameters of model to see if is performing good on train data and validation data.
- Test set is totally unseen that is used after correct training of model, it depicts the real-world testing of model on unseen data. If a model performs as good on testing data as it is for training, then model is considered to be reliable for that task.

TABLE II. PERFORMANCE METRICS RESULTS

Performance Metrics	MobileNet SSD	YOLOv5
mAR (Mean Average Recall)	0.9565	0.8450
mAP (Mean Average Precision)	0.9125	0.7549
IoU (Intersection over Union)	0.9045	0.8020
False Positive Rate	0.053	0.078
False Negative Rate	0.053	0.078
Inference Speed	~ 18ms/image (CPU)	~ 41ms/image (CPU)
Memory Usage	1.3 GB	7 GB
Model Size	6.6 mbs	15 mbs
Class-wise Performance	90%	83%
F1 score	0.92	0.81

To evaluate and measure the model performance AUC method were used. This method is used to check the ability of the model to detect accurately among the different classes. The higher the AUC, the better the performance of the model is. Fig. 7 illustrates the AUCs of the MobileNet model.

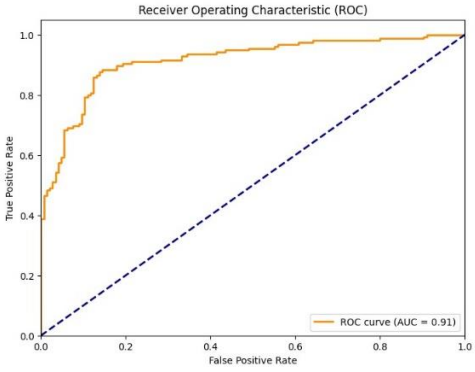

Fig. 7. ROC AUC curve.

The graph in Fig. 7 provides the following results:

- Since AUC = 0.91, the model is able to distinguish perfectly between all positive and negative class points.

The graph in Fig. 8 and 9 illustrate the results of the confusion matrix. The confusion matrix plot shows the predicted vs. true labels, and the values in each cell represent the percentage of the correct and incorrect classifications. Diagonal values are high as they show values for correct classification and off diagonal values are incorrect classification. As per the graphs the MobileNet model prove that it detects the classes efficiently over the Yolov5 model.

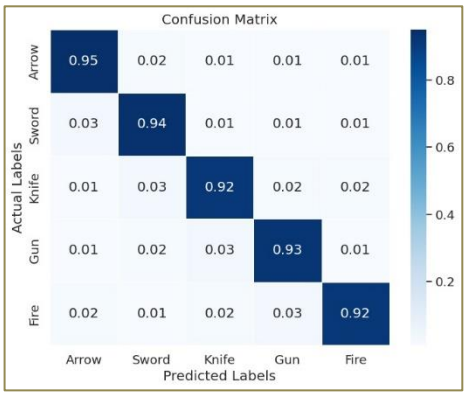

Fig. 8. Confusion matrix for mobilenet SSD model.

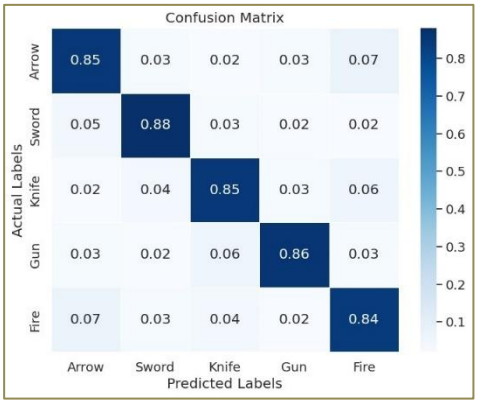

Fig. 9. Confusion matrix for YOLO model.

6) Model validation: In this research, the model validation was a meticulous process that contributed significantly to the success of the object detection models. The researcher dedicated time and efforts to ensure the annotations were accurate and comprehensive, as this foundation would directly impact the performance of the models in real-world scenarios. This validation step is carried out by ML experts who as their impartiality is crucial as the context of the labeling process, a ML expert is often involved in performing this step to validate the accuracy and quality of the labels assigned to the data [31]. There were experts in ML who volunteering to examine the validity of the model. The feedback from the experts were that all the dataset was accurately labeled since it was at first a manual step that takes a lot of time and efforts.

For the validity of the model, Table II examines the success rates, encompassing accuracy and F1-measure outcomes. The MobileNet SSD model exhibits an impressive success score of 0.92. Moreover, it achieves an accuracy rating of 96.5%. These findings collectively validate the superior performance of the

MobileNet model over the YOLO model in detecting threatening objects.

7) Discussion: In conclusion, MobileNetSSD performs better than YOLOv5 in the scenarios of detecting threatening objects due to its fast inference speed, memory efficiency, optimization for small objects, and training strategy as shown in Table II. Below are additional reasons why MobileNet model preferable over YOLO5 model. Certainly, here's the list of scenarios tailored to the context of the problem, considering the involvement of detection for five classes including: fire, gun, knives, arrows, and swords with a dataset of 2000 images per and a deployment on a mobile platform:

a) Mobile-Optimized Inference Speed: MobileNet SSD's fast inference speed is crucial for mobile deployments. It ensures that objects are detected rapidly on the mobile device, enhancing real-time detection capabilities.

b) Memory Efficiency for Mobile Devices: Deploying on mobile devices demands efficient memory usage. MobileNet SSD's architecture reduces memory requirements, allowing smooth operation on resource-constrained mobile platforms.

c) Real-Time Threat Detection on Mobile: MobileNet SSD's quick detection of objects like guns and knives is vital for real-time threat detection scenarios on mobile devices, such as identifying potential weapons in public spaces.

d) Streaming Video Analysis on Mobile: MobileNet SSD's fast inference speed aligns well with streaming video analysis on mobile devices. This is valuable for continuous monitoring using mobile cameras.

e) Optimization for Small Objects on Mobile: MobileNet SSD's specialization in detecting small objects, like arrows or knives, is advantageous for accurate detection on mobile screens, where these objects might appear relatively small.

f) Responsive Fire Detection on Mobile: Fast detection of fire instances using MobileNet SSD on mobile devices is critical for timely response to fire incidents, aiding firefighting efforts and safety protocols.

g) Edge Computing for Mobile: Deploying MobileNet SSD on mobile platforms extends the benefits of edge computing. The model's lightweight architecture is suitable for processing data on the device, reducing latency.

h) Mobile Surveillance Solutions: MobileNet SSD's deployment on mobile devices allows for portable surveillance solutions. Users can leverage their mobile phones for security monitoring, quickly detecting threats like fires or intruders.

i) Accurate Object Detection on Mobile: MobileNet SSD's optimization for small object detection ensures accurate identification of objects like arrows or swords on mobile screens, where details matter.

j) Reduced Data Transmission: MobileNet SSD's on-device detection reduces the need for transmitting sensitive data to remote servers, maintaining user privacy and potentially reducing data costs.

k) User-Friendly Mobile Applications: The combination of fast detection and accuracy makes MobileNet SSD suitable for developing user-friendly mobile apps that offer intuitive and effective object detection functionalities.

l) Cost-Effective Mobile Deployments: MobileNet SSD's low computational demands align with mobile platforms, making it a cost-effective choice for deploying object detection capabilities on mobile devices

V. Recommendations for Future Work

Several recommendations can be made for future study that will extend the present study's findings. Below are some possible recommendations for future studies:

1) Expand the scope of the study: The current study may have focused on a specific aspect or application of the topic. Future studies could expand the scope of the research to include other related areas, applications, or datasets.

2) Improve the performance of the model: The current study may have achieved good results with the model used, but, there may be other models or techniques that could improve performance further. Future studies could explore alternative models or techniques for the task and compare their performance.

3) The current study may have some limitations due to the dataset used. Future studies could address these limitations by using different datasets, models, or evaluation metrics.

4) Explore ethical considerations: The current study may not have explicitly addressed the ethical implications of the research. Future studies could explore the ethical considerations of the research and investigate ways to ensure that the technology is used ethically and responsibly.

Acknowledgment

My deepest gratitude and sincere appreciation go to all those who have contributed to the completion of this thesis. My supervisor, my family, and my friends. Their unwavering support, guidance, and encouragement have been invaluable throughout this academic journey. This thesis stands as a testament to the collective efforts and unwavering support from each and every one of you. Thank you for being a part of this remarkable journey and for helping me reach this significant milestone in my academic career. This research stands as a testament to the collective efforts and unwavering support from each and every one of you. Thank you for being a part of this remarkable journey and for helping me reach this significant milestone in my academic career.

***Abstract*—Mammography is a non-invasive method to study breast tissues for abnormalities. Computer-aided diagnosis (CAD) can automate the process of diagnosing malignant and benign tumors accurately. However, accurate results can be hampered by the presence of the pectoral muscle, which has a similar opacity to the breast tissue area. Detecting and removing pectoral muscles is not trivial due to various factors, and there are artifacts present near the pectoral muscle that can hamper proper segmentation. Given the significance of the topic, it is crucial to devise an accurate method for automatically detecting the muscle area in a mammography image and eliminating it from the rest of the image. This process of removing the pectoral muscle from the breast image can aid in precise segmentation and diagnosis of the tumor area, ultimately leading to faster diagnosis and better outcomes for patients. This study examined two segmentation algorithms, Level Set and Region Growing, for segmenting the pectoral muscle. An Improved Region Growing-based (IRG) algorithm was also proposed and showed promising results in automatically segmenting the pectoral muscle. All algorithms were tested on the MIAS dataset, and radiologists evaluated the results, showing an accuracy rating of up to 83% for IRG. The results indicated that IRG outperformed Level Set considerably due to many optimizations and modifications. IRG can be used as part of the preprocessing unit of an automated cancer diagnosis system.**

Keywords*—Breast cancer; preprocessing pectoral muscle segmentation; level set algorithm; region growing algorithm

I. Introduction

According to the World Health Organization (WHO), there were an estimated 2.3 million women diagnosed with breast cancer, and 685,000 died in 2020. Along with lung cancer, breast cancer is the most prevalent cancer worldwide, representing 12.3% of total diagnosed cancers in 2018. However, if the disease is caught early, treatments can be highly effective, with five-year survival probabilities of 90% and greater in advanced economies [1]. Unfortunately, this rate significantly drops to 66% in India and 40% in South Africa [2]. Mutebi and Anderson [1] mention that early detection is crucial for effective treatments and more so in the developing world since advanced-stage cancer treatments can be very costly and require advanced medical procedures along with a trained medical workforce to provide that treatment. These resources are not widely available in developing countries; hence, patients in these countries must get their cancers diagnosed early. To detect breast cancer early, WHO recommends yearly cancer screening for women at higher risk for developing this disease, which includes factors such as genetics, age, smoking, and drinking, among others. In addition, getting these screenings requires a trained radiologist to examine the mammography image carefully. Trained radiologists are scarce in many rural areas and often, an appointment with a specialist can be expensive for a big majority in the developing world. Furthermore, radiologists are also prone to intra/inter-observer variability errors.

One of the solutions to this problem is Computer-aided diagnosis (CAD) systems, which are highly recommended to assist radiologists in detecting breast tumors and outlining their borders. CAD systems usually use algorithms that include thresholding, region-based techniques, and edge detection techniques [3]. Mammography is an inexpensive and non-invasive method through which one can diagnose breast cancer in its early stages. As these images need interpretation by a radiologist, this may develop some problems due to fatigue, repetition, and the need for a great deal of attention to detail and other factors. Mammography can show changes in the breast up to two years before a physician can feel them. Computer-aided detection and diagnosis are considered to be one of the most promising approaches that may improve the efficiency of mammography.

In breast CAD, accurate breast segmentation is a crucial preprocessing step to speed up the subsequent processes without losing important anatomical information. However, breast and pectoral muscle segmentation is challenging, especially in scanned mammograms. This mostly happens due to the presence of some artifacts, such as duct tape and tags or it might be caused because of low contrast along the breast skin line and homogeneity between pectoral and breast tissues. Although many methods have been proposed for removing breast boundary and pectoral muscle and segmenting them, only a few have been evaluated quantitatively using all the images in the MIAS (Mammographic Image Analysis Society) database [4]. When performing mammography, the muscle area in the image can often appear similar to the tumor, making accurate segmentation difficult. To address this issue,

removing the muscle area before the segmentation stage is recommended. This study presents an improved method for accurately and quickly detecting and removing the pectoral muscle area from the mammography image, thereby preparing it for segmentation. Unlike existing methods, this method considers the separation of the muscle area during segmentation, avoiding the challenges posed using the information given about the tumor area, which may be unavailable in some datasets.

This empirical study is based on two well-known segmentation methods and proposed an improved robust approach based on a set of adjustments to these methods on the MIAS database [5] to assist CAD in its preprocessing step. This paper has studied and implemented two different types of popular algorithms, namely Level Set and Region Growing. Many novel findings and implementations of these algorithms have been discussed due to the direct comparison that has been done between these two algorithms, and their findings are compared along with suggestions on what type of mammogram each algorithm performs better or worse. Moreover, an Improved Region Growing algorithm (IRG) was proposed, which introduced the concept of dynamic thresholding. The threshold values were used based on testing to find what number of iterations would make the segmentation jump out in the breast tissue. This modification improved the accuracy of the algorithm; furthermore, it also provided insights on how this method can be used and further improved using machine learning techniques to predict the best threshold value for each image. This research also includes a web-based application that is based on the IRG algorithm, which can be used by anyone to access the API (Application Programming Interface), which can be integrated into classification systems as a preprocessing step. This facility will reduce the time required for future research projects focusing on classification since they can directly call the API and get the segmented images instead of writing segmentation algorithms themselves.

This paper is organized as follows. Section II contains the literature review of the proposed method to segment the pectoral muscle regions. This is followed by Section III, which contains the methodology, including design and implementation. Section IV highlights the results and discussion and finally, the paper is concluded in Section V.

II. Literature Review

Accurately removing breast pectoral muscle is challenging for researchers due to the difference in size, shape, and position of the breast in a mammogram [6]. As indicated by [7], there are four main types of problematic images within the most popular datasets used by researchers: MIAS [5] and DDSM [8]. These include images with tape artifacts, images with axillary fold, images with the invisible contour of the pectoral muscle, the level, and images with no pectoral muscle at all. Due to these issues, many different algorithms have been proposed to segment the pectoral muscle effectively from the mammogram. These classifications are visualized in Fig. 1.

The following section presents previous works proposed by other researchers for pectoral muscle segmentation. To make it easier for readers to follow this section, papers are categorized based on whether they belong to Intensity-based, Edge-based, or Deep learning-based algorithms.

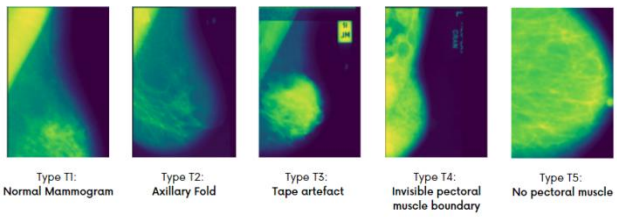

Fig. 1. Classification of the type of mammograms from the MIAS dataset

A. Intensity-based Algorithms

Intensity-based algorithms make use of the difference in the intensity in the mammography image. The pectoral muscle has a high intensity compared to the breast tissue. These techniques use these properties to segment the pectoral muscle out of the mammogram, assuming the pectoral muscle will have a higher intensity [9]. Such techniques include region growing, thresholding, and watershed.

Watershed algorithms are derived from mathematical morphology that segments the images into homogenous regions first introduced in 1978 [10]. Region growing uses the difference in the intensity of the pixels within an image. Region growing uses a starting seed value; from that, adjacent pixels are added depending on the homogeneity criteria assigned. Pixels are continually compared to the ones within the region and added until all adjacent pixels are too dissimilar [11].

Vikhe and Thool [12] used a thresholding-based segmentation technique using contrast enhancement and got an acceptable rate of 96.56%, verified by a certified radiologist. However, the result of this technique was affected by images with invisible contours between the pectoral muscle and the breast tissue.

Taifi et al. [13] used a watershed transformation technique to extract the pectoral muscle from the mammogram. The result was promising, with 90-99% accuracy and 86-99% for precision. There were, however, instances where this algorithm over-segmented the mammogram.

Gómez et al. [14] proposed a region-growing method with seed and threshold methods. The initial seed value used was (10,10). This algorithm's novelty is from its method of calculating the image threshold. The result was 91.92% for the mini-MIAS dataset. As with other intensity-based methods, this method struggles with the invisible contour between the pectoral muscle and the breast tissue.

Hazarika and Mahanta [15] proposed another region-growing-based segmentation method to remove pectoral muscle in mediolateral oblique view mammograms. This method uses a triangular region to estimate the area of the pectoral muscle, after which the region-growing algorithm is applied with automatic starting seed selection. Later, the segmented region is refined to increase the accuracy of the output. This method had an acceptable rate of 86.67% based on 150 images of the mini-MIAS dataset; the accuracy rate is sufficiently accurate.

The threshold-based segmentation methods, including the region growing, have performed relatively well; however, there are a few limitations attached to this method. For example, these methods over-segment or under-segment the images with unclear pectoral muscle and breast tissue boundaries, and they do not consist of any spatial information of the image [9].

B. Edge-based Algorithms

Edge-based segmentation methods use changes in the brightness of the images to identify different regions and segment out the pectoral muscle based on the sharp differences in the brightness of the breast tissue. Straight-line modelling of the pectoral muscle boundaries is used in this method to segment the breast muscle out of the mammography image.

Rampun et al. [4] used canny edge detection and contour growing techniques to segment the image. However, this method fails when the canny method cannot detect any edge between the regions and an invalid selection of the initial contour is made. Moreover, this method also overestimates the pectoral muscle boundary when artifacts are present in the image.

Level Set is also an edge detection technique introduced in 1988 by Osher and Sethian, which represents curves or surfaces as a level set of a higher dimensional hyper-surface [16]. The level set is suited to handle problems in which the evolving interfaces can develop sharp corners and cusps and change in topological features, topology, and images with a relatively high level of noise.

Li et al. [17] proposed a new level of set-based methodology on numerous medical imaging photographs. Comparing their results to a smooth model, the researchers concluded that their proposed method outperforms the smooth model in accuracy, efficiency, and robustness.

Zhou et al. [18] used a correntropy-based level set to segment the pectoral muscle in the mammogram and concluded that this method is considerably less time-consuming and complex and gives excellent results compared to the other state-of-the-art methods.

Anitha and Peter [19] proposed a Kernel-Based Fuzzy Level Set (KFLS) to preprocess the image and to segment the image into several clusters based on the breast structure. The results based on this method showed a high percentage of sensitivity and accuracy of 93.32 and 94.31, respectively.

The line/edge detection methods have advantages when handling noisy data, as they can easily be adjusted to noise. However, it requires large storage and more computational requirements.

C. Deep Learning-based Algorithms

Due to the variability of the shape, size, and type of breast in the mammograms, there has been a lot of interest in utilizing deep learning-based algorithms to segment the pectoral muscle.

Wang et al. [20] first applied some image normalization to the input image and then trained the model using 2000 digital images with a dice-similarity coefficient of 0.8879 based on 825 of those images. Ali et al. [21] are also using this technique with Gaussian and median filters. The accuracy rate achieved was around 97%. A similar technique is applied by Kim et al. [22]. They trained their model on the 322 images of the min-MIAS dataset with an accuracy rate of 95.88% accuracy.

Rampun et al. [7] used a Convolutional Neural Network (CNN) inspired by a holistically nested edge detection network to automatically model the characteristics of the pectoral muscle.

A hybrid breast cancer classification technique was proposed by [23]. Three deep learning models, including ResNet50, Inception-V3, and AlexNet, were used for feature extraction. The Term Variance feature selection is used to select the best features. The multiclass support vector machine was applied to classify the MIAS dataset.

While deep learning models report a higher accuracy rate, they require large datasets to be trained and a very high computational power for the neural networks to get trained. A large dataset for mammograms is not readily available, so this is a hurdle for deep learning techniques at this stage.

D. Further Readings and Research Potential

Wavelet-based algorithms are also used for muscle segmentation and are not discussed in the literature review but can be helpful for some readers. This technique uses a short-term Fourier transform. The spatial frequency of the image is identified by the wavelets. Ferrari et al. [24] proposed a wavelet technique; their method was tested on 84 MLO mammograms from the min-MIAS dataset with 0.58% false positive and 5.77% false-negative percentages, which indicates a good percentage of accurate segmentations.

The Wavelet technique has an advantage in the fact that all information required to segment the image is given by the wavelet decomposition. However, this technique does result in some lost information about the image in the process. There can be further improvements in the mentioned techniques for example, the choice of the initial seed in a region growing currently does not consider the shape and size of the pectoral muscle, which can be used to increase the accuracy rate further.

III. Methodology

This section covers the methodology of the major components in the study, namely the preprocessing steps, the Level Set and Region Growing algorithms, and some details about the development of the Web Application. The overall structure of the proposed method is shown in Fig. 2. The process of removing the pectoral muscle from a mammogram is broken down into three steps – preprocessing, pectoral muscle segmentation, and performance evaluation.

A. Preprocessing

Before a mammogram is fed into a segmentation algorithm, it will be preprocessed. Details of all the preprocessing steps can be found here. The first two preprocessing steps are the removal of empty space (bar) and automatic left flipping. This needs to be done because both the Level Set and Region Growing algorithms require the pectoral muscle region to be on the top-left corner of the mammogram. Otherwise, the pectoral muscle region cannot be detected. Fig. 3 and Fig. 4 show the

outcomes of the Level Set algorithm when the bar removal and automatic flipping preprocessing steps were not applied.

Another preprocessing step is the application of contrast on the mammogram. This increases the brightness differences between the pixels in the breast region and the pectoral muscle region, allowing both the segmentation algorithms to detect the pectoral muscle boundary more easily. Fig. 5 shows how the Level Set algorithm fails to detect the boundary of the pectoral muscle region (overshooting) when contrast is not applied on a mammogram.

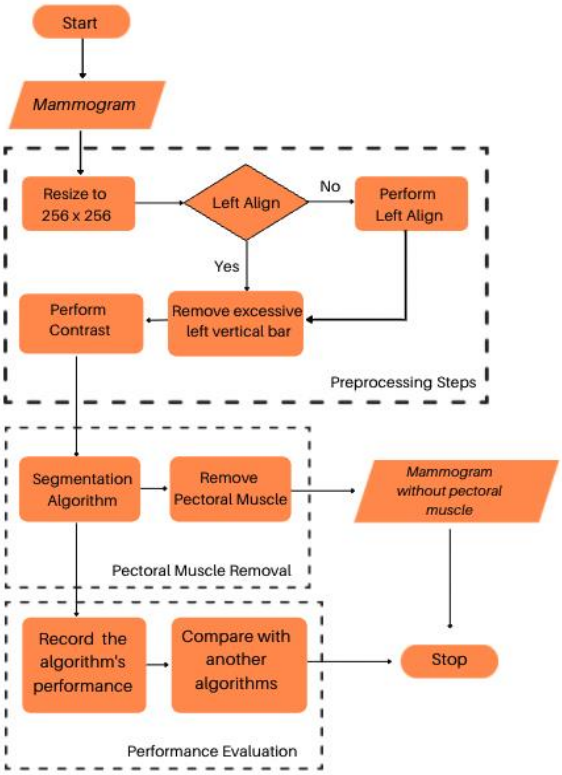

Fig. 2. The overall structure of the proposed method.

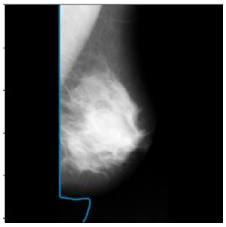

Fig. 3. Boundary found by the Level Set algorithm (denoted by the blue line) if the empty space on the left is not removed.

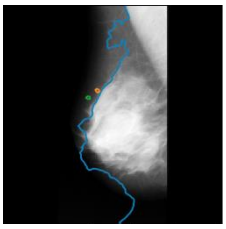

Fig. 4. Boundary found by the Level Set algorithm (denoted by the blue line) if the image is not automatically flipped to the left.

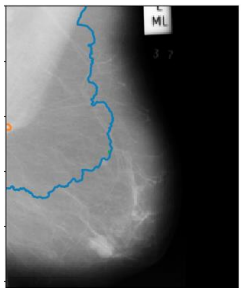

Fig. 5. Boundary found by the Level Set algorithm (denoted by the blue line) if contrast is not applied to the mammogram.

B. Segmentation

1) Level set algorithm: The Level Set image segmentation algorithm is widely used in the field of image processing and is now frequently employed in image segmentation. It is one of the active contour models that can handle complex topologies and capture boundaries and is specially used in images with intensity inhomogeneity, such as medical images [25] [26]. Researchers often prefer this method because it is flexible, easy to understand, and easy to employ. Level set models are based on the evolution of the zero level [16]. Let's assume that the closed interface $t:[0,\infty]\rightarrow Rn$ is an initial circle in 2-D/3D space when $t = 0$. In order to complete the evolution, a zero-level set function (φ) was constructed. In the general case, let 0 be a closed, disjoint, $(N - 1)$ dimensional initial hypersurface. Hence, φ can be defined by

$$xt,t=\mp r \quad (1)$$

where, r is the distance from x to the hyper-surface 0. φ is positive if x is outside of 0 and negative if it is inside. Since motion can be seen as:

$$xt,t=0 \quad (2)$$

Find the partial derivative of both sides of formula Eq. 2, by the chain rule, can get:

$$\varphi t+\Delta.xt \quad (3)$$

The speed of evolution is one of the crucial parameters; hence, it is defined as below:

$$V=xt.n \quad (4)$$

where, $n=\Delta\varphi\Delta\varphi$ is a normal vector or mean curvature, the final curve evolution equation is

$$\varphi t=V.\Delta\varphi \quad (5)$$

Level set methods can usually be divided into two main categories, which are edged-based and region-based.

C. Improved Region Growing (IRG) Algorithm

The Region-Growing Algorithm is an intensity-based segmentation algorithm. The algorithm consists of three main steps. First, a particular pixel is assigned as the initial seed, and a fixed threshold value is chosen. Second, the seed is then compared with its adjacent pixels at each iteration. If the difference between the initial seed and the adjacent pixel is within the threshold value, the adjacent pixel will merge with

the initial seed to form a region. Lastly, the algorithm will terminate when all the adjacent pixels are too dissimilar.

An additional step was implemented to improve the accuracy of the original algorithm in removing the pectoral muscle region. This involves checking if similar adjacent pixels are still found after running the algorithm for a predefined maximum number of iterations. If so, the algorithm will restart with a lower threshold value, in other words, stricter criteria for grouping similar pixels. This approach prevented the algorithm from removing the breast region; see more in the Segmentation Section. The flowchart of the Improved Region Growing (IRG) algorithm is shown in Fig. 6.

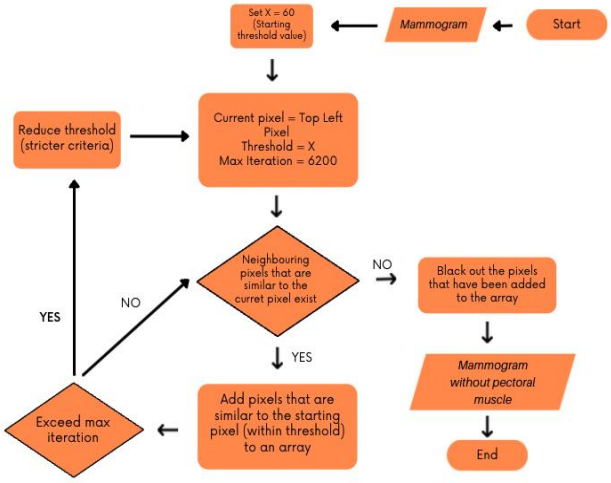

Fig. 6. Flow chart of the Improved Region Growing (IRG) algorithm to remove the pectoral muscle region from a mammogram

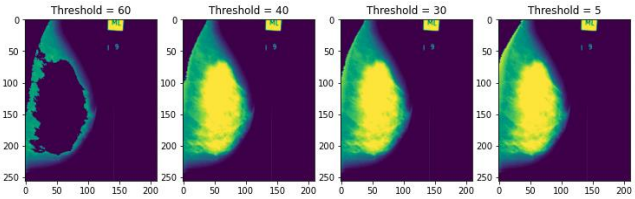

Fig. 7. The result of the improved region-growing algorithm varies with different thresholds used.

In the IRG algorithm, the threshold value is an important parameter as it determines the criteria, whether strict or loose, when grouping the pixels in the mammogram. Different thresholds would result in different results, as shown in Fig. 7. Segmentation for the mammogram (mdb003.pgm) works best when the threshold is set to 40. In this research, it was observed that different images require a different threshold to run well. Fig. 8 shows the various optimal thresholds needed by the different mammograms. Therefore, fixing one predefined threshold value before the algorithm runs would result in some mammograms not being segmented well. To solve this problem, the algorithm was modified by adding an additional step. The step involves restarting the algorithm with a lower threshold value (stricter criteria) once the algorithm has run for a predefined number of iterations. The logic behind this change is that if the algorithm runs for more than the predefined number of iterations, this means that the boundary found by the algorithm has crossed the pectoral muscle boundary, resulting in overshooting. By doing this, all mammograms will be segmented using the optimal threshold value.

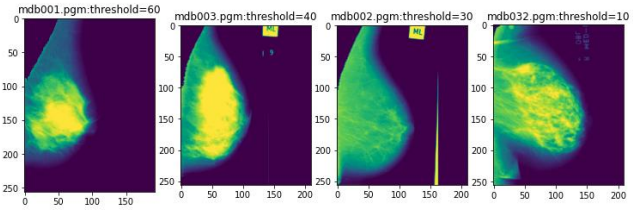

Fig. 8. Different performance results based on a variety of threshold values.

IV. Results and Discussion

A. Evaluation of results by professional radiologists

To make sure the algorithm has removed the pectoral muscle from the mammogram completely and correctly, especially mammograms in which the pectoral muscle region is not easily seen, two radiologists were invited to evaluate the results. Both the segmentation algorithms are run with all 322 mammograms in the MIAS dataset. This section will first discuss the evaluation criteria and how the images in the MIAS dataset are classified into different categories. Then, the performance of the Level Set and Region Growing algorithm will be discussed.

B. Performance Evaluation

Each segmented mammogram can either be evaluated as acceptable or unacceptable. Table I describes the evaluation criteria. Pectoral removal is acceptable if the segmentation algorithm removes the entire pectoral muscle region from the mammography images. Pectoral removal is not acceptable if the algorithm does not remove the entire pectoral muscle region (see second row of Table I) or removes the entire muscle and some breast regions that may contain a tumor (see third row of Table I).

TABLE I. Evaluation Criteria

Evaluation	***Mammogram***	***Criteria***
Acceptable		The segmentation algorithm removes the pectoral muscle region from the mammogram completely.
Unacceptable		The algorithm does not remove the entire pectoral muscle region. Part of it has not been removed (red boundary)
Unacceptable		The algorithm removes the entire pectoral muscle region, and removes some of the breast regions that might contains tumor (red circle).

C. Classification of the MIAS dataset

To better understand the performance of each segmentation algorithm, all 322 mammograms in the MIAS dataset are classified into the five types as outlined in Table II. Different types of mammograms, along with their total numbers, brief descriptions, and examples, are presented in Table II.

TABLE II. CLASSIFICATION OF INPUT IMAGES OF THE MIAS DATASET

Type Code	*Count*	*Description & Image No.*	*Mammogram*
T1	210	Normal Mammogram. mdb187.pgm	T2	84	Mammograms have an inner boundary (axillary fold) within the pectoral muscle region which results in high false positives when detecting the pectoral muscle boundary [7]. mdb039.pgm	T3	14	Mammograms that contain tape artefact. mdb002.pgm	T4	8	Mammograms in which the contour of the pectoral muscle region is invisible. mdb288.pgm	T5	6	Mammograms in which the pectoral muscle region is not visible. mdb236.pgm	
D. Performance of the Segmentation Algorithms

As mentioned earlier, a professional radiologist was invited to evaluate the mammograms segmented by the Level Set algorithm and two professional radiologists to evaluate the mammograms segmented by the Improved Region Growing algorithm (IRG). The results of each algorithm were also evaluated by the development team. The results are presented in Tables III, IV, V, VI and VII. For each category of mammogram (as described in Table II), the tables show the number of mammograms classified into that category (count), followed by the number of segmented images classified by the evaluator as acceptable or unacceptable respectively. Finally, the acceptance rate for each category is recorded, and an overall acceptance rate is reported at the bottom.

1) Level set: Tables III and IV show the Level Set (LS) results of the radiologist and the team's evaluation respectively.

2) Improved Region Growing (IRG): For the results of the Improved Region Growing (IRG) algorithm, Tables V and VI show the results of the two radiologist's evaluations, and table VII shows the results of the team's evaluation.

TABLE III. EVALUATION OF LS METHOD BY RADIOLOGIST

Type Code	*Count*	*Acceptable*	*Unacceptable*	*Success Rate*
T1	210	113	97	54%
T2	84	6	78	7%
T3	14	5	9	36%
T4	8	2	6	25%
T5	6	3	3	50%
Overall Acceptance Rate				40%

TABLE IV. EVALUATION OF LS METHOD BY THE TEAM

Type Code	*Count*	*Acceptable*	*Unacceptable*	*Success Rate*
T1	210	115	95	55%
T2	84	3	81	4%
T3	14	5	9	36%
T4	8	2	6	25%
T5	6	3	3	50%
Overall Acceptance Rate				39.75%

TABLE V. EVALUATION OF THE IRG METHOD BY RADIOLOGIST 1

Type Code	*Count*	*Acceptable*	*Unacceptable*	*Success Rate*
T1	210	168	42	80%
T2	84	50	34	60%
T3	14	5	9	36%
T4	8	2	6	25%
T5	6	5	1	83%
Overall Acceptance Rate				71.42%

TABLE VI. EVALUATION OF IRG METHOD BY RADIOLOGIST 2

Type Code	*Count*	*Acceptable*	*Unacceptable*	*Success Rate*
T1	210	167	43	80%

T3	14	2	12	14%
T4	8	2	6	25%
T5	6	4	2	67%
Overall Acceptance Rate				70.40%

TABLE VII. EVALUATION OF IRG METHOD BY THE TEAM

Type Code	*Count*	*Acceptable*	*Unacceptable*	*Success Rate*
T1	210	161	49	77%
T2	84	50	34	60%
T3	14	3	11	21%
T4	8	0	8	0%
T5	6	3	3	50%
Overall Acceptance Rate				67.30%

E. Analysis

The IRG method performs better than the LS method in terms of the following aspects:

1) Removal of the pectoral muscle region from normal mammograms: The IRG method can generally remove the pectoral muscle more accurately than the LS method. Following the performance evaluation methodology, this means that the IRG method is more likely to remove the entire pectoral muscle region and is less likely to leave out part of the pectoral muscle. Fig. 9 and Fig. 10 show the performance differences between these two algorithms.

2) Removal of the pectoral muscle region from mammograms that contain axillary fold: The LS method performs poorly because the algorithm cannot properly segment a mammogram containing an axillary fold (Type T2). The axillary fold causes the algorithm to detect a false pectoral muscle contour, which results in incomplete pectoral muscle removal. In the radiologist's and team's evaluation, the algorithm only achieves a 7% and 4% acceptance rate, respectively. On the other hand, the IRG method is less likely than the LS method to detect a false contour. It achieves a higher acceptance rate when segmenting a Type T2 mammogram.

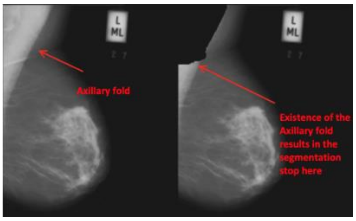

Fig. 9. An example of how the LS method fails to remove the entire pectoral muscle region.

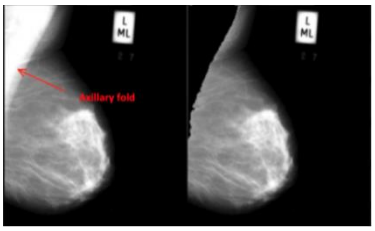

Fig. 10. An example of how the IRG method successfully removes the entire pectoral muscle region.

Fig. 11 compares the acceptable rate between the LS and IRG methods when segmenting the different types of mammograms.

Another observation that can be made is that both algorithms do not work well (acceptance rate less than 50%) with mammograms that contain tape artifacts and those that have invisible pectoral muscle contours (Type T3 and T5). This is because both segmentation algorithms are designed to identify a region based on the boundary found. First, the algorithm does not work well with type T3 mammograms because the boundary that is identified is the artifact boundary. Next, the type T5 mammogram will also not be segmented well by the algorithms as its boundary is not visible.

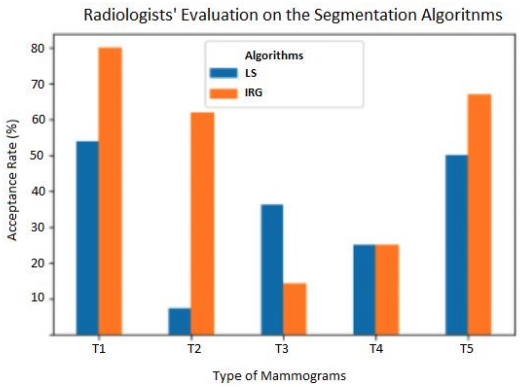

Fig. 11. Group bar chart comparing the result between the LS method and IRG method.

V. Conclusion

While the automatic pectoral muscle removal system is a complete system, it contains a few limitations on the preprocessing steps, segmentation algorithms, and web application. The result tabulation shows that none of the algorithms works well with mammograms containing the tape artifact (type T3). This shows that the existing preprocessing steps are not enough to ensure that both segmentation algorithms run well. The IRG method performs significantly better than the LS method. However, both algorithms have limitations. First, both algorithms do not work well with type T2 mammograms. For instance, the IRG method achieves an 80% acceptance rate on the normal mammogram (Radiologists' evaluation for T1), yet it only achieves a 62% and 60% acceptance rate on type T2 mammograms (Radiologists' evaluation for T2). Considering the number of T2 mammograms in the MIAS dataset (84 out of 322), it can be said that this type of mammogram is very common. Therefore, the low acceptance rate to segment this type of mammogram is a big limitation of the algorithm. Second, both algorithms fail when the mammogram contains an invisible pectoral muscle contour (type T4). While the LS method achieves a 25% acceptance rate, the IRG method performs poorly when segmenting the type T4 mammograms. Next, it is noticed that both segmentation algorithms cannot remove the pectoral muscle completely from a mammogram if it contains an axillary fold. Fig. 12 shows a type T2 mammogram in which the pectoral muscle is not removed completely.

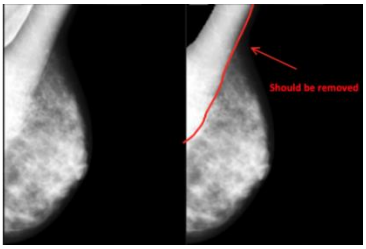

Fig. 12. A mammogram in which the pectoral muscle region is not removed completely.

One possible improvement that could be made to the IRG method to solve this problem is to place a triangle over the mammogram image to estimate the pectoral muscle region. The triangle can be drawn using the difference between the

intensity of the pectoral muscle region and the breast region, along with some mathematical formulas [15]. Having estimated the pectoral muscle boundary, the region growing algorithm can be modified to dynamically adjust the threshold value based on where the current pixel is. For example, a higher threshold value can be used when the current pixel lies within the estimated boundary. In other words, a looser criterion is used for grouping similar pixels if the current pixel is within the boundary. This will allow the algorithm to completely avoid the false pectoral boundary and group the pectoral muscle region. Fig. 13 shows how the algorithm could be improved by drawing an additional triangle before the algorithm runs.

Fig. 13. An example of how a triangle can be placed on top part of the mammogram.

The study has a constraint of not validating the algorithm's performance with other datasets. Additionally, utilizing deep networks can enhance the accuracy of the proposed technique by extracting improved features from segmented images. In the future, it is recommended to automatically crop the tumor region and utilize pre-trained networks.

ACKNOWLEDGMENT

The Initial part of this work was carried out when the first author was affiliated with Monash University Malaysia.

***Abstract*—The leading cause of death nowadays is chronic disease. As a result, personal wellbeing has received a considerable boost as a healthcare preventative strategy. A notable development in data-driven healthcare technology is the creation of a prediction model for chronic diseases. In this situation, computational intelligence is used to analyze electronic health data to provide clinicians with knowledge that will help them make more informed decisions about prognoses or therapies. In this study, various classification algorithms have been implemented namely, Decision Tree, K-Nearest Neighbors, Logistic Regression, Multilayer Perceptron, Naïve Bayes, Random Forest, and Support Vector Machines to examine the medical records of patients in Kuwait who had chronic conditions. For predicting diabetes, the support vector machines classifier was the best classifier for predicting diabetes and kidney chronic diseases. For diabetes, it achieved 88.5% accuracy, and 93.6% f1-score, while for kidney; it achieved 94.9% and 92.6% accuracy and f1-score respectively. For predicting heart disease, MLP was the best and achieved 84.7%, and 87.8% accuracy and f1-score respectively.**

***Keywords*—Chronic diseases; Electronic Health Records (EHR); machine learning; classification**

I. Introduction

Healthcare systems and governments from all around the world are very interested in finding ways to improve healthcare outcomes while lowering costs. Accurate patient risk assessments from both patients and clinicians are essential to achieving this improvement. The usage of electronic health records (EHRs) for digitally recording patient healthcare contacts has increased significantly in tandem with this focus on improving outcomes (Hsiao et al., 2014). As a result, disease risk prediction technologies that may use EHR data to evaluate patient risk have drawn a lot of interest [1].

There is now a lot of interest in applying machine learning techniques to create disease risk prediction tools from EHR data since machine learning algorithms have experienced significant growth in use. “What is the distribution of accuracy with which all EHR-coded medical occurrences may be anticipated?” is a logical place to start. We provide an answer to this query for coded diagnoses since it has not previously been addressed [2].

By using computational intelligence techniques, this study was able to extract pertinent information from electronic medical records that might be used by doctors to deliver effective care. Electronic health records (EHRs) are instantaneous, patient-centered records with secure access for authorized individuals. EHRs are distinguished by the capability of authorized clinicians to generate and manage health data in digital format, which may be shared with other doctors across various healthcare organizations. The Arabic region faces significant challenges due to chronic ailments. Chronic disease-related mortality has been linked to a sizable number of deaths, according to Kuwait's Ministry of Health [3]. Their statistics show that 41% of fatalities were attributable to heart disease, 15% to cancer, 3% to respiratory problems, and 3% to diabetes. Additionally, according to Kuwait's national plan report on chronic diseases for the years 2017 to 2025, cardiovascular disorders are the main cause of mortality there [4].

The goal of this study is to create a predictive analytics model that can predict the onset of three common chronic diseases diabetes, heart disease, and kidney disease early on using electronic health records that contain important information about patients from their hospital visits. A key component of prevention is prediction, which enables healthcare organizations to give top priority to patients with the greatest needs and make the best use of their scarce resources.

To attain the research objectives, the authors conducted a study that involved defining the methodology, study population, study sample, study tools, verifying the validity and reliability of the tools, and utilizing statistical treatment in analyzing the results. The study population comprised all healthcare stakeholders in Kuwait hospitals, and the study sample consisted of (30) medical sector workers, from which a random sample was selected. The study sample's frequencies and percentages were computed, and they are represented in the basic data that includes Gender: (43% males and 56.7% females), Age: (26.7% less than a year, 43.3% between 30 to 40 years, 16.7% between 40 to 50 years, and 13.3% over 50 years), Position: (16.7% manager, 40% attending physician, and 43.3% technician), Number of years of experience (33.3% less than three years, 6.7% between three years to less than six years, and 60% more than six years), and Computer skills: (3.3% weak, 36.7% medium, 60% good). The paper evaluates physicians' perceptions on the current management of chronic diseases in primary healthcare centers using electronic health

record systems, shedding light on the practical implications of using EHR for disease management.

From Table V in Appendix A, it can be observed that the general average for the first dimension, technological infrastructure environment, had a response rate (High), an arithmetic means of (2.66), a standard deviation of (.409), and phrase No. (27) appeared in the first order. (The need to employ e-health solutions to improve the quality of the healthcare sector.) Phrase No. 22 came in second place (There is a need to establish a well-designed primary health care network) with an arithmetic mean (2.87), a standard deviation (.346), and a response rate (High), and it was followed in the last position by phrase No. 23 (There is a need for the establishment of a well-designed primary health care network). (25) (Health informatics is already implemented in the State of Kuwait.) with an arithmetic mean (2.43), and a standard deviation (.679) with a response score (High), and the rest of the expressions came with a response score (High), The standard deviations for the expressions in the first dimension varying between (.681 - .305), which are regarded as low values. This implies that the study sample's reactions to these assertions were consistent. The emergence of the technical infrastructure environment can be explained by the fact that there are numerous opportunities for developing information systems in Kuwaiti hospitals, in addition to the possibility of directing a large investment towards developing the state's infrastructure relying on electronic systems in facilitating work in the medical field, beginning with data recording, and progressing to electronic solutions.

Table VI in Appendix B shows that the overall average for the second dimension, administration, and organization, had a (High) response rate, an arithmetic mean of (2.62), and a standard deviation of (.473). Phrase 31, (The need for high-quality services in the public and private sectors of healthcare.) came in first place with an arithmetic mean (2.93), a standard deviation (.254), and a response score (High), and phrase 32 came in second place (The need for a national health information management strategy to guide public health policies.) Assuming an arithmetic mean (2.27), The rest of the expressions received a response score (High) and a standard deviation (.828), while the standard deviations for the expressions in the second dimension varying between (.254-.828), indicating homogeneity of opinions of the study sample towards these statements. The need to establish a national plan for health information management to lead public health policies might explain the appearance of the administration and organizations with a high level of responsiveness. It also mentioned the need to enhance the quality of services in the field of health care in general, by focusing on health insurance and trying to reduce health expenditures. The occurrence of phrase No. (34) in the last order can be explained by the fact that, despite the availability of an integrated framework for information and technology, this framework is not primarily relied upon in the field of medical care in Kuwait.

The previous study's recommendations emphasized the need of using electronic medical records to register patients' health information rather than paper records. Furthermore, the study emphasized the need for predictive analytics models that can anticipate the emergence of chronic illnesses at an early stage utilizing electronic health information. The study concentrated on diabetes, heart disease, and chronic kidney disease. Heart disease is a major cause of death in the United States; it kills 610,000 of people each year, accounting for one in every four fatalities. [5]. Diabetes is recognized as a chronic illness with the world's fastest growing rate at the same time [6]. Diabetes affects 415 million people worldwide, accounting for 12% of total medical spending ($673 billion) [6]. Diabetes affected 29.1 million Americans in 2012, accounting for around 9.3% of the population [6]. About 700 million people worldwide are affected with Chronic Kidney Disease (CKD) each year, resulting in the deaths of almost 1.2 million people [7]. Cardiovascular diseases such as myocardial infarction, stroke, and heart failure are more prevalent in chronic renal disease patients [7]. Patients who have both illnesses have a worse prognosis [8].

The following are the primary contributions of the article:

- Using electronic health records instead of paper records.
- Using accessible datasets from patients' medical records, machine learning techniques are used to predict the existence of chronic illnesses.
- Examining medical records of all patients to ensure proper diagnosis of chronic disorders.
- Identifying new patients with comparable symptoms and illness development phases based on physician supervision and medical record analysis for a specific type of chronic disease.

The second half of the paper will go into similar research, while Section III will examine the datasets used in the study. The fourth part will offer a full description of the suggested technique. Following that, Section V will show the test findings and assess the proposed strategy. Finally, Section VI will give findings and recommendations for further research.

II. Related Work

Yaser et al. [9], has presented a research paper. The fundamental contribution of this work is the development of a medical recommendation system that employs the closest neighbor’s classification approach and the collaborative filtering methodology. The suggested strategy was evaluated based on two criteria: statistical correctness and efficacy in giving patient counseling. The results showed that the suggested method outperformed earlier approaches in diagnosing patients, which was ascribed to the use of the "close neighbors" strategy. The suggested technique exhibited great accuracy in patient diagnosis and gave suitable therapy recommendations. However, due to the restrictions of patient data privacy, getting exact hospital data remains a substantial barrier for the suggested strategy.

Chicco et al. [10], presented another paper. A dataset of 491 patients from the United Arab Emirates was analysed to find independent risk variables for CKD at stages 3-5. The authors utilised two strategies, one based on classic univariate biostatistics testing and the other on machine learning. The biostatistics tests revealed that 68.42% of clinical parameters were significant but lacked accuracy. As a result, the authors

used Random Forests to determine feature ranking. The study proved that computational intelligence could predict significant CKD development with or without time information, and that the most important clinical variables alter when the temporal component is incorporated. The benefit of this study is that it provides a full examination of risk variables connected with CKD at stages 3-5 and applies machine learning techniques to determine the most essential clinical characteristics. However, the scientists did not examine the therapeutic significance of the findings, instead focused on developing and strengthening computational intelligence technologies.

Hohman et al. [11], presented The MENDS project which has successfully proved its capacity to satisfy principles and criteria aimed at optimising the project and supporting the CDC's DMI. The project team used statistical approaches to obtain credible prevalence estimates from EHR data that appropriately represent the underlying populations at geographic target levels. The team was able to generate more reliable local, state, and national prevalence estimates by using the breadth of clinical data. The initiative also provided an opportunity for the DOH to expand its EHR-based surveillance beyond federal programme requirements. However, obstacles such as outreach, communication, paperwork, research, and training have hindered the project's timeframe. The team is also comparing prevalence figures from other national chronic illness surveillance systems to determine their validity. The capacity to combine standard public health monitoring techniques with EHR-based surveillance and gain relevant insights from the data is one of the project's advantages. The drawbacks include the technical work and expense necessary to comply with federal rules, as well as the additional outreach, communication, documentation, investigation, or training that is required.

Kumari and Seema [12], used four distinct classifiers to detect diabetes and heart disease: Nave Bayes, Decision Tree, Support Vector Machine (SVM), and Artificial Neural Networks (ANN). The results showed that SVM had the best accuracy rate for heart disease at 95.556%, while Nave Bayes had the highest accuracy rate for diabetes at 73.588%. The benefit of employing these classifiers is that they can help clinicians find successful therapies and best practices, resulting in better and more direct healthcare for patients. However, these classifiers have the disadvantage of requiring a significant quantity of data to reach accuracy and can be time-consuming to train.

Perotte et al. [13], have evaluated the usefulness of employing electronic healthcare data and ICD-10 pain-related diagnostic clusters to self-reported data, which is considered the gold standard, in identifying persons with Musculoskeletal Chronic Pain (MSCP). The study had a 61% response rate, and the findings indicated that the prevalence of MSCP was somewhat lower when detected by electronic health records (14.7% weighted prevalence) than when found with survey questionnaires (25.9% weighted prevalence). The study found a poor level of agreement between the two MSCP categories (kappa agreement statistic = 0.21). When compared to MSCP determined using self-report as the benchmark, using electronic health data exhibited a sensitivity of 30.9%, specificity of 91.0%, and positive predictive value of 54.5%. When age and gender were taken into consideration, patients with MSCP identified through electronic health records or self-report had higher levels of pain-related disability, pain severity, depressive symptoms, and long-term opioid use, compared to individuals with single-site chronic pain identified through the same method. This study demonstrates the use of electronic health records in identifying people with MSCP, potentially leading to a greater detection of people with significant chronic pain in studies that are population-based. The study's weaknesses, however, include a low survey response rate and a lack of agreement between the two MSCP categories.

Hazazi and Wilson [14] aimed to evaluate physicians' perceptions on the current management of Noncommunicable Diseases (NCDs) in Primary Healthcare Centers (PHCs), emphasising on the role of the Electronic Health Record (EHR) system, according to a separate article provided by. The study included semi-structured interviews with 22 Ministry of Health physicians who worked in chronic illness clinics at PHCs. While physicians recognised the benefits of using EHRs, such as improved accuracy in patient documentation and access to patient information, they also identified areas for improvement, such as the lack of a patient portal for patients to access their health information and the system's inability to facilitate multidisciplinary care. In general, doctors viewed the EHR system favorably, although its influence on patient care at chronic illness clinics remained limited.

Areej and Malibari [15] used EO-LWAMCNet, MSSO-ANFIS, T-RNN, and DLMNN algorithms to predict heart and kidney illnesses in real time. On two separate datasets, the suggested model has an accuracy of 93.5% and 94%. The suggested model's merits include its capacity to forecast chronic illnesses including heart and renal disease in real time, its optimal performance, and its short execution time. The suggested model, however, has numerous shortcomings, notably its high cost and inability to distinguish between positive and negative predictions.

III. DATA

In this study, an electronic healthcare record (EHR) dataset comprising information about patients in Kuwaiti hospitals was constructed. Each row in the dataset represents a single patient, and the columns indicate all the patient's attributes/features, as detailed in Table I. This dataset was created for the purpose of predicting diabetes, heart disease, and chronic kidney disease by combining all characteristics from original datasets into a single dataset file for use in training and testing prediction models, in addition to the personal information of all patients during all hospital visits. This EHR dataset will be published soon after the government approval. Diabetes illness data was obtained from the Irvine's Center for Machine Learning and Intelligent Systems, California University [16]. Rather than more than 60,000 individual patients, this study includes clinical data from over 100,000 unique interactions. The information was gathered from roughly 74 million patient visits involving 17 million people [16]. This study's data was gathered over a ten-year period, from 1999 to 2008, and includes many credits that correspond to the seasons of confirmation and release for diabetes patients. The records

include information on laboratory tests and procedures, diagnoses, and drugs given during the hospitalization.

The dataset utilized in this work for heart disease prediction was collected from the UCI Machine Learning Repository of Irvine C.A, University of California and was freely accessible online [17]. The cardiac disease datasets utilized in this study have identical properties and example designs. Only 14 of the 76 raw qualities in these datasets are considered essential, including anticipated property. The Cleveland Clinic Foundation dataset has 303 patient records, whereas the Hungarian Institute of Cardiology dataset contains 294 patient records. This study examined a dataset of 491 individuals from the United Arab Emirates published by Al-Shamsi et al. for chronic renal disease [18]. The data for this study was gathered at Tawam Hospital in Al-Ain (Abu Dhabi, United Arab Emirates) in 2008. The dataset offered 491 patients, 241 women and 250 males, with an average age of 53.2 years. Each patient was given a chart with 13 clinical variables that represented the results of laboratory tests and examinations as well as data from the dataset. The authors used multivariable Cox proportional hazards to identify the risk variables that cause CKD at stages 3-5. However, the analysis did not include a prediction phase, which may have recovered more relevant information or previously unknown patterns in the data.

TABLE I. NAME AND TYPE OF EACH FEATURE OF THE EHR DATASET

Feature Name	Type	Feature Name	Type
Encounter ID	Numeric	Examide	Numeric
Patient number	Nominal	Insulin	Numeric
Race	Nominal	Anemia	Nominal
Gender	Numeric	Creatinine hosphokinase	Nominal
Age	Numeric	Blood pressure	Numeric
Weight	Nominal	Serum creatinine	Numeric
Admission type	Nominal	Smoking	Nominal
Discharge disposition	Numeric	Specific gravity	Nominal
Admission source	Numeric	Albumin	Numeric
Time in hospital	Nominal	Red blood cells	Numeric
Payer code	Nominal	Pus cells	Nominal
Medical specialty	Numeric	Bacteria	Nominal
Number of lab procedures	Numeric	Blood Urea	Numeric
Number of procedures	Numeric	Sodium	Numeric
Number of medications	Numeric	Potassium	Numeric
Number of outpatient visits	Numeric	Hemoglobin	Numeric
Number of emergency visits	Numeric	White Blood Cell Count	Numeric
Number of inpatient visits	Nominal	Hypertension	Numeric
Diagnoses 1	Nominal	CoronaryArtery Disease	Nominal
Diagnoses 2	Nominal	Appetite	Nominal
Diagnoses 3	Numeric	A1c test result	Nominal
Number of diagnoses	Nominal	Change of medications	Nominal
Glucose serum test result	Nominal	Readmitted	Nominal

IV. METHODOLOGY

The task stated previously is to apply binary classification to predict the existence of diabetes, heart, and kidney chronic diseases using the data said earlier. This part will display the classification models applied in this study. The proposed method architecture is described in Fig. 1.

A. Data Acquisition

In this step, we gather electronic health record (EHR) information from medical facilities, healthcare centers, or publicly available datasets, while guaranteeing that the data is anonymized and compiles with applicable privacy regulations.

B. Data Preprocessing

Before we use the datasets for prediction, we analyze them to obtain their drawbacks. In the diabetes datasets, we observed that there are many features with missing value ratio, as shown in Fig. 2.

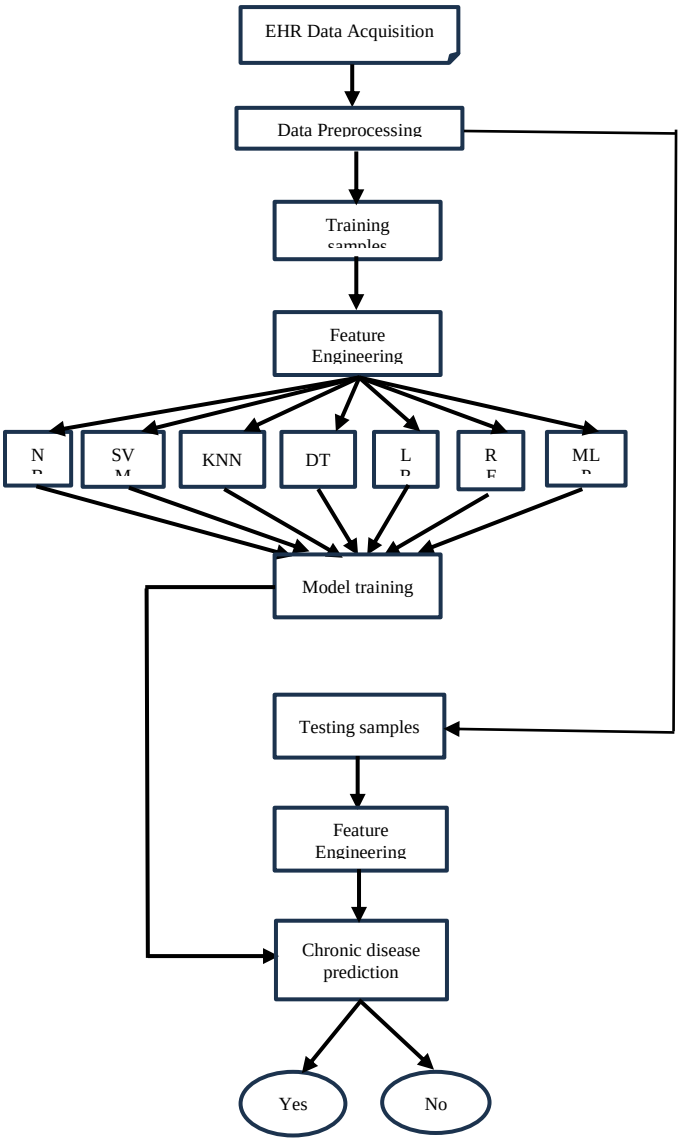

Fig. 1. Proposed method architecture.

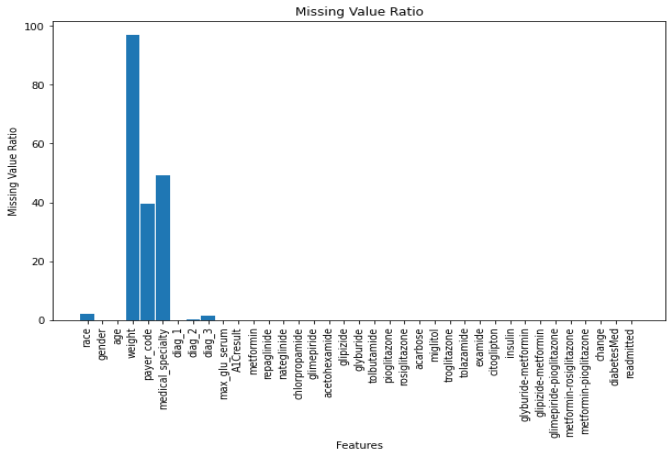

Fig. 2. Features with missing value ratio in diabetes dataset.

After applying feature reduction based on missing value ratio with ratio more than or equal 40%, "weight", "payer_code" and "medical_specialty" features have been dropped from dataset. Then we are dealing with features that have less than 40%, we have "diag_1", "diag_2", "diag_3" and "race" features. We have removed any row that have a missing value in any features and this through the following:

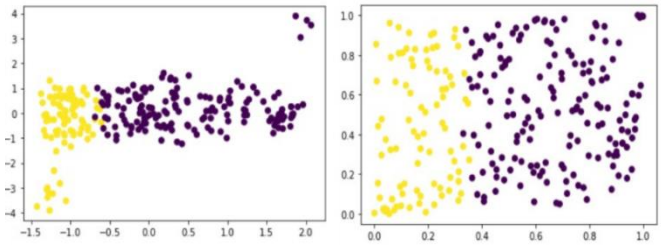
- Retrieving the index of the row where all three (diag_1, diag_2 and diag_3) values are missing and storing it in a set.
- Retrieving the index of the rows where only diag_1 value is missing and appending the same in the set.
- Retrieving the index of the rows where only diag_2 value is missing and appending the same in the set.
- Retrieving the index of the rows where only diag_3 value is missing and appending the same in the set.
- Retrieving the index of the rows where only race value is missing and appending the same in the set.
- Then drop all rows that have an index in the set.

Now we have a dataset without missing value. The next step is to remove columns (features) that have no relation with our output; in another word "featureless" such as "encounter_id" and patient_nbr".

So, we now have a clean dataset without any missing value and featureless columns but there are some columns still with text not numbers. In order to that, we have labeled these columns with integer numbers. Then to make our classifiers and model avoid overfitting, we make data regularization to all data.

Pearson's Correlation Coefficient helped us identify the connection between two quantities by assessing the intensity of their association. Also, it provides a metric ranging from -1 to +1 to quantify this relationship. A value of one signifies a strong correlation, while zero indicates no correlation. A heatmap is a visual representation of data in two dimensions, utilizing color to convey information. This graphical method assists users in visualizing both simple and complex data. This heat map is shown in Fig. 4 in Appendix C below. We observed the last row, "target" and noted its correlation scores with different features. "examide", "citoglipton" and "metformin-rosiglitazone" features are not correlated with "target". They don't contribute much to the model, so we dropped them.

To treat the outliers, we used Quantile Transformer. This technique converts the features into a uniform or normal distribution. Therefore, this conversion typically causes the most common values of a feature to be more widely distributed. Furthermore, this preprocessing scheme is considered robust as it effectively lessens the influence of minor outliers in the dataset. Fig. 3 shows the difference between applying Standard Scalar vs. Quantile Transformation. In Standard Scalar, Fig. 3(a), the Y-axis has eight units, whereas X-axis has only 3.5 units, indicating that Outliers have affected the scales. After applying Quantile Transformation, the Y-axis, and X-axis are equally scaled as shown in Fig. 3(b). The outliers are still present in the dataset, but their impact has been reduced.



(a) (b)

Fig. 3. (a) Standard scalar.(b) Quantile transformation.

We applied these preprocessing processes to heart and kidney chronic diseases datasets as they had the same problems, imbalance, and outliers.

C. Feature Engineering

Feature engineering involves identifying and extracting meaningful features from electronic health record (EHR) data that may be associated with chronic diseases. This process includes both feature extraction, which involves identifying relevant features, and feature selection, which involves selecting the most informative features for predicting the diseases.

D. Split Data

After Partitioning the dataset into appropriate training, validation, and testing subsets, using a suitable ratio, as follows, the training set contains 70% of the data, the validation and the test set are 15% each.

E. Classifiers

1) Naïve Bayes (NB): The "Naïve Bayes Classifier" refers to straightforward probability-based classifier which utilizes Bayes' theorem with dependable assumptions of independence. It anticipates that the proximity or lack of a particular class component will depend on the proximity or lack of any other element [19]. Conditional probabilities are necessary for the Naive Bayes calculation. It employs the Bayes hypothesis, a method for computing probability

through frequency counting of different qualities and attributes combinations in the collected data. The Bayes Theorem estimates the likelihood of an event, given the possibility of an earlier event. The Bayes hypothesis can be stated as follows [24]. When "b" addresses the current event for the needy and "a" addresses a previous occasion, Bayes' theorem can be formulated in the following manner:

$$Prob\ (a|b)\ = \frac{Prob\ (b|a) * Prob(b)}{Prob(a)} \qquad (1)$$

Here, Prob $(a|b)$ denotes the probability of "b", and Prob $(b|a)$ represents the probability of "b" given "a". The main benefit of the Naive Bayes classifier is the minimal training data it requires to compute mean and variance parameters essential for classification. Under the assumption of independent variables, Variances of for each class's variables need to be calculated only, rather than the overall variance. The reason for using the naïve bayes is that it is fast, scalable and useful for dealing with missing data.

2) Support Vector Machine (SVM): SVM is a supervised learning technique used for regression and classification tasks, known as Support Vector Regression (SVR) and Support Vector Classification (SVC), correspondingly. It is recommended for use with more diminutive datasets as the processing time for larger datasets is lengthy [20]. The fundamental principle of SVM involves determining the hyperplane which efficiently splits the dataset's features to distinct domains, where the points closest to the hyperplane are designated as support vectors, and their distance from the hyperplane is known as the margin. This algorithm aims to locate a hyperplane that minimizes the likelihood of misclassifying cases in the test dataset [21]. SVM is very useful when the data is not distributed regularly, and it doesn't suffer from overfitting.

3) K-Nearest Neighbor (KNN): KNN is a supervised learning algorithm that employs proximity to classify or forecast the grouping of a singular data point [22]. Although support vector machines (SVM) can be used for classification and regression tasks, it is commonly used as a classification technique, relying on the concept that analogous points are usually in proximity to one another. KNN is a lazy learning technique that doesn't generalize the training data points, resulting in a quick training phase. It predicts the classification of a new sample point using data from multiple classes. Additionally, KNN is non-parametric, making no assumptions about the data, and the model is derived directly from the data [24]. KNN was used since it doesn't need to be trained before producing predictions, and so new data can be supplied without disrupting the system's accuracy.

4) Decision tree: The classification process can be directed using decision trees [23]. They are arranged in a simple tree structure, with terminal nodes displaying the results of decisions and non-terminal nodes representing tests on one or more attributes. By using information gain and gain ratio measures as splitting models, C4.5 improved the ID3 decision tree induction algorithm. The decision tree construction algorithm can be summed up as follows: 1) Decide which attribute best distinguishes the values of the output attribute. 2) Make a distinct branch of the tree for each attribute value. 3) Create subgroups from the instances to correspond with the attribute values of the chosen node. For each subgroup, stop the attribute selection process if the following conditions are met: a) When all of the instances in a subgroup have the same value for an output attribute, the attribute selection process for the current path is stopped, and the branch on the current path is marked with the chosen value. b) There is only one node in the subgroup or no other distinguishing characteristics can be found. Label the branch with the output value seen in most of the remaining cases, just like in (a). 5) Repeat the procedure above for each subgroup created in (3) that has not been designated as terminal [24].

5) Random forest: The random forest algorithm, as explained in [25], is composed of multiple decision trees that are trained on a bootstrapped sample of the data set, where one-third of the data is reserved for testing as the out-of-bag sample. To introduce more diversity and reduce correlation among decision trees, feature bagging injects another instance of randomness. Before training, the random forest algorithm requires three crucial hyperparameters to be specified: node size, number of trees, and number of sampled features. The random forest classifier can be employed to address both regression and classification tasks, and the method of determining the prediction varies depending on the type of problem. For a regression task, the decision trees' predictions are averaged, while for classification tasks, the predicted class is determined through a majority vote, selecting the most frequent categorical variable [25].

6) Logistic Regression (LR): Logistic regression is a machine learning technique which is categorized as a supervised machine learning model. It is also regarded as a discriminative model that aims to differentiate between classes or categories [25]. Logistic regression is commonly used for prediction and classification problems such as Fraud detection, Disease prediction, and Churn prediction. This analytical approach in medicine can anticipate the probability of disease or illness for a particular population, enabling healthcare organizations to establish preventive care measures for individuals with a higher susceptibility to specific conditions [26].

7) Multi-Layer Perceptron (MLP): Three layers make up an MLP, a feed-forward neural network: an input layer, an output layer, and a hidden layer [25]. While the output layer completes various tasks like classification and prediction, the input layer receives the input signal for processing. There are numerous hidden layers that make up the computational engine of the MLP that lie between the input and output layers. Data flows forward from the input layer to the output layer, much like a feed-forward network in an MLP. The MLP neurons are trained with the backpropagation learning algorithm. Since MLPs can approximatively solve any continuous function, they can solve problems that cannot be

linearly separated. They are used in a variety of tasks including classification, pattern recognition, forecasting, and approximation. [27]. We used MLP as it is very flexible and can be used for learning mapping from inputs to outputs generally.

V. Experimental Results

To evaluate the proposed model, several experiments have been carried out using different parameters as shown in Table II. All experiments have been done using Python programming language by Jupiter notebook editor with some machine learning toolboxes (e.g. Scikit-learn, NumPy, and matplotlib).

TABLE II. Parameters of Some Proposed Models

Algorithm	Parameters
SVM	**Kernel functions** = {linear, sigmoid, RBF}
KNN	Number of neighbors (n) = {30, 40, 50}
MLP	Number of hidden layers (h) = {5, 10, 20}

The accuracy and f1-score are calculated to examine how classification is carried out. As a result of the classifier, four cases are taken into consideration.

- True Positives (TP): The sample size correctly assigned to that class.
- True Negatives (TN): The sample size correctly excluded from that class.
- False Positives (FP): The sample size wrongly excluded from that class.
- False Negatives (FP): The sample size wrongly assigned to that class.

The number of accurate and wrong classifications in each potential prediction of the classified variables is used to evaluate how effective the classification model is. The accuracy is calculated using the following formula:

$$\text{Accuracy} = \frac{TP+TN}{TP+TN+FP+FN} \quad (2)$$

We have utilized three medical datasets related to diabetes, heart, and kidney disease. These datasets were all retrieved from the UCI machine learning library [15, 17, 18]. The objective is to compare all classifiers, including Naïve Bayes, KNN, SVM, DT, RF, LR, and MLP, and to categorize the diseases depending on parameter choices. The accuracy of several classifiers for diabetes and heart disease datasets is shown in Table III. After applying some experiments with different parameters shown in Table II, we decided on the best hyperparameters for SVM, KNN, and MLP classifiers. For SVM, three kernel functions have been utilized and the RBF kernel has achieved the highest accuracy on diabetes and kidney datasets. Three values for the number of neighbors were used for the KNN classifier and the best one was 40. In MLP, the best number of hidden layers was 10, which achieved the highest accuracy on the heart dataset.

In Table IV, a recognized confusion matrix is obtained to estimate four measures, accuracy, precision, recall, and f-score.

TABLE III. Accuracy of All Classifiers for Diabetes, Heart, and Kidney Datasets

Dataset	Classifier	Accuracy	Precision	Recall	F-score
Diabetes	Naïve Bayes	88.3%	85.5%	78.1%	83.5%
	SVM	**88.5%**	**92.4%**	**99.8%**	**93.6%**
	KNN	88.2%	57.3%	51.5%	49.5
	DT	82.2%	91.2%	85.8%	84.2%
	RF	88.4%	44.1%	51.5%	47.2%
	LR	88.3%	69.2%	52.3%	48.5%
	MLP	75.1%	39.5%	20.4%	26.4%
Heart	Naïve Bayes	83.1%	83.6%	82.5%	81.6%
	SVM	83.6%	83.8%	81.4%	81.5%
	KNN	83.1%	83.5%	80.6%	81.5%
	DT	80.9%	79.8%	78.8%	78.8%
	RF	84.2%	84.5%	84.4%	85.1%
	LR	82.6%	82.8%	83.6%	84.9%
	MLP	**84.7%**	**88.5%**	**87.4%**	**87.8%**
Kidney	Naïve Bayes	86.8%	82.6%	77.6%	74.7%
	SVM	**94.9%**	**94.5%**	**90.2%**	**92.6%**
	KNN	81.8%	85.7%	53.6%	54.8%
	DT	89.9%	88.5%	68.4%	82.3%
	RF	86.8%	84.6%	71.0%	75.3%
	LR	85.8%	87.4%	67.2%	71.1%
	MLP	89.8%	65.7%	68.5%	66.4%

TABLE IV. Confusion Matrix of SVM, DT, and MLP classifiers for Diabetes, Heart, and Kidney chronic datasets

Dataset	Classifier	Precision	Recall	F-measure	Class
Diabetes	NB	0.85	0.85	0.83	Yes
		0.86	0.89	0.84	No
	SVM	0.93	1.00	0.92	Yes

	MLP	0.66 0.65	0.81 0.57	0.72 0.61	Yes No

The classification outcomes are presented as a matrix by the confusion matrix. It includes information for actual and predicted classes made using the classification framework. The cell represents the sample size that was classified as true when they were actually true (i.e., TP) and those classified as false while quiet (i.e., TN), respectively. The remaining two cells represent the number of incorrectly classified pieces. In fact, the cells denoting the sample size labeled false when they were actually true (i.e., FN) and the sample size labeled true when they were wrong (i.e., FP) [28]. After the confusion matrices are constructed, the following formulas can determine the precision, recall, and F-measure:

$$\text{Precision} = \frac{TP}{(TP + FP)} \tag{3}$$

$$\text{Recall} = \frac{TP}{(TP + FN)} \tag{4}$$

$$\text{F-measure} = \frac{2 * TP}{(2 * TP + FP + FN)} \tag{5}$$

VI. Conclusion and Future Work

In this study, we generated electronic healthcare records with symptoms data sourced from three distinct datasets in the UCI machine learning repository for predicting diabetes, heart disease, and chronic kidney disease. Data of the patients were trained with various classifiers, including Naïve Bayes, SVM, Decision Tree, Random Forest, Logistic Regression, and Multilayer Perceptron. The results of this study indicate that data mining techniques can be effectively employed to identify and predict chronic diseases. The results indicate that the Support Vector Machine (SVM) algorithm was the most successful in predicting diabetes and kidney diseases, while the Multilayer Perceptron (MLP) algorithm was the optimal choice for predicting heart disease. The Naïve Bayes and Random Forest algorithms also demonstrated strong performance across all datasets.

Separability-based Quadratic Feature Transformation to Improve Classification Performance

Usman Sudibyo, Supriadi Rustad, Pulung Nurtantio Andono, Ahmad Zainul Fanani
Faculty of Computer Science, Universitas Dian Nuswantoro, Semarang, Indonesia

***Abstract*—Feature transformation is an essential part of data preprocessing to improve the predictive performance of machine learning (ML) algorithms. Box-Cox transformation with the goal of separability is proven to align with the performance improvement of ML algorithms. However, the features mapped using Box-Cox transformation preserve the order of the data, so it is ineffective when used to improve the separability of multimodal distributed features. This research aims to build a feature transformation method using quadratic functions to improve class separability that can adaptively change the order of the data when necessary. Fisher score (Fs) measures the separability level by maximizing the Fisher's Criteria of the quadratic function. In addition to increasing the Fs value of each feature, this method can also make the feature more informative, as evidenced by the increasing value of information gain, information gain ratio, Gini decrease, ANOVA, Chi-Square, reliefF, and FCBF. The increase in Fs is particularly significant for bimodally distributed features. Experiments were conducted on 11 public datasets with two statistical-based machine learning algorithms representing linear and nonlinear ML algorithms to validate the success of this method, namely LDA and QDA. The experimental results show an improvement in accuracy in almost all datasets and ML algorithms, where the highest accuracy improvement is 0.268 for LDA and 0.188 for QDA.**

***Keywords*—Separability; feature transformation; quadratic function; fisher's criterion; fisher score**

I. INTRODUCTION

Machine Learning (ML) is an essential branch of artificial intelligence widely used for pattern recognition, image processing, text classification, intrusion detection systems, etc. [1]. However, the ML algorithm's success depends on the features' quality. The resulting model is also good if the features are good [2]. Therefore, improving features to suit ML algorithms' needs is an essential topic in feature engineering [3]. Feature transformation is one of the feature engineering techniques that can be used to improve features before being input into the ML algorithm [2], [4]. There have been many studies that discuss feature improvement through transformation techniques, where with the proper feature transformation, feature quality can be improved [5], [6].

Feature transformations developed to improve feature quality are generally grouped into three: first, feature transformations that only change the scale (e.g., Min-Max normalization, Z-Score normalization) [7], second nonlinear feature transformations that do not change the order of the data (e.g. log transform [8], square root transform [9], Box-cox transform, Yeo-Johnson transform [10]), and third, nonlinear feature transformations that can change the order of the data (e.g. kernel function in SVM) [11], [12]. Some machine learning algorithms are sensitive to scale differences, so normalization or standardization is needed to uniform the scale of features. Paper in [13] discusses the effect of various data normalization methods on support vector machine (SVM) algorithms and technical indicators to predict stock index price movements. The result is a slight increase in accuracy performance. Paper in [6] proposed mixed feature transformation methods such as CDF transformation and Symmetric log1p transformation, where feature transformation can substantially improve the performance of neural ranking models compared to directly using raw features. Paper in [14] compares the effect of Box-Cox transformation to improve two-dimensional images with advanced low-light image enhancement techniques. Paper in [15] addresses issues in nonlinear stochastic degradation modeling and prognostics from the Box-Cox transform (BCT) perspective, where BCT is used to transform nonlinear degradation data into near-linear data. Adaptive Box-Cox (ABC) transformation was introduced by [16], where adaptive parameter tuning is used to normalize data in various distributions that cannot be properly normalized using conventional data transformation algorithms, including log and square root transformations.

In general, feature transformation aims to change the data distribution to be close to Gaussian in order to improve ML performance, such as log transformation [8], [17], square root transformation [18], Box-Cox transformation [14], [19]–[23], and Yeo-Johnson transformation [10], [24]. However, the experimental results of Bicego & Baldo, 2016 [20] showed different results. Their findings show that ML classification accuracy improves when the data distribution is far from Gaussian and is more related to the class separability problem. This finding is corroborated by [21], [25]–[27], which state that, based on the fisher criterion, features with greater class separability are considered more informative and can improve ML classification performance. Based on these findings, ML classification performance can be improved when features have large separability. This transformation can improve class separability, even in cases where the original dataset is not linearly separable.

Bicego and Baldo's research above uses the Box-Cox transformation, where this transformation is monotonous because it cannot change the order of the data [20]. This condition causes the Box-Cox transformation not to produce maximum separability. In addition, the result of the Box-Cox transformation is determined by a parameter that is searched using the grid search method so that getting the best parameter of each feature associated with the maximum fisher value

requires high computational costs [21]. Bicego and Baldo's empirical analysis of the behavior of the Box-Cox transform for pattern classification opens up opportunities for the analysis of different nonlinear data pre-processing methods that can improve class separability.

This research proposes a quadratic feature transformation for preprocessing that is directly designed to maximize the class separability of each feature. The idea is to optimize the quadratic function parameters using Fisher's optimization criterion to obtain maximum class separability. In this way, each feature is transformed using a quadratic function to have a higher fisher score compared to the original feature's fisher score. The quadratic transformation process is performed at the preprocessing stage, making it flexible to be combined with various ML algorithms. Since this technique is directly geared towards maximizing the fisher score, while the mean and variance of each class can be easily calculated, it has the potential to be applied to multi-class data. Various feature quality test metrics, such as Information Gain [28]–[30], Gain ratio [31], Gini Decrease [32], Anova [33], [34], Chi-Square [35], ReliefF [36], [37], and Fast Correlation-Based Feature selection (FCBF) [38], [39], are used to test the feature quality of the proposed Box-Cox transformation and Quadratic transformation, before finally comparing their respective performance.

The classification algorithms used in this study are Linear Discriminant Analysis (LDA) and Quadratic Discriminant Analysis (QDA), which represent linear and nonlinear ML algorithms. Although LDA has proven to be an excellent classification and dimensionality reduction algorithm, it produces poor vector projections on multimodal data [40]–[42]. With feature transformation, it is expected that the multimodal influence on LDA can be reduced. QDA was chosen because it is one of the most commonly used classifiers in practice and is quite simple. In addition, QDA has been shown to improve performance when paired with the nonlinear feature extraction technique quadratic Fisher transformation [43].

The contributions of this research include:

1) Development of separability-based feature transformation to optimize the classification task of machine learning algorithms.

2) The chosen quadratic transformation is generally able to improve feature quality based on fisher score, information gain, chi-square, relief, and FCBC values on the dataset studied.

This paper is organized into several sections, starting with an introduction in Section I, followed by a brief explanation of fisher score and quadratic function in Section II, research methodology containing the dataset and the proposed method in Section III, results and discussion in Section IV, and then closed with a conclusion in Section V.

II. Preliminary Works

To prepare for a better understanding of this research, some feature transformation techniques, fisher score, and quadratic function definition and application will be introduced.

A. Feature Transformation Technique

In some literature, the use of the term feature transformation is often equated with feature engineering, feature extraction, and feature construction [44]. However, this study consistently uses the term feature transformation as a univariate feature engineering technique.

Feature transformations, which T. Verdonck et.all 2021[2] call feature engineering, are grouped into two, namely univariate and multivariate feature engineering techniques. Univariate feature transformations on continuous variables can improve symmetry, normality, or model fit, such as logarithmic transformation, Box-Cox transformation, and Yeo-Johnson transformation. Multivariate feature transformations aim to reduce the dimensionality of the data by creating new features that are linear combinations of the original variables, such as PCA, LDA, SVD, UV (non-negative) decomposition, and tensor decomposition.

The study of feature transformation has progressed quite well. The following studies are related to feature transformation. A feature transformation method based on Mutual Information (MI) is proposed by [45], where the Probability Density Function (PDF) of features in the class is assumed to be Gaussian. The gradient descent technique is used to maximize the mutual information between features and classes. Experimental results show that the proposed MI projection consistently outperforms other methods for various cases. Most of these Medical decision support systems (MDSS) focus on feature transformation-based methods and their integration with machine learning models for the prediction of risks associated with Heart failure (HF). However, the improvement in accuracy on test data is not followed by training data. This study proposes a more robust approach that integrates stacked autoencoder grids with neural network models to address the problem[46]. Most feature engineering in the input space relies on manually defined transformation functions. However, research [12] builds transformation functions automatically learned through autoencoders for latent representation extraction and multi-layer perceptron (MLP) regressors. The transformation function built in this way can also improve the performance of LSVM and JST, when embedded as a preprocessing step. A random projection-based feature transformation method using Metaheuristic Optimization Algorithm [47] is proposed to map data points from the original space to a new binary space, where the random projection process is formulated as an optimization problem. The transformation of features to binary space is needed when the system requires coarse quantization of measurements. A new guided FT method called minimax probabilistic feature transformation (MPFT) was proposed for multi-class datasets [48]. The idea of this method is based on trying to control the probability of correct classification of future test points as large as possible in the transformed feature space. Past tax default prediction by applying diverse feature transformation techniques and advanced machine learning approaches was proposed by [49]. A combination of feature transformations, such as logarithmic and square root transformations, is able to improve tax default prediction performance. A feature transformation method to improve classification performance referred to as weight-matrix

learning (WML), was proposed by[50]. The way this method works is that WML is identified as an off-center technique with a center of 0.5 similarity.

B. Fisher Score (Fs)

Fs belongs to the classical supervised feature selection filter method, which aims to score features based on the ratio of data scatter between classes and data scatter within classes. Fs is used to measure the class discriminant properties of each feature independently. Features with higher Fisher scores are more discriminant than features with lower scores [51]. Fisher score has been widely used for feature selection on gene microarray data [52]–[57]. This study uses the fisher score as a basis for improving separability because it is conceptually easy to understand, easy to implement on various functions, and Fs is an efficient approach to data dimensionality reduction [58]. Fisher score Fs(k) is used to measure the separability of classes at the kth feature of a dataset. Mathematically, Fs(k) is calculated using Eq. (1)[52].

$$Fs(k) = \frac{\sum_{i=1}^{c} n_i (\mu_i^k - \mu^k)^2}{\sum_{i=1}^{c} n_i (\sigma_i^k)^2} \tag{1}$$

$$\text{with} \quad \mu_i^k = \sum_{j=1}^{n_i} \frac{x_{ij}^k}{n_i} \quad ; \quad \mu^k = \sum_{j=1}^{N} \frac{x_j^k}{N}$$

$$\sigma_i^k = \sum_{j=1}^{n_i} \frac{(x_{ij}^k - \mu_i^k)^2}{n_i - 1} \tag{2}$$

where c, N, n_i, μ_i^k, μ^k, and σ_i^k respectively are the number of classes, the total number of samples, the number of samples of the i-th class, the mean value of the k-th feature of the i-th class, the mean value of the k-th feature for the whole class, and the variance of the k-th feature of the i-th class.

C. Quadratic Function

Throughout the literature review, no quadratic functions were found to be used for the purpose of increasing the separability of classes in features. However, there are many uses of quadratic functions for different purposes. Quadratic kernel-free non-linear support vector machine (QSVM) uses quadratic functions as decision boundaries that are able to separate data in a non-linear manner. The decision boundary is built from a multivariate quadratic function that can replace the kernel trick in SVM when faced with problems that cannot be separated linearly [59]. The QSVM method was successfully used for credit scoring models [60] and improved accuracy and efficiency. This method, called Quadratic Fisher Discriminant Analysis (QFDA), uses linear and quadratic basis functions to improve classification accuracy by considering data variance. This method aims to maximize the fisher criterion in the transformation space using a transformation matrix[61]. Before the transformation, each feature is squared, and the features are multiplied, resulting in a significant increase in the number of features and high computational cost. One disadvantage of the QFDA method is that it may only work well if the class mean values are equal or if the vital information for classification lies in the variance of the data rather than the mean value.

From a mathematical point of view, a quadratic function is a polynomial of degree 2. Its highest exponent on the independent variable (i.e., x) is 2. The general form of the parabolic quadratic function, as shown in Eq. (5), is defined as follows [62].

Definition (General form). For fixed constants b, c ∈ R and nonzero a ∈ R, the function f : R → R given by

$$f(x) = ax^2 + bx + c \tag{3}$$

is a (real) quadratic function written in general form.

Quadratic functions are capable of transforming data to be closer for data in the same group and further away for data from different groups. This ability is the basis for using quadratic functions for feature transformation.

III. Research Methodology

A. Datasets

This study used 11 datasets, which are presented in Table I. Ten datasets were downloaded from the Keel data repository (https://sci2s.ugr.es/keel/category.php?cat=clas), including Sonar, WDBC, Ringnorm, New Thyroid, Wisconsin, Parkinson's, Splice, Balance, Spectf, and Hayes Roth. One Hungarian dataset was downloaded from https://www.openml.org/. Table I consists of five columns containing dataset information (code, dataset, features, samples, and class) and one column containing different methods using the same data. The number of features is between 4 and 60, the sample size is between 160 and 7400, and the targets consist of two classes and three classes. The data type varies from numeric, categorical, binary, and there are no missing values in all datasets. The data information is summarized in Table I.

TABLE I. Profile Dataset and Accuracy Performance of State-of-the-Art Methods

Code	Dataset	Features	Samples	Class	Method
d-1	SONAR	60	208	2	2DCSCA[47]

d-4	New Thyroid	5	215	2	Hybrid GPFC[63]
d-5	Wisconsin	9	683	2	SSDA[65]
d-6	Parkinson	22	195	2	2DCSCA[47]
d-7	Hungarian	11	1190	2	RFSA -MCC[51]
d-8	Splice	60	3190	2	RMB-SSVM[66]
d-9	Balance	4	625	3	GPMO[67]
d-10	Spectf	44	267	2	RFSA -MCC[51]
d-11	Hayes-Roth	4	160	3	SSDA[65]

B. Proposed Method

The proposed method can find the best parameters of the quadratic function in Eq. (3) generated by maximizing the Fisher score [68], [69], which is the ratio of variance between classes and variance within classes. The result of maximizing the Fisher score is a closed-form solution of the quadratic function parameters described in Section III (B) (1), while the feature transformation procedure is described in Section III (B) (2).

1) Separability-based quadratic feature transformation: Based on the Fisher Score function of Eq. (1) and the quadratic function of Eq. (3), Eq. (4) is generated as the basis for obtaining the best parameters.

$$Fs(k) = \frac{\sum_{i=1}^{c} n_i^k \left[a(\theta_i^k - \theta^k) + b(\mu_i^k - \mu^k) \right]^2}{\sum_{i=1}^{c} \left[n_i^k \sum_{j=1}^{n_i^k} \frac{(a((x_{ij}^k)^2 - \theta_i^k) + b(x_{ij}^k - \mu_i^k))^2}{n_i^k - 1} \right]} \quad (4)$$

The Mean square of the k-th feature, i-th class.

$$\theta_i^k = \sum_{j=1}^{n_i^k} \frac{(x_{ij}^k)^2}{n_i^k} \quad (5)$$

The Mean square of the k-th feature

$$\theta^k = \sum_{j=1}^{N} \frac{(x_j^k)^2}{N} \quad (6)$$

Arg_max(Fs(k)) Eq. (4) yields the optimal parameters a, b, and c formulated in Eq. (7) to Eq. (9).

$$a^k = 2R^k \quad (7)$$

$$b^k = -Q^k \pm \sqrt{(Q^k)^2 - 4R^k P^k} \quad (8)$$

$$c^k = 0 \quad (9)$$

Where is

$$A_i^k = (\theta_i^k - \theta^k); B_i^k = (\mu_i^k - \mu^k) \quad (10)$$

$$P^k = \sum_{i=1}^{c} A_i^k B_i^k \sum_{i=1}^{c} v((x_i^k)^2) - \sum_{i=1}^{c} A_i^2 \sum_{i=1}^{c} c(x_i^k, (x_i^k)^2) \quad (11)$$

$$Q^k = \sum_{i=1}^{c} (B_i^k)^2 \sum_{i=1}^{c} v((x_i^k)^2) - \sum_{i=1}^{c} (A_i^k)^2 \sum_{i=1}^{c} v(x_i^k) \quad (12)$$

$$R^k = \sum_{i=1}^{c} (B_i^k)^2 \sum_{i=1}^{c} c(x_i^k, (x_i^k)^2) - \sum_{i=1}^{c} (A_i^k B_i^k) \sum_{i=1}^{c} v(x_i^k) \quad (13)$$

Variance of the k-th feature of i-th class

$$v(x_i^k) = \frac{\sum_{h=1}^{n_i^k} (x_{h,i}^k - \mu_i^k)^2}{n_i^k - 1} \quad (14)$$

The Squared variance of kth feature, i-th class

$$v((x_i^k)^2) = \frac{\sum_{h=1}^{n_i^k} ((x_{h,i}^k)^2 - \theta_i^k)^2}{n_i^k - 1} \quad (15)$$

Covariance between x_i^k and $(x_i^k)^2$ of the kth feature of the i-th class

$$c(x_i^k, (x_i^k)^2) = \frac{\sum_{h=1}^{n_i^k} (x_{h,i}^k - \mu_i^k)((x_{h,i}^k)^2 - \theta_i^k)^2}{n_i^k - 1} \quad (16)$$

2) Transformation procedure: Each feature is separately parameterized using Eq. (7) to Eq. (9). The following procedure is used for feature transformation:

a) Select the kth feature for which parameters are to be calculated.

b) Split the feature into training and testing data.

c) Square each element of the feature (x^k) and add it as a new feature (x^k)^2.

d) Using the training data, calculate the mean of the kth feature of the i-th class, the average of the kth feature, the variance of the kth feature of the i-th class, the squared variance of the kth feature of the i-th class, the covariance between x_i^k and $(x_i^k)^2$ of the kth feature of the i-th class, respectively, using Eq. (2), (14), (15), and (16) to obtain the optimal parameters, b, and c in Eq. (7) to Eq. (9).

e) Transform each feature element x_i^k , both training and testing, using Eq. (3).

C. Experimental Design

All 11 datasets were preprocessed, which included converting categorical data types to numerical and standardizing the datasets in the range between 1 and 2 [19]. Fig. 1 presents the experimental design where the data is split into training and testing using the Cross-validation technique with k = 10. The training data was used to obtain the quadratic function parameters as described in detail in Section III (B) (2), and the Box-Cox transformation parameter λ in the range of -5 to +5 as in Bicego and Baldo's study, which chose the best λ based on the highest fisher score. These parameters are used to transform training and testing data features based on quadratic and Box-Cox functions. The quality of the transformed training data features was measured using the Fisher score, Information gain, Gain ratio, Gini Decrease, Anova, Chi-square, ReliefF, and FCBF to ensure they were good inputs for training the two statistical machine learning algorithms LDA [70] and QDA[71]. The resulting ML model was tested with the transformed testing data to evaluate model performance. Model performance is measured by the accuracy (Acc) metric using Eq. (17).

$$Acc = \left(\frac{Tp + Tn}{Tp + Tn + Fp + Fn} \right) * 100 \quad (17)$$

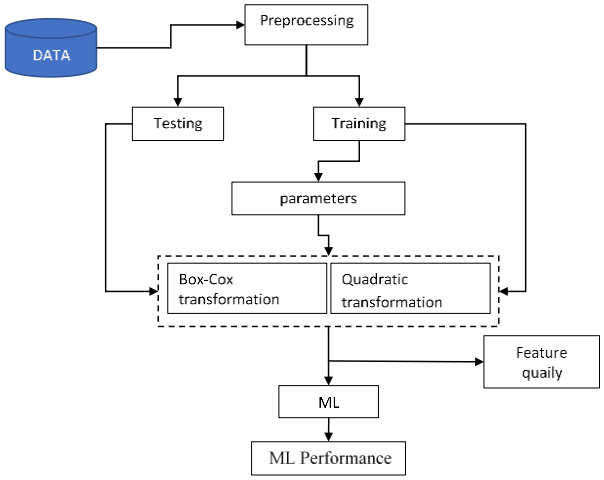

Fig. 1. Experimental design of quadratic and Box-Cox transformations.

where Tp, Tn, Fp, and Fn are components in the confusion matrix that respectively show the number of true positives, true negatives, false positives, and false negatives.

This study compares feature quality and ML performance before and after transformation to assess the efficacy of the proposed transformation, as well as comparisons with ML performance by other researchers. Seven metrics compare feature quality before and after transforming using quadratic and Box-Cox functions. The algorithm is trained using transformed training data and then tested using transformed testing data to determine ML performance. The results are compared with the performance before transformation. The accuracy of the proposed method is compared with the results of other researchers for the same dataset, including Huan Wan, et al 2018 [65], Jinsong Wang, et al 2020 [72], R Ksantini et al 2012 [73], Eslam Hamouda, et al 2021[47], Syed Muhammad Saqlain, et al 2019 [51], Jianbin Ma, et al 2019 [63], and Min Gan, et al 2021[74], and Peiyang Li, et al 2018 [75].

IV. Results and Discussion

A. Comparison of Feature Quality Before and After Transformation

The success of feature transformation is measured by comparing the quality of features before and after transformation. This research uses eight widely used feature quality measurement methods.

1) Fisher score: Since class separability is the basis for transforming features in this research, the higher the Fs, the better the feature quality. Fig. 2 presents the Fs of each feature from the d-3 (Ringnorm) dataset consisting of 20 features before and after transformation. As shown in Fig. 2, the Box-Cox and Quadratic transformations produce features with larger Fs than the original features, and the quadratic transformation produces better Fs improvement than the Box-Cox transformation on all features. Except for d-6 and d-9 datasets, the superiority of the quadratic transformation also occurs in other datasets, namely superiority in 41 out of 60 features, 25 out of 30 features, 3 out of 5 features, 9 out of 9 features, 8 out of 11 features, 38 out of 60 features, 37 out of 44 features, and 4 out of 4 features, respectively for d-1, d-2, d-4, d-5, d-7, d-8, d-10, and d-11. For the d-6 dataset of 22 features, the quadratic transform outperforms the Box-Cox in 11 features and vice versa in the other 11 features. For dataset d-9, the Box-Cox transform outperformed the quadratic transform for all features. In general, the quadratic transform produces more features with higher Fs for the whole dataset.

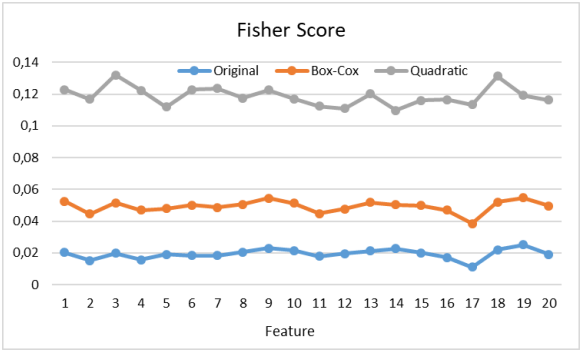

Fig. 2. Comparison of fisher score for d-3 (Ringnorm) dataset.

2) Information gain: Information Gain measurements for all datasets show that the Box-Cox transformation does not change the information gain value, meaning that the Box-Cox transformation does not increase the information gain value. On the other hand, except for datasets d-9 and d-11, the quadratic transformation generally produces features with greater information gain values, although this is not the case for every feature. Fig. 3 presents the information gain value of each feature for the d-3 (Ringnorm) dataset, which consists of 20 features. The increase in information gain in this dataset is observed for all features. An extreme case occurs in datasets d-9 and d-11, where the quadratic transformation does not increase the information gain value of each feature.

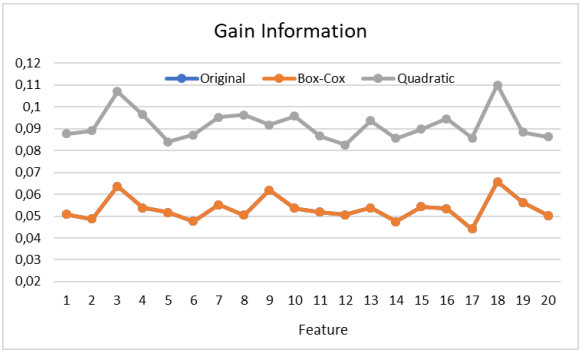

Fig. 3. Comparison of gain information for d-3 (Ringnorm) dataset.

3) Gain ratio: The Gain Ratio measurement shows similar results to the Information Gain, where the Box-Cox transformation does not change the Gain Ratio value. Except for d-9 and d-11 datasets that did not experience an increase in gain ratio in all features, the quadratic transformation generally increased the gain ratio value of a number of features in other datasets. The number of features that have

increased gain ratio values is different for each dataset, namely 29 out of 60, 13 out of 30, 20 out of 20, 2 out of 5, 4 out of 9, 8 out of 22, 3 out of 11, 15 out of 60, 18 out of 44 features, respectively for datasets d-1, d-2, d-3, d-4, d-5, d-6, d-7, d-8, d-10. Fig. 4 presents the Gain Ratio value of each feature for dataset d-3 (Ringnorm). It can be seen that the quadratic transformation increases the gain ratio of each feature.

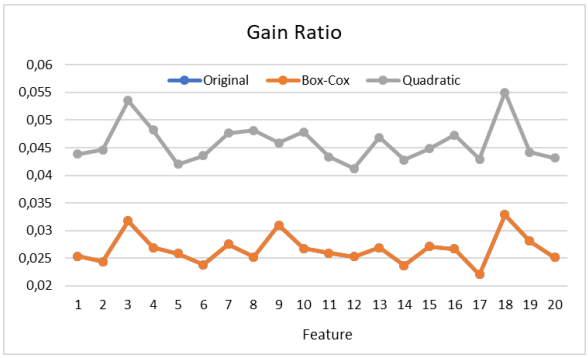

Fig. 4. Comparison of gain ratio for d-3 (Ringnorm) dataset.

4) Gini decrease: The Gini decrease measurement shows similar results to the Information Gain and Gain ratio, where the Box-Cox transformation does not change the Gini decrease value. Except for d-9 and d-11 datasets that did not experience an increase in gain ratio across all features, the quadratic transformation generally increased the Gini decrease value of a number of features in the other datasets. The number of features that have increased gain ratio values is different for each dataset, namely 27 out of 60, 13 out of 30, 20 out of 20, 2 out of 5, 5 out of 9, 9 out of 22, 5 out of 11, 15 out of 60, 17 out of 44 features, respectively for datasets d-1, d-2, d-3, d-4, d-5, d-6, d-7, d-8, d-10. Fig. 5 presents the Gini decrease value of each feature for dataset d-3 (Ringnorm). It can be seen that the quadratic transformation results in an increase in Gini decrease for all features.

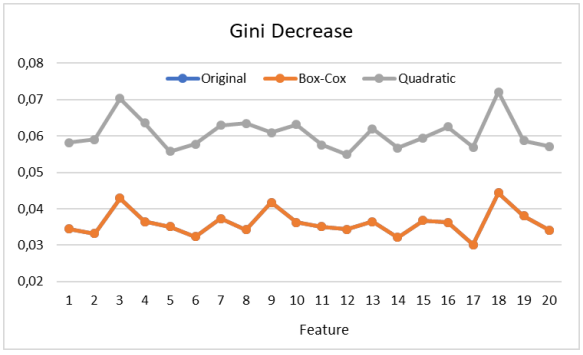

Fig. 5. Comparison of gini decreases for d-3 (Ringnorm) dataset.

5) Analysis of Variance (ANOVA): Except for the Hungarian and Balance datasets, ANOVA measurements show that the Box-Cox transformation improves most of the features in most datasets. The improvement in ANOVA values by Box-Cox transformation occurs in 58 out of 60, 25 out of 30, 20 out of 20, 3 out of 5, 7 out of 9, 19 out of 22, 60 out of 60, 31 out of 44, 4 out of 4 features for datasets d-1, d-2, d-3, d-4, d-5, d-6, d-8, d-10, d-11 respectively. The quadratic transformation gives slightly better ANOVA measurement results than the Box-Cox transformation. Except for dataset d-7, most datasets have an increase in ANOVA values. Even an increase in ANOVA values in each feature is observed in datasets d-3, d-8, d-9, and d-11. In the other six datasets, the increase in ANOVA values occurred in 59 out of 60, 27 out of 30, 3 out of 5, 8 out of 9, 19 out of 22, 30 out of 44 features, for datasets d-1, d-2, d-4, d-5, d-6, d-10, respectively. Fig. 6 presents the ANOVA values of each feature for dataset d-3 (Ringnorm) before and after undergoing Box-Cox and Quadratic transformations. It can be seen that the Quadratic transformation generally improves the ANOVA value better than the Box-Cox transformation.

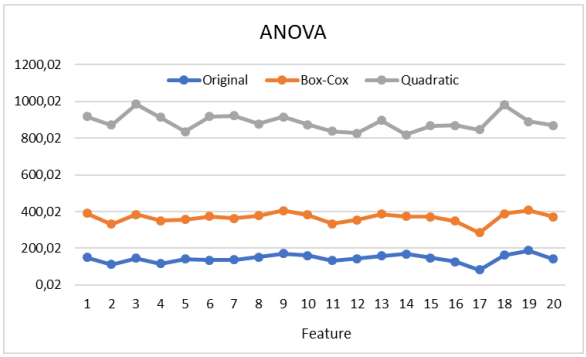

Fig. 6. Comparison of ANOVA for d-3 (Ringnorm) dataset.

6) Chi-Square: In Chi Square measurement in Box-Cox transformation, none of the features experienced changes in Chi Square value as produced by Information gain, Gain ratio, and Gini Decrease. For the quadratic transformation, except d-9 and d-11, the increase in Chi Square value occurred for 36 out of 60, 19 out of 30, 20 out of 20, 3 out of 5, 6 out of 9, 12 out of 22, 5 out of 11, 49 out of 60, 24 out of 44 features, respectively for datasets d-1, d-2, d-3, d-4, d-5, d-6, d-7, d-8, d-10. Fig. 7 presents the results of measuring the Chi-Square value of each feature for dataset d-3 (Ringnorm). It can be seen that the quadratic transformation results in an increase in the Chi-Square value of all features.

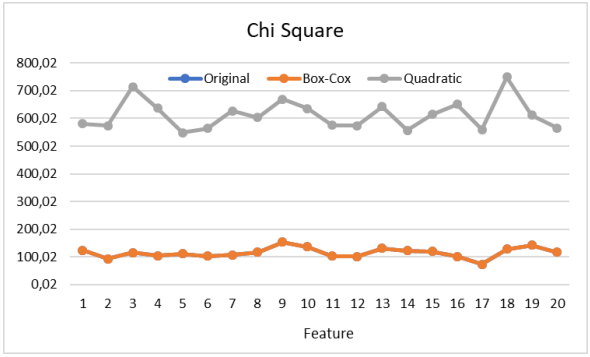

Fig. 7. Comparison of chi square for d-3 (Ringnorm) dataset.

7) ReliefF: Measurements using the ReliefF method provide varied results for both Box-Cox and Quadratic transformations, where in each dataset, features experience an increase in their ReliefF value. In Box-Cox transformation, the increase in reliefF value occurs in 35 out of 60, 28 out of 30, 2 out of 20, 3 out of 5, 8 out of 9, 19 out of 22, 4 out of 11, 29 out of 60, 2 out of 4, 25 out of 44, 3 out of 4 features, respectively for datasets d-1, d-2, d-4, d-5, d-6, d-7, d-8, d-9, d-10, d-11. The quadratic transformation generally gives slightly better ReliefF measurement results than the Box-Cox transformation. However, compared to the Box-Cox transformation, the number of features that have improved ReliefF values is less for datasets d-2, d-8, and d-10. However, the number of features that have improved ReliefF values is more in five datasets and the same in three other datasets. The increase in ReliefF value by Quadratic transformation occurs in 37 out of 60, 26 out of 30, 10 out of 20, 4 out of 5, 8 out of 9, 19 out of 22, 6 out of 11, 28 out of 60, 4 out of 4, 24 out of 44, 3 out of 4 features, respectively for datasets d-1, d-2, d-4, d-5, d-6, d-7, d-8, d-9, d-10, d-11. Fig. 8 presents the ReliefF value of each feature for dataset d-3 (Ringnorm) before and after undergoing Box-Cox and Quadratic transformations. On the d-3 dataset, the Quadratic transformation appears to increase the ReliefF value on ten features and decrease it on ten other features. In comparison, the Box-Cox transformation increases the ReliefF value on two features and decreases it on the other 18 features.

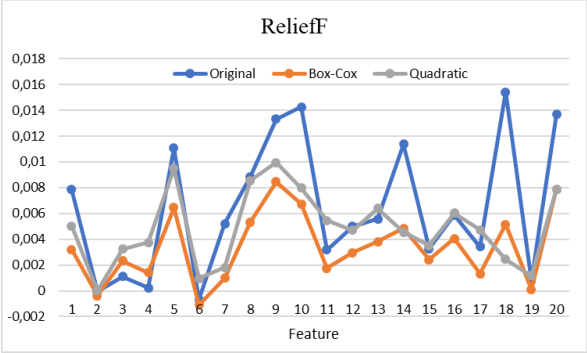

Fig. 8. Comparison of reliefF for d-3 (Ringnorm) dataset.

8) Fast Correlation Based Filter (FCBF): Measurement using FCBF gives very different results where Quadratic is better than Box-Cox regarding the number of features that have increased FCBF value. In quadratic transformation, out of 11 datasets, there are 10 datasets whose number of features has increased, where the increase in FCBF value occurs in 28 out of 60, 13 out of 30, 20 out of 20, 2 out of 5, 8 out of 9, 8 out of 22, 9 out of 11, 20 out of 60, 20 out of 44, 3 out of 4 features, respectively for datasets d-1, d-2, d-3, d-4, d-5, d-6, d-7, d-8, d-10, d-11. Except for datasets d-3, d-7, and d-11, the FCBF value from Box-Cox transformation has slightly increased in the other 8 datasets. The increase occurs in 2 out of 60, 3 out of 30, 3 out of 5, 1 out of 9, 2 out of 22, 2 out of 60, 4 out of 4, 1 out of 44 features, respectively, for datasets d-1, d-2, d-4, d-5, d-6, d-8, d-10. Fig. 9 presents the measurement results of each feature on dataset d-3 (Ringnorm), where all features have increased from 20 features.

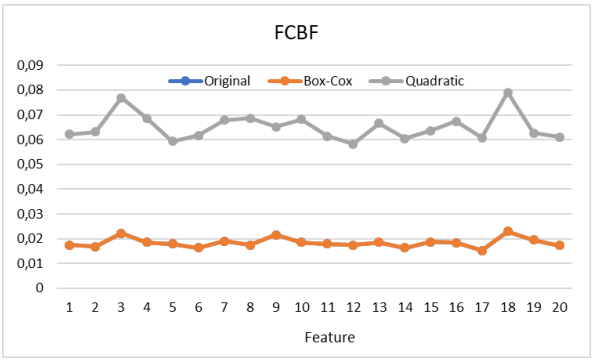

Fig. 9. Comparison of FCBF for d-3 (Ringnorm) dataset.

B. *Effects of Quadratic and Box-Cox Transformations on ML Performance*

This study uses two statistical-based machine learning algorithms, LDA and QDA. The performance results of each algorithm are presented in Tables II and III. Table II shows the comparison of LDA accuracy performance before and after Box-Cox and Quadratic transformations on 11 datasets. Experimental results on all datasets before and after quadratic transformation show an increase in accuracy performance. The highest increase in accuracy occurred on the Hayes Roth dataset, which was 0.268, and the lowest occurred on the Wisconsin dataset, which was 0.015. Experimental results on all datasets before and after the Box-Cox transformation also experienced an increase in accuracy performance. The highest increase in accuracy of 0.115 occurred on the Ringnorm dataset, and the lowest occurred on the WDBC dataset of 0.002. Compared to Box-Cox, Quadratic transformation generally produces a more significant increase in accuracy, ranging from 1.56% to 49.26%.

TABLE II. COMPARISON OF ACCURACY ALGORITHMS LDA BEFORE AND AFTER BOX-COX AND QUADRATIC TRANSFORMATION

dataset	Original	Box-Cox	Quadratic
Sonar	0.751	0.785	**0.834**
WDBC	0.956	0.958	**0.974**
Ringnorm	0.763	0.878	**0.941**
New Thyroid	0.934	0.939	**0.954**
Wisconsin	0.959	0.972	**0.974**
Parkinson	0.883	0.898	**0.908**
Hungarian	0.830	0.840	**0.848**
Splice	0.804	0.856	**0.884**
Balance	0.864	0.874	**0.912**
Spectf	0.746	0.765	**0.780**
Hayes Roth	0.544	0.606	**0.812**

Table III shows the comparison of QDA accuracy performance before and after Box-Cox and Quadratic transformations. Except for Ringnorm and Spectf datasets, where the accuracy is more or less the same, quadratic transformation improves QDA accuracy for all datasets. In comparison, Box-Cox transformation increases the accuracy on

seven datasets and decreases the accuracy on four datasets, namely Ringnorm, Balance, Spectf, and Hayes Roth. In general, both Box-Cox and Quadratic transformations improve accuracy on most datasets, whereas quadratic transformation improves accuracy on more datasets. Concurrent improvement in accuracy by Box-Cox and Quadratic transformations was observed in seven datasets, namely Sonar, WDBC, New Thyroid, Wisconsin, Parkinson, Hungarian, and Splice. On the Balance, Spectf, and Hayes-roth datasets, the Box-Cox transformation is shown to decrease accuracy, while the Quadratic transformation increases accuracy.

TABLE III. COMPARISON OF ACCURACY ALGORITHMS QDA BEFORE AND AFTER BOX-COX AND QUADRATIC TRANSFORMATION

dataset	Original	Box-Cox	Quadratic
Sonar	0.779	0.809	**0.818**
WDBC	0.956	0.961	**0.965**
Ringnorm	**0.979**	0.964	0.971
New Thyroid	0.967	0.985	**0.986**
Wisconsin	0.958	**0.972**	0.968
Parkinson	0.882	0.918	**0.923**
Hungarian	0.825	0.838	**0.844**
Splice	0.846	0.859	**0.889**
Balance	0.918	0.837	**0.963**
Spectf	**0.794**	0.791	**0.794**
Hayes Roth	0.649	0.609	**0.837**

C. Performance of LDA and QDA Based on Quadratic Transformation Compared to Other Methods

Table IV presents the performance comparison between LDA and QDA with methods from other researchers. It shows that the LDA algorithm in the 2nd column, six datasets have higher accuracy than other methods (OM) as listed in the 4th column of Table IV; they are Sonar, WDBC, Wisconsin, Parkinson, Hungarian, and Splice datasets. Compared to QDA, as shown in the 3rd column of Table 4, it indicates that QDA excels on seven datasets: Sonar, Ringnorm, New Thyroid, Parkinson, Splice, Balance, and Hayes Roth.

TABLE IV. COMPARISON OF THE OTHERS METHODS (OM) ACCURACY WITH QUADRATIC TRANSFORMATION

Dataset	LDA	QDA	OM
Sonar	**0.834**	0.818	0.768
WDBC	**0.974**	0.965	0.967
Ringnorm	0.941	**0.971**	0.953
New Thyroid	0.954	**0.986**	0.972
Wisconsin	**0.974**	0.968	0.970
Parkinson	0.908	**0.923**	0.862
Hungarian	**0.848**	0.844	0.845
Splice	0.884	**0.889**	0.868
Balance	0.912	**0.963**	0.939
Spectf	0.780	0.794	**0.827**
Hayes Roth	0.812	**0.837**	0.818

LDA and QDA outperformed other methods only on Sonar, Parkinson, and Splice datasets.

D. Discussion

The results of separability measurement using the Fisher score on each feature of the dataset before and after quadratic and Box-Cox transformation show that all features have increased separability. This result proves the success of the proposed method that aims to improve class separability. Compared to Box-Cox, the improvement in class separability of quadratic transformation is generally better. It happens because the quadratic transformation can change the order of the data that the Box-Cox does not have [20].

The results of measuring seven metrics show that the Box-Cox transformation cannot improve the quality of features in 4 matrices, namely Information gain, Gain ratio, Gini decrease, and Chi-Square. This finding indicates a relationship between transformations that do not change the order of the data and the ability of these transformations to improve the quality of the features of the four metrics above. This finding is reinforced by the results of the quadratic transformation on features that do not change the order of the data, where the feature quality also does not change. Thus, Box-Cox transformation is unsuitable for Information gain-based ML such as decision Tree and Random Fores. In contrast, quadratic transformation still has the opportunity to improve ML performance.

The quadratic transformation has been shown to improve separability, which in turn improves the performance of the LDA and QDA algorithms. Although the performance improvement varies for each dataset and algorithm used, it shows that the dataset's characteristics play a role. Likewise, the algorithm used where LDA provides a significant increase in accuracy compared to the QDA algorithm. It shows that the linear ML algorithm has an advantage over the QDA algorithm.

The quadratic transformation can work like the Box-Cox transformation in terms of transforming features to be more linearly separable between data groups, as shown by Bicego and Baldo. In some instances, the quadratic transformation can change the order of the data, which helps handle bimodal features, which Box-Cox lacks. The closed-form formulation to obtain the optimal quadratic parameters can be determined deterministically, whereas in Box-cox the optimal parameters are determined using Maximum Likelihood (MLE) or Grid search [14], [21]. It is clear that the computation time of the quadratic transform is more efficient.

Our research supports the findings of Bicego and Baldo that accuracy performance is more related to class separability than Gaussianity. We emphasize that from experimental results, using the quadratic transform where the separability effect is higher than Box-Cox also results in better accuracy. This result adds to the finding that Baldo's statement applies not only to the Box-Cox transform but also to the quadratic transform.

Based on the experimental results, we recommend the following for future research, namely:

- Quadratic transformation can detect the presence of bimodal distributed features by measuring the degree of change in the fisher score of features before and after

transformation. However, it needs to be researched more deeply on how much the right level of change is.

- Quadratic transformation can improve the Fisher score's ability to assess informative features.
- Overlapping features have a low Fisher score value. If this feature is transformed using a quadratic function, the new feature formed will also has a low Fisher score.
- Informative features with a high fisher score, when transformed using a quadratic function, the Fs value will not experience significant changes.

V. CONCLUSION

Feature engineering through quadratic transformation can be used to improve class separability. It can also be used to transform bimodal distributed data into unimodal. Unimodal features have a better fisher score than bimodal features, so if the dataset contains unimodal features, it can improve the performance of the ML algorithm. The proposed feature transformation method can improve the feature's fisher score and seven feature quality test metrics, i.e, Information Gain, Gen ratio, Gini Decrease, ANOVA, Chi-Square, ReliefF, and FCBF. Experimental results on 11 datasets using ML algorithms, namely LDA and QDA, show that feature transformation using quadratic functions can significantly improve the accuracy performance of ML algorithms.

Detecting Data Poisoning Attacks using Federated Learning with Deep Neural Networks: An Empirical Study

Hatim Alsuwat
Department of Computer Science, College of Computers and Information Systems
Umm Al-Qura University, Makkah, Saudi Arabia

***Abstract*—The advent of intelligent networks powered by machine learning (ML) methods over the past few years has dramatically facilitated various facets of human lives, including healthcare, transportation, and entertainment. However, the use of ML in intelligent networks raises serious concerns about privacy and security, particularly in the context of data poisoning attacks. In order to address these concerns, this research paper presents a novel technique for detecting data poisoning attacks in intelligent networks, focusing on addressing privacy and security concerns associated with the use of machine learning (ML) methods. The research combines federated learning and deep learning approaches to analyze network data in a distributed and privacy-preserving manner. The technique employs a federated neural network to identify malicious data by analyzing network traffic, leveraging the power of Bayesian convolutional neural networks for efficient and accurate detection. The research follows an empirical approach, conducting experimental analyses to evaluate the proposed technique's effectiveness in terms of network security and data classification. The results demonstrate significant performance, including high throughput, quality of service, transmission rate, and low root mean square error for network security. Furthermore, the technique achieves impressive accuracy, recall, precision and malicious data analysis for data detection. The findings of this research contribute to enhancing the security and integrity of intelligent networks, benefiting various stakeholders, including network administrators, data privacy advocates, and users relying on secure network communication.**

***Keywords*—Poisoning attacks; deep learning; network security; data classification; malicious data**

I. Introduction

In recent years, the widespread use of systems and the data they generate has increased significantly, thanks to rapid advancements in technology [1]. This has led to a surge in the velocity at which data is produced, enabling systems to access and utilize it without requiring detailed programming. As an application of artificial intelligence, machine learning (ML) techniques enable systems to produce meaningful results by learning data on their own [2]. These techniques are extensively applied in cybersecurity, where they are used to identify malware, malicious network traffic, and improper system behavior [3]. Commercial products, such as Exabeam, Fortscale, and E8 Security, leverage these and related ML techniques for cybersecurity.

However, to bypass such detection systems and compromise the security of critical areas by exploiting flaws in ML methodologies, attackers have resorted to deploying adversarial ML techniques. Adversarial ML is a strategy employed in the field of ML that aims to deceive methods using nefarious input in either training or decision-making time.

When building a machine learning algorithm, the first step is to collect data, such as a set of images for developing computer vision applications. Ideally, this data should be collected and labeled in a controlled and secure environment [4]. However, this is a time-consuming and costly operation that not all organizations and individuals can afford. Therefore, they sometimes collect data from the Internet or other untrusted sources. For example, when building security systems, users may download labeled data from external vendors, such as VirusTotal, for malware data annotation.

However, applying ML in Internet of Things (IoT) environments poses unique security challenges, as attackers may tamper with sensors and modify the training data. A poisoning attack, also known as a targeted misclassification or bad behavior assault, allows adversaries to significantly reduce overall performance, introduce backdoors and neural Trojans, and cause targeted misclassification or bad behavior [5].

The study of how adversarial approaches could exploit ML algorithms and the development of effective defenses against their exposure led to the creation of the discipline of adversarial machine learning (AML). AML has been extensively researched in various disciplines, including intrusion detection and picture categorization. However, IoT systems have not been thoroughly studied in this regard.

Although the prevalence of data-driven applications and our growing reliance on networked systems have many advantages, they have also raised serious security concerns [6]. Data poisoning attacks, in which malicious actors inject harmful data into the system to manipulate its behavior and compromise its performance, are a serious security risk. These attacks have the potential to have devastating effects, including incorrect decisions, privacy breaches, and possibly catastrophic outcomes in crucial systems like those that control finance, healthcare, and industry. Effective detection and mitigation of data poisoning attacks may not be possible with current security measures and data classification techniques. Furthermore, since sensitive data is frequently made available

to a single entity or server, centralized approaches to data analysis raise privacy issues. There is a growing interest in investigating decentralized and privacy-preserving techniques, like federated learning, which enables local data analysis while aggregating knowledge globally, to address these problems.

The main goal of this paper is to suggest a novel method for detecting data poisoning attacks with a focus on classifying malicious data using federated and deep learning techniques. The goal of the paper is to tackle the problem of spotting and countering malicious activity in networked systems while protecting data security and privacy. The proposed method enables decentralized data analysis and guarantees that sensitive data is stored and protected locally by using federated learning and a federated adversarial neural network. The analysis of harmful network data is further improved by using BCNN, producing more precise and trustworthy results.

The major contributions of this research study are as follows:

- The study suggests a novel method for identifying data poisoning attacks that focuses on the classification of malicious data. The suggested approach improves the capacity to recognize and counteract malicious activities within the network by utilizing federated and deep learning techniques.
- To analyze network data, spread across various participants, the research introduces the use of a federated adversarial neural network. With this strategy, sensitive information is stored locally, privacy is maintained, and effective analysis of malicious activity is still possible.
- The analyzed data is collected and processed using a cloud module. This federated learning system's participants can communicate with each other easily thanks to the cloud-based approach's efficient data handling.
- In this study, harmful network data is analyzed using a BCNN. The ability of BCNNs to capture model parameter uncertainty allows for more accurate analysis and classification of malicious data.
- The research makes use of real-world datasets, such as the Duchenne Smile Dataset, Product Dataset, and Sentiment Dataset, to show the effectiveness of the suggested attack approach.

The proposed method was chosen based on the distinct advantages of combining federated learning and deep learning approaches for effectively detecting data poisoning attacks in intelligent networks.

Acknowledging the limitations of existing methods in addressing data poisoning attacks in intelligent networks, such as scalability and sensitivity to biased data distributions, emphasizes the need for our proposed approach. By overcoming these constraints, our method offers a compelling alternative to enhance the effectiveness of detecting and mitigating such attacks.

The rest of this paper is organized into four sections. In Section II, we provide a comprehensive review of the existing literature, focusing on data poisoning attacks and their detection. Section III describes the system model used in this research and the architecture of our proposed technique. Section IV presents the results of our experimental analysis, which evaluates the effectiveness of our proposed technique. Finally, in Section V, we summarize our research and its contributions, discuss the implications of our findings, and identify areas for future work.

II. Literature Review

In recent years, the potential threats posed by adversarial machine learning (AML) have been widely studied by researchers. In this section, we provide a comprehensive review of the existing literature on data poisoning attacks and their detection techniques in machine learning.

In the realm of machine learning applications, the data generated for training and testing models is susceptible to manipulation by malicious actors who can gain control over a multitude of devices [7]. Biggio et al. [8] conducted the first systematic poisoning assault against the linear regression method by taking control of many devices, and introduced the TRIM algorithm, which is a more potent method than conventional methods for identifying poisoning spots on training data. Khalid et al. [9] highlighted potential AML attacks and training data poisoning risks, and provided examples of these assaults, including a less damaging training data poisoning attack. The study in [10] proposed a data poisoning attack that modifies labels of labeled data and affects machine learning systems' capacity to categorize data. To guarantee label clearing against this assault, they then put forth a defense method based on the k-nearest neighbors (K-NN) algorithm.

Adversarial attacks are a critical threat to the integrity of machine learning models, and adversaries can manipulate the data generated for these applications by commandeering multiple devices [11]. Within this context, the TRIM algorithm proposed in [12] has been shown to be a more effective and powerful technique for identifying poisoning points in training data, and it was the first systematic attack against the linear regression method. In [13], the author identified potential adversarial machine learning (AML) attacks and risks associated with training data poisoning, including a less harmful attack on training data. Additionally, [14] described a data poisoning attack that modifies the labels of labeled data and impairs the ability of machine learning systems to classify data. To combat this attack, the authors proposed a defense method based on the k-nearest neighbors (K-NN) algorithm. It is highly improbable for training data to represent all possible scenarios, and "adversarial areas" near the decision boundary are particularly vulnerable locations for machine learning models. As a result, adversaries may use trial and error or reverse engineering to uncover "adversarial samples" that are not covered by the training data. Indeed, adversaries can use trial and error or reverse engineering to uncover "adversarial samples" and deceive the model, endangering its integrity. These evasion attacks are experimental and frequently used [15]. For instance, creator [16] utilized a generative network

called Malware-GAN to make ill-disposed malware samples for a black-box classifier, causing the classifier to fail after the assault.

An attack is viewed as causal when an attacker approaches training data and is allowed to harm it. The author in [17] showed that a peculiarity identification strategy on network traffic that had been polluted by refuse traffic infusion enhanced the bogus negative rate to 28 percent for single preparation period harming and to more than 70% for multi-preparing period harming. They also presented a cure strategy that can reject harmful preparation information and is less vulnerable to exceptions for extensive inconsistency detection. The study in [18] proposed the RONI safeguard strategy, which was effective, but had limitations in that it must be tested and trained on spam email data. Furthermore, it could potentially dispose of important information from training data, requiring further examination.

The authors in [19] endeavored to address a limitation that had been encountered by several previous studies. In addition, the authors in [20] proposed a detrimental attack that has the potential to bypass current safeguards with ease. The attack was subjected to testing against a range of hypothetical adversaries, providing valuable insights into its efficacy. The study in[21] also suggested a detrimental attack that utilizes a generative approach to expedite the generation of manipulated data by leveraging the gradient of the model. These advances in adversarial machine learning highlight the urgent need for developing more robust and effective techniques to detect and mitigate these attacks.

In the literature, several studies have proposed techniques to detect data poisoning attacks and other adversarial attacks in machine learning. Data poisoning attack detection tools currently available have some drawbacks and restrictions. Some defense strategies, such as the K-NN algorithm, aren't robust enough to handle complex data poisoning attacks, leaving room for attackers to get around these strategies and successfully poison the training data. When used on contaminated training data, some detection techniques may produce a high percentage of false negatives, failing to accurately detect some cases of data poisoning. Additionally, some current solutions might be effective against the kinds of attacks but fall short when faced with fresh or unexpected attack patterns, which restricts their applicability in real-world situations. Additionally, some proposed techniques are less applicable to a variety of real-world datasets because they rely on data for testing and training, such as spam email data. Additionally, some techniques are impractical for use in real-world applications because of their inability to scale effectively to large datasets or distributed environments. Additionally, although BCNNs demonstrate promise in capturing uncertainty and identifying adversarial samples, their ability to estimate uncertainty may not be accurate enough to defend against all possible data poisoning attacks. Finally, the limited collaborative defense mechanisms used in current methods fail to fully capitalize on the benefits of federated learning and distributed learning for improved detection. Together, these flaws highlight the need for a more thorough and potent method to deal with the constraints imposed on current solutions. The proposed method integrates federated learning, adversarial neural networks, and BCNNs to close this research gap. It hopes to accomplish this by developing a more reliable and scalable method of identifying data poisoning attacks. The proposed method seeks to improve the defense against data poisoning attacks through careful experimental analysis, ultimately advancing the field of adversarial machine learning research.

III. System Model

This section presents a novel technique for detecting data poisoning attacks based on federated and deep learning techniques. The overview of the proposed approach is shown in Fig. 1. By randomly flipping labels in a section of the training dataset, the data poisoning process creates poisoned datasets with varying poisoning rates that include both legitimate and adversarial samples. The method uses an adversarial neural network integrated with a federated learning approach to counter these poisoning attacks. Participants (clients) in this collaborative setting use local datasets to jointly train a global model. As a result of the inclusion of adversarial elements in the learning process, the model is better equipped to fend off poisoning attacks during the federated learning procedure. To further improve model robustness, the proposed technique makes use of BCNNs. The ability of BCNNs to capture prediction uncertainty allows for more accurate detection of potential adversarial samples. Each of the poisoned datasets is used to train a separate BCNN during the phase of model training and evaluation. The effectiveness of both the global model and the BCNNs is then evaluated using results from a shared test dataset. Analyzing the BCNN predictions' levels of uncertainty on the test dataset is a step in the process of detecting data poisoning attacks. The method effectively identifies potential data poisoning attacks by establishing an uncertainty threshold. The detailed description of each step of the proposed approach is presented in the subsequent subsections.

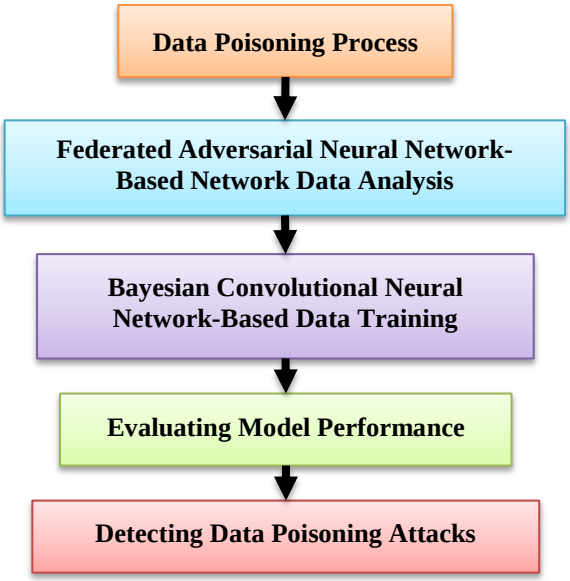

Fig. 1. Overview of the proposed approach.

A. Data Poisoning Process

To simulate the information poisoning attack on data classes, training datasets were created. To prevent a bias towards poisoning a significant amount of either normal data or attack data, normal observations were randomly selected, and most of the normal traffic observations were pooled. After randomizing the data, a Python script was used to determine the number of labels to flip based on a specified rate. To demonstrate the impact of data poisoning on classifiers, the data was poisoned at four rates (rpoison), as outlined in Algorithm 1.

Algorithm 1: Data Poisoning Process

Input: Sanitized Training Dataset (D^5)
Output: Poisoned Training Datasets $\left(D_5^P, D_{10}^P, D_{20}^{P_2}, D_{30}^P\right)$
Steps:
Randomise D^5 observations should not be biased by poisoning either normal or attack observations.
For every rate rpoison of data poisoning [0.05,0.1,0.2,0.3]
Evaluate a number of labels to flip Lpoison=D5*rpoison
Flip Lpoison labels within Ds
End for
Return poisoned training datasets $D_5^P, D_{10}^P, D_{15}^P, D_{30}^P$

B. Federated Adversarial Neural Network-based Network Data Analysis

Participants in federated learning may not always have the same learning objectives or method structures. The central server sends the most recent global model parameters to the chosen participants (mt) at the beginning of each communication round. Then, using the relevant local data, these participants go on to update and train their local models. Each participant uploads their updated model to the central server following the local training process. The central server then averages the models that were uploaded and incorporates the resulting information into the central model. This update procedure is implemented as shown in Eq. (1), ensuring that the central model gains from the group learning of all participants while maintaining the security and privacy of the data. The federated learning approach is a flexible and strong framework that can be applied to various scenarios because it allows participants to maintain their individuality when defining their learning objectives and selecting the best method structures.

$$M_{t+1} = M_t + \frac{1}{m_t}\sum_{k=1}^{m_t} u_t^k \tag{1}$$

In Eq. (1), u_t^k represents the method updates submitted by the k^{th} participant, and Mt represents the current global method at the t^{th} iteration. A federated learning system can achieve high accuracy when users download the same method with the same initialization, which is averaged by the central method with all valid uploads. We now introduce a new method, presented in Eq. (2), for training supervised federated learning models.

$$f(x) := \frac{1}{n}\sum_{i=1}^{n} f_i(x_i), \psi(x) := \frac{1}{2n}\sum_{i=1}^{n} \|x_i - \bar{x}\|^2 \tag{2}$$

where, $\lambda \geq 0$ is a penalty specification, $x := (x_1, x_2, \dots, x_n) \in \mathbb{R}^{nd}$ are local methods, and $x := \frac{1}{n}\sum_{i=1}^{n} \bar{x}_i$ is average of local methods. Since Eq. (2) has a unique solution, which we designate by Eq. (3), F is strongly convex due to assumptions on fi that we will make.

Here in Eq. (2), $\lambda \geq 0$ is a penalty specification, $x := (x_1, x_2, \dots, x_n) \in \mathbb{R}^{nd}$ represents the local methods, and $x := \frac{1}{n}\sum_{i=1}^{n} \bar{x}_i$ is the average of the local methods. Since Eq. (2) has a unique solution, which we designate as Eq. (3), F is strongly convex due to the assumptions we make on fi.

$$x(\lambda) := (x_1(\lambda), \dots, x_n(\lambda)) \in \mathbb{R}^{\mathrm{nd}} \tag{3}$$

We further let $\bar{x}(\lambda) := \frac{1}{n}\sum_{i=1}^{n} x_i(\lambda)$. We now provide a statement regarding the new formulation's justification. Let's now examine the limit case $\lambda \to \infty$. The ideal local models should be forced to be mutually identical by this limit case while minimising the loss f, according to intuition. This limit situation will specifically be solved using Eq. (4).

We also define $\bar{x}(\lambda) := \frac{1}{n}\sum_{i=1}^{n} x_i(\lambda)$. We now provide a statement regarding the justification for the new formulation. Let us consider the limit case $\lambda \to \infty$. In this limit, the ideal local models should be forced to be identical to each other while minimizing the loss function f, according to intuition. This limit situation is specifically solved using Eq. (4).

$$\min\{f(x): x_1, \dots, x_n \in \mathbb{R}^d, x_1 = x_2 = \cdots = x_n\} \tag{4}$$

Eq. (4) is the equivalent global formulation. Therefore, we define xi(∞) as the optimal solution to Eq. (4) for each i, and let x(∞) := (x1(∞), . . . , xn(∞)).

For vectors $x = (x_1, \dots, x_n) \in \mathbb{R}^{nd}$ and $y = (y_1, \dots, y_n) \in \mathbb{R}^{nd}$, we define the standard inner product and norm as follows: $\langle x, y\rangle := \sum_{i=1}^{n} \langle x_i, y_i\rangle, \| x \|^2 := \sum_{i=1}^{n} \|x_i\|^2$. Note that the separable structure of f implies that $((\nabla f(x))_i = \frac{1}{n}\nabla f_i(x_i))$, i.e., $\nabla f(x) = \frac{1}{n}\left(\nabla f_1(x_1), \nabla f_2(x_2), \dots, \nabla f_n(x_n)\right)$.

Furthermore, note that f is L_f-smooth with with $L_f := \frac{L}{n}$ and μ_f-strongly convex with $\mu_f := \frac{n}{n}$. Clearly, ψ is convex by construction, and it is given that ψ is L_ψ-smooth with $L_\psi = \frac{1}{n}$. We can observe that $(\nabla\psi(x))_i = \frac{1}{n}(x_i - \bar{x})$, which, in turn, implies by Eq. (5), (6), and (7).

$$\psi(x) = \frac{n}{2}\sum_{i=1}^{n} \|(\nabla\psi(x))_i\|^2 = \frac{n}{2} \| \nabla\psi(x) \|^2 \tag{5}$$

$$\psi(x(\lambda)) \leq \frac{f(x(\infty)) - f(x(0))}{\lambda} \tag{6}$$

$$f(x(\lambda)) \leq f(x(\infty)) \tag{7}$$

For every $\lambda > 0$ and $1 \leq I \leq n$, we have by (8):

$$x_i(\lambda) = \bar{x}(\lambda) - \frac{1}{\lambda}\nabla f_i(x_i(\lambda)) \tag{8}$$

We have $\sum_{i=1}^{n} \nabla f_i(x_i(\lambda)) = 0$. By subtracting a multiple of the local gradient from the average model, the best local models Eq. (5) can be obtained. Note that at optimality, the local gradients always add up to zero. This is clearly true for $\lambda = 0$, but it is less clear that this is true for $\lambda = \infty$, or for any $\lambda > 0$.

Let P(z):=$\frac{1}{n}\sum_{i=1}^{n} f_i(z)$. Then, according to Eq. (9), x(∞) is the unique minimizer of P.

$$\| \nabla P(\bar{x}(\lambda)) \|^2 \leq \frac{2L^2}{\lambda}(f(x(\infty)) - f(x(0))) \quad (9)$$

If α ⩽ 2L , we then by (10) have the following.

$$\mathbb{E}\left[\|x^k - x(\lambda)\|^2\right] \leq \left(1 - \frac{\alpha\mu}{n}\right)^k \|x^0 - x(\lambda)\|^2 + \frac{2na\sigma^2}{\mu} \quad (10)$$

where, $\mathcal{L} := \frac{1}{n}\max\left\{\frac{L}{1-p}, \frac{\lambda}{p}\right\}$ and by (11), we have the following.

$$\sigma^2 := \frac{1}{n^2}\sum_{i=1}^{n}\begin{pmatrix} \frac{1}{1-p}\|\nabla f_i(x_i(\lambda))\|^2 \\ +\frac{\lambda^2}{p}\|x_i(\lambda) - \bar{x}(\lambda)\|^2 \end{pmatrix} \quad (11)$$

Let us determine the values of p and α that lead to the fastest rate for pushing the error within a $\left(\mathcal{O}(\varepsilon) + \frac{2na\sigma^2}{\mu}\right)$ - neighborhood of the optimum. In other words, we aim to achieve Eq. (12).

$$\mathbb{E}\left[\|x^k - x(\lambda)\|^2\right] \leq \varepsilon\|x^0 - x(\lambda)\|^2 + \frac{2\mathrm{nn}\,\sigma^2}{\mu} \quad (12)$$

The parameter $p^* = \frac{\lambda}{L+\lambda}$ reduces the predicted number of communications for attaining as well as the number of repetitions. The optimal expected number of communications is $2\frac{L+\lambda}{\mu}\log\frac{1}{\varepsilon}$, while best number of iterations is $2\frac{L+\lambda}{\mu}\log\frac{1}{\varepsilon}$. We employ relativistic average discriminator D_{Ra} to render the output image virtually identical to the original. According to Eq. (13), the objective functions are as follows:

$$\begin{aligned} \mathcal{L}_{Ra,D} &= -\mathbb{E}_x[\log(D_{Ra}(x))] \\ &\quad - \mathbb{E}_{x,v,}[\log(1 - D_{Ra}(G(x,v,c)))] \\ \mathcal{L}_{Ra\_G} &= -\mathbb{E}_{x,0,\mathcal{C}}[\log(D_{Ra}(G(x,v,c)))] \\ &\quad - \mathbb{E}_x[\log(1 - D_{Ra}(x))] \\ D_{Ra}(x) &= \mathrm{sigmoid}\big(H(x) - \mathbb{E}_{x,v,c}[H(G(x,v,c))]\big) \\ D_{Ra}(G(x,v,c)) &= \mathrm{sigmoid}\begin{pmatrix} H\big(G(x,v,c)\big) \\ -\mathbb{E}_x[H(x)] \end{pmatrix} \end{aligned} \quad (13)$$

The parameter $p^* = \frac{\lambda}{L+\lambda}$ reduces the predicted number of communications required to achieve the desired accuracy, as well as the number of repetitions needed. The optimal expected number of communications is $2\frac{L+\lambda}{\mu}\log\frac{1}{\varepsilon}$, while the optimal number of iterations is $2\frac{L+\lambda}{\mu}\log\frac{1}{\varepsilon}$.

To make the output image virtually identical to the original, we employ the relativistic average discriminator D_{Ra} . According to Eq. (13), the objective functions are as follows:

The output of the non-changed layer is denoted as H(•). The probability that certifies the real image as genuine is higher than the probability that certifies the generated image as genuine. This can be improved by minimizing the loss function $\mathcal{L}_{Ra,D}$.

To further reduce the loss, we subject the generator to a cycle consistency loss, which is described by Eq. (14) as follows:

$$\mathcal{L}_{cyc} = \mathbb{E}_{x,v,c}[\| x - G(G(x,v,c),v,1-c) \|_1] \quad (14)$$

To identify the source of the image, we add a helper classifier called D_{ind} on top of the discriminator network. According to Eq. (15), the loss function for the image attribution model is as follows:

$$\begin{aligned} \mathcal{L}_{\text{ind}} = \\ -\mathbb{E}_{x,t}\big[\log\big(D_{\text{ind}}(t = 01 \mid x)\big)\big] - \quad \mathbb{E}_{x,v,c,t}\big[\log\big(D_{\text{ind}}(t = 01 \mid \\ G(x,v,c))\big)\big] \end{aligned} \quad (15)$$

The picture producing model fundamentally affects the unraveling organization (c) since it is a common organization, and picture interpretation strategy utilizes essentially less examples than the picture age model does. We integrate the accompanying matched antagonistic misfortune condition (16) to more likely guarantee the fitting of the picture interpretation model:

Since the image generation model is a shared network, it significantly affects the decoding network (c). Moreover, the image attribution method uses significantly fewer samples than the image generation model. To better ensure the fitting of the image attribution model, we integrate the following paired adversarial loss condition as shown in Eq. (16).

$$\begin{aligned} \mathcal{L}_{pis} = -\mathbb{E}_{x_0,x_v}\left[\log\left(D_{pis}(x_0,x_v)\right)\right] - \mathbb{E}_{x,v\mathcal{C}}\big[\log\big(1 - \\ D_{pis}(x,G(x,v,c))\big)\big] \end{aligned} \quad (16)$$

In this scenario, D_{pis} is used to determine if two images belong to the same class. Our objective is to translate x_0 into an output image y that contains variation v, for input image x_0 and action (v, c = 01). Moreover, our goal is to remove variation v from input image xv using the action (v, c = 10).

To achieve this, we add an additional classifier called D_{var} on top of the discriminator network to identify different types of image variations. The classification loss during training of the discriminator network is given by Eq. (17).

$$\mathcal{L}^r_{\text{var}} = -\mathbb{E}_{x,v}[\log(D_{var}(v \mid x))] \quad (17)$$

Discriminator network may categorize real image x into variant type v by minimizing formula. Classification loss during training the generator network is as shown in Eq. (18)

The discriminator network can categorize the real image x into variant type v by minimizing the formula mentioned above. The classification loss during training of the generator network is given by Eq. (18).

$$\mathcal{L}^f_{\text{var}} = -\mathbb{E}_{x,v,c}[\log(D_{var}(v \mid x))] \quad (18)$$

The first condition in Eq. (18) states that the image produced by adding variation v to the input image x_0 should be accurately classified into class v. The second condition states that the image produced by removing variation v from the paired image xv should be classified into class v.

The values of x_m range from 0 to 1. The following Eq. (19) can be used to obtain the final output image.

$$x_{\text{out}} = x + (x_t - x) \odot x_m \tag{19}$$

$\odot$ element-wise product is located. By using Eq. (20), we add the next restriction for the mask x_m:

$$\mathcal{L}_{\text{mask}} = \left(\frac{1}{W}\sum_k |x_m[k]|\right)^2 \tag{20}$$

Here, W represents the number of pixels, and $x_m[k]$ refers to the k^{th} pixel of x_m. The formula shown above encourages minimizing alterations to the source image. Based on the foregoing discussion, the overall loss of the image translation model is given by Eq. (21):

$$\mathcal{L}_D = \mathcal{L}_{\text{Ra\_}D} + \lambda_{\text{pis}}\mathcal{L}_{\text{pis}} + \lambda_{\text{var}}\mathcal{L}_{\text{var}}^r + \lambda_{\text{ind}}\mathcal{L}_{\text{ind}}$$
$$\mathcal{L}_G = \mathcal{L}_{Ra\_G} - \lambda_{pis}\mathcal{L}_{\text{pis}} + \lambda_{\text{cyc}}\mathcal{L}_{\text{cyc}} + \lambda_{\text{var}}\mathcal{L}_{\text{tar}}^f + \lambda_{\text{ind}}\mathcal{L}_{\text{ind}} + \lambda_{\text{mask}}\mathcal{L}_{\text{mask}} \tag{21}$$

The hyperparameters $\lambda_{\text{pis}}, \lambda_{\text{var}}, \lambda_{\text{ind}}, \lambda_{\text{cyc}}$, and λ_{mask} control the relative significance of each term in Eq. (21) as outlined in Algorithm 2.

Algorithm 2: FANN

Input: K clients are indexed by k, C is client fraction, the T communication rounds are indexed by t, B is local minibatch size, E is number of local epochs, and η is learning rate, PGD Attack $A_{s,\epsilon,\alpha}$: where s, ϵ, α are number of PGD steps, perturbation ball size, step size, r is the adversarial ratio, q is the scale factor.

Output: The global model θ.

On server

Initialize θ_0

For every round $t = 1,2, \ldots \ldots T$ do

$$m \leftarrow \max(1, CK)$$
$$S_t \leftarrow (random\ set\ of\ m\ clients)$$

For every client $k \in S_t$ in parallel do

$$\theta_{t+1}^k \leftarrow client\ update\ (k, \theta_t)$$

End for

$$\theta_{t+1}^k \leftarrow FedWAvg\ (\theta_t, \{\theta_{t+1}^k\} k \in S_t)$$

End for

Return θ_{t+1}

Client update (k,θ)

$$b_{nat} \leftarrow (set\ of\ B) - n_{adv} samples$$
$$b \leftarrow b_{bat} U b_{adv}$$

End for

End for

Return θ

C. Bayesian Convolutional Neural Network-based Data Training

BCNNs are a type of neural network that combines the CNN architecture and Bayesian inference principles to model uncertainty in deep learning tasks. In contrast to conventional CNNs, which provide point estimates of the model parameters, BCNNs estimate the model posterior distribution over the parameters, providing a principled method for dealing with model uncertainty. This feature is especially helpful when there is little or noisy data available, enabling more accurate predictions. BCNNs also allow for incorporating prior information and hypotheses, which can improve model performance in challenging real-world datasets. Additionally, BCNNs provide a natural method for model averaging, improving the generalizability of the model. In our work on identifying data poisoning attacks, BCNNs' uncertainty estimation is essential, as it can highlight areas of high ambiguity and possible adversarial inputs, resulting in a more accurate identification of such attacks.

Bayesian neural networks train a model by inferring the model posterior. However, accurate inference of the model posterior is computationally demanding, and even for moderately sized models, it can become intractable. Therefore, the model posterior is usually approximated. One popular and successful method for approximating the model posterior is variational inference. Fig. 2 provides an overview of the BCNN Architecture.

The BCNN architecture process is shown in Fig. 3. The "Start" symbol marks the beginning of the process at the top. Taking input data, which stand for the input set and the corresponding output set, respectively, is the first step. The next step in the flowchart is the "Feature Extraction" module. Utilizing techniques like convolution, non-linear transformations (relu), max-pooling, and local normalization, features are in this case extracted from the input data. The "Feature Selection" module is the next step in the flowchart after feature extraction. To further hone the extracted features, additional feature selection is carried out in this step using non-linear transformations (relu). The "Prediction" module is the next step in the process, where the final output probabilities are computed.

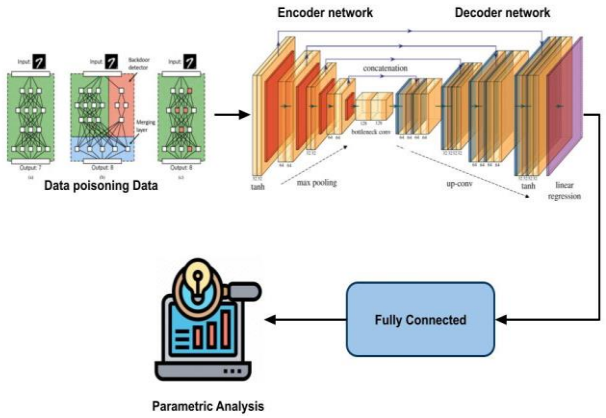

Fig. 2. Overview of the BCNN architecture.

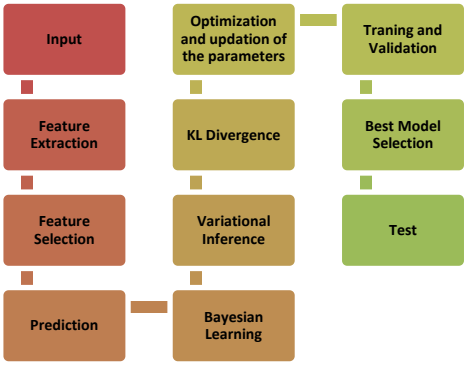

Fig. 3. Flowchart of BCNN architecture process.

The softmax operation provides a probability distribution for each output class C. The flowchart then moves to the "Bayesian Learning" phase, where variational inference is used to obtain the model posterior by approximating it with the variational distribution. The "KL Divergence" step computes the KL divergence, which is reduced through optimization of the model parameters W and b to increase the log evidence lower bound. The "Training and Validation" phase trains the model on the training set and assesses its performance on the validation set after each epoch. The "Best Model Selection" step chooses the model with the best validation performance. The "Test" step tests the chosen model on the test set to evaluate its final performance metrics. The "End" symbol marks the end of the process. The detailed process is presented in this section.

Given the input set $X = x_1, x_2, \ldots, x_N$ and the corresponding output set $y = y_1, y_2, \ldots, y_N$, the function $f(X) = y$ estimates the output y from the inputs X. Bayesian learning provides a principled approach to obtain the model posterior $p(f|X, y)$. To calculate the posterior, two components are required. First, a prior distribution $p(f)$ that captures a prior belief about the estimator functions. Second, a likelihood function $p(y|f, X)$ that indicates how likely it is for the model f to predict the output y given the observations X. More specifically, given an unseen data point $(x*, y*)$, the posterior is obtained by integrating over all possible estimator functions f that are parametric models with a parameter set θ, as shown in Eq. (22):

$$p(y^* \mid \mathrm{x}^*, \mathrm{X}, \mathrm{y}) = \int p(y^* \mid f)p(f \mid \mathrm{x}^*, \mathrm{X}, \mathrm{y})df = \int p(y^* \mid f)p(f \mid \mathrm{x}^*, \theta)p(\theta \mid \mathrm{X}, \mathrm{y})df d\theta \quad (22)$$

The integral in Eq. (22) is intractable because the distribution $p(\theta|X, y)$ is intractable. Therefore, the variational approach is to approximate $p(\theta|X, y)$ with a variational distribution $q(\theta)$. The candidate $q(\theta)$ should be as similar as possible to the original intractable distribution. The similarity between $p(\theta|X, y)$ and q(\theta) can be measured by the Kullback-Leibler (KL) divergence. Reducing the KL divergence is equivalent to increasing the log evidence lower bound based on the parameter set θ, as shown in Eq. (23):

$$\mathrm{KL}_{\mathrm{V1}} = q(\theta)p(F \mid \mathrm{X}, \theta)\log_p \int (\mathrm{y} \mid F)\, dF d\theta - \mathrm{KL}(q(\theta) \parallel p(\theta)) \quad (23)$$

Maximizing the KL divergence results in a variational distribution that approximates the posterior. The approximation $q(\theta)$ simplifies Eq. (23) to Eq. (24).

$$q(y^* \mid \mathrm{x}^*) = \int p(y^* \mid f)p(f \mid \mathrm{x}^*, \theta)q(\theta)df d\theta \quad (24)$$

During inference, the network parameters θ are sampled from $q(\theta)$. The feature extraction module at stage l, denoted as $g^{(l)}$, extracts the features $H^{(n)}$ as specified by Eq. (25).

$$H^{(n)} = g^{(l)}\left(H^{(l-1)}; W^{(l)}, b^{(l)}\right) = \text{normalize}\left(\text{pool}\left(\text{relu}\left(W^{(l)} * H^{(l-1)} + b^{(l)}\right)\right)\right) \quad (25)$$

The $*$ operator denotes convolution, which is one of the specific processes that go into feature extraction, along with non-linear transformations, max-pooling, and local normalization. After the convolution operation, a dot product is computed, which is followed by a non-linear transformation specified in Eq. (26) within the feature selection module f (l).

$$H^{(n)} = f^{(l)}\left(H^{(l-1)}; W^{(l)}, b^{(l)}\right) = \left(\text{relu}\left(W^{(l)} \cdot H^{(l-1)} + b^{(n)}\right)\right) \quad (26)$$

In Eq. (26), $H^{(l-1)}$ denotes the activation of the (l - 1) th hidden layer, and (.) denotes the dot product. To provide a probability distribution over every output class C, as represented in Eq. (27), the softmax operation is used as the final step in the prediction module.

$$p(C \mid X; W, b) = \text{softmax}\left(W^{(n)} \cdot H^{(l-1)} + b^{(n)}\right) \quad (27)$$

The DCNN model architecture is constructed by stacking the feature extraction, selection, and prediction modules, as shown in Eq. (28).

$$p(C \mid X; W, b) = \text{softmax}\left(f^{(5)}\left(f^{(4)}\left(g^{(3)}\left(g^{(2)}\left(g^{(1)}(X)\right)\right)\right)\right)\right) \quad (28)$$

During this optimization, local connections and weight sharing are implemented, resulting in a reduction in the number of parameters. Eq. (29) and Eq. (30) can be used to define 1-D and 2-D convolutional operations in a CNN, respectively:

$$\mathrm{o}_{i,k} = (\mathrm{x} * \mathrm{v})_{i,k} = \sum_{l,m} \mathrm{x}_{(i-1)s+m,l} \mathrm{V}_{m,l,k,} \quad (29)$$

$$\mathrm{O}_{i,j,k} = (\mathrm{X} * \mathrm{V})_{i,j,k} = \sum_{l,m,n} \mathrm{X}_{(i-1)s+m,(j-1)s+n,l} \mathrm{V}_{m,n,l,k} \quad (30)$$

In Eq. (29), x is the 1-D input, v is the convolutional kernel, and o is the output. Similarly, V and O are the corresponding kernel and output in Eq. (30), where X is the input of the 2-D convolutional operation. The number of data points skipped between two convolutional operations is referred to as the stride, denoted by s.

The data is split into training, validation, and test sets. The method is then trained on the training set, and after every epoch, the method is validated. After training, the model with the best validation kappa score is selected and evaluated on the test set.

Deep neural networks are capable of extracting features from raw input data. However, the quality and quantity of the training data are important requirements for achieving good performance. When the available data is limited, the network may not converge. In such cases, a pre-processing step can be applied to eliminate redundancy and reduce the feature dimensionality, which can help the network converge.

Consider a deep learning method with a model specification W. The training dataset consists of M samples, denoted as $S = (x1, y1), (x2, y2), (xM, yM)$, and so on. The model parameters are calculated using the Bayes formula, as shown in Eq. (31):

$$p(\mathrm{W} \mid \mathrm{S}) = \frac{p(\mathrm{S}|\mathrm{W})p(\mathrm{W})}{p(\mathrm{S})} = \frac{p(\mathrm{S}|\mathrm{W})p(\mathrm{W})}{\int_{\mathrm{W}} p(\mathrm{S}|\mathrm{W})p(\mathrm{W})\mathrm{dW}} \quad (31)$$

The prior distribution, denoted by $p(W)$, is based on an assumption, knowledge from the past, or experience. The likelihood function is $p(S|W)$, where $p(S)$ denotes the distribution of the training samples, and the predicted distribution of the model specification W is $p(W|S)$. However, the Bayes formula cannot be used directly to obtain the specification evaluation because it is challenging to calculate p(S). To address this issue, a new distribution, $q(W)$, is developed to approximate $p(\theta|S)$. The idea of Kullback-Leibler (KL) divergence can be used to calculate the difference between $q(W)$, and $p(W|S)$. Eq. (32) is used to express the KL divergence.

$$\begin{aligned} \mathrm{D_{KL}}\big(q(\theta) \parallel p(\theta \mid \mathrm{S})\big) &= \int_{\mathrm{W}} q(\mathrm{W}) \log \frac{q(\mathrm{W})}{p(\mathrm{WS})} \mathrm{dW} \\ &= \int_{\Theta} q(\mathrm{W}) \log \frac{q(\theta)\int_{\mathrm{W}} p(\mathrm{SW})p(\mathrm{W})\mathrm{dW}}{p(\mathrm{SW})p(\mathrm{W})} \mathrm{dW} \\ &= \int_{\Theta} q(\mathrm{W})p(\mathrm{S})\mathrm{dW} - \int_{\Theta} q(\mathrm{W}) \log \frac{p(\mathrm{SW})p(\theta)}{q(\mathrm{W})} \mathrm{dW} \quad (32) \end{aligned}$$

The goal of variational inference is to maximize the second term on the left-hand side of (33), which corresponds to $q(\theta)$, while minimizing the KL divergence.

$$\begin{aligned} q^*(\mathrm{W}) &= \underset{q(\mathrm{W})}{\operatorname{argmin}} \, \mathrm{DKL}\big(q(\mathrm{W}) \parallel p(\mathrm{W} \mid \mathrm{S})\big) \\ &= \underset{q(\mathrm{W})}{\operatorname{argmax}} \int_{\mathrm{W}} q(\mathrm{W}) \log \frac{p(\mathrm{S}|\mathrm{W})p(\mathrm{W})}{q(\mathrm{W})} \mathrm{dW} \quad (33) \end{aligned}$$

Assuming that q(W) is a joint Gaussian distribution and that each specification W_i in the specification matrix W follows an independent Gaussian distribution allows us to transform the variational problem into an optimization problem, as shown in Eq. (34):

$$(\mathrm{W}) = N(\mathrm{W}, \mu, \sigma^2) = \prod_i^{n_{W_i}} N(W_i, \mu_i, \sigma_i^2) \quad (34)$$

In Eq. (34), the mean value matrix and standard deviation are denoted by μ and σ, respectively. Determining the optimal values of the mean and standard deviation matrices, as shown in Eq. (35), will yield the ideal distribution $q(W)$:

$$\begin{aligned} \mu^*, \sigma^* = \underset{\mu_{1,\sigma},\sigma}{\operatorname{argmax}} & \sum_{k=1}^{n_\rho} \mathbb{E}_{q(\sigma_2 \varepsilon_k + u_k)}\big[\log\big(p(\sigma_k \varepsilon_k + u_k)\big)\big] \\ & + \sum_{k=1}^{n_\theta} \mathbb{E}_{q_k(\sigma_k \varepsilon_k + u_k)}\big[\log\big(q_k(\sigma_k \varepsilon_k + u_k)\big)\big] \\ & + \frac{N_N}{N} \sum_{j=1}^{N/N_B} N_B^N \sum_{i=1}^{N_n} \mathbb{E}_{q(\varepsilon)}\big[\log\big(p(\mathbf{y}_i \mid \mathbf{x}_i, \mu, \sigma, \varepsilon)\big)\big] \quad (35) \end{aligned}$$

IV. Experimental Analysis

In our evaluation, we present the compelling results of our proposed method for detecting data poisoning attacks in intelligent networks. Our approach consistently outperformed the referenced methods, achieving a significantly higher detection rate. The visualizations, including precision-recall curves and confusion matrices, vividly illustrate the superior performance and robustness of our method. These results provide strong evidence of the effectiveness and practical relevance of our approach in bolstering network security against data poisoning attacks.

A. Experimental Setup

The purpose of the experimental setup is to assess how well the suggested attack and defense strategies work. The Duchenne Smile Dataset, Product Dataset, and Sentiment Dataset are three real-world datasets used in the evaluation. Using customary cross-validation methods, these datasets are preprocessed and divided into training, testing, and validation sets. The suggested strategy is put into practice for the attack method using Python's NumPy and sklearn libraries. The datasets are subjected to the attack to evaluate its potential to undermine network security and jeopardize data classification. The suggested method is also put into practice for the defense method using Python's sklearn and NumPy libraries. The defense mechanism is applied to the datasets to test its efficacy in defending the network against threats and enhancing the accuracy and dependability of data classification. A comparison between the proposed methods and current methods, like K-Nearest Neighbors (KNN) and Malware-GAN, is done to ensure thorough evaluation. Throughput, Quality-of-Service (QoS), transmission rate, Root Mean Square Error (RMSE), accuracy, recall, precision, and malicious data analysis are just a few of the performance metrics that are measured and compared.

B. Dataset Description

This section provides a brief overview of the real-world datasets used in our experimental analysis in this section. These datasets are used to assess how well the attack and defense strategies we've suggested improve network security and data classification.

Duchenne Smile Dataset: The aim of this dataset is to determine whether a facial image contains a Duchenne or non-Duchenne smile. The task-creation and label-collection processes were performed using the Amazon Mechanical Turk platform. The dataset consists of 2,134 entries, with 64 regular employees producing 17,729 labels.

Product Dataset: The objective of this dataset is to determine whether two products are the same for each item in the dataset, which comprises pairs of items with descriptions. Participating employees were required to determine whether the two descriptions apply to the same item before providing their labels. This dataset contains 8,315 items, with 176 average workers providing 24,945 labels in total.

Sentiment Dataset: This dataset consists of a tweet about a specific firm for each item. The participating employees were tasked with determining whether the sentiment expressed in the tweet is favorable or unfavorable to the business. We created

1,000 objects using the AMT platform and collected labels from 85 regular workers. This dataset contains a total of 20,000 labels.

C. Performance Matrices

We use a set of performance metrics that cover various facets of the models' performance to assess the efficacy of our suggested attack and defense strategies.

Network throughput refers to the amount of data that can be successfully transported over a network in a certain period. It is measured in bits per second (bps) and can also refer to data packets per time slot or packets per second (pps). The aggregate throughput, also known as system throughput, is the total data rates sent to all network endpoints.

Quality-of-service (QoS) is a critical issue in wireless sensor applications, and each application has specific QoS requirements. Accuracy is one specification used to assess classification models, and it refers to the percentage of correct predictions made by a method. Recall and precision are measures of quantity and quality, respectively. A higher recall indicates that the method provides more relevant results, while a higher precision indicates that the method provides more relevant results than irrelevant ones. Precision is evaluated by dividing the total number of true positives (TP) by the total number of TP plus false positives (FP), while recall is calculated as the product of the number of TP divided by the sum of the TP and false negatives (FN).

Root means square error (RMSE) is a commonly used method for assessing the accuracy of forecasts, and it measures the Euclidean distance between the measured true values and forecasts. The standard deviation of residuals is also known as RMSE.

D. Comparative Analysis

Table I presents a comparative analysis between our proposed method and existing methods, based on network security and data classification. The analysis considers various parameters, including throughput, QoS, transmission rate, RMSE, accuracy, recall, precision, and malicious data analysis. The datasets analyzed include the Duchenne Smile Dataset, Product Dataset, and Sentiment Dataset.

Fig. 4 represents a comparative analysis between our proposed method and existing methods for network security. The graph shows that our proposed technique achieved a throughput of 96%, QoS of 83%, transmission rate of 89%, RMSE of 61%, accuracy of 95%, recall of 69%, precision of 79%, and malicious data analysis of 75%. In comparison, the KNN method achieved a throughput of 86%, QoS of 77%, transmission rate of 85%, RMSE of 55%, accuracy of 91%, recall of 65%, precision of 72%, and malicious data analysis of 69%, while the Malware-GAN method obtained a throughput of 94%, QoS of 79%, transmission rate of 88%, RMSE of 59%, accuracy of 93%, recall of 66%, precision of 75%, and malicious data analysis of 73%.

Significant performance differences are found when comparing the proposed method to the current network security methods. Compared to the KNN and Malware-GAN methods, our suggested technique outperformed them in all performance metrics. These findings suggest that when compared to the KNN and Malware-GAN methods, the proposed method is more effective and reliable in the context of network security analysis. The proposed method's efficiency in addressing network security issues is demonstrated by the higher throughput and transmission rate, better accuracy, and MDA.

Fig. 5 provides an analysis based on data classification between our proposed method and existing techniques. The graph shows that our proposed technique achieved a throughput of 95%, QoS of 85%, transmission rate of 93%, RMSE of 69%, accuracy of 96%, recall of 75%, precision of 85%, and malicious data analysis of 86%. In comparison, the KNN method achieved a throughput of 89%, QoS of 81%, transmission rate of 91%, RMSE of 63%, accuracy of 92%, recall of 71%, precision of 81%, and malicious data analysis of 79%, while the Malware-GAN method obtained a throughput of 95%, QoS of 85%, transmission rate of 93%, RMSE of 69%, accuracy of 96%, recall of 75%, precision of 85%, and malicious data analysis of 86%.

The proposed approach performs better than existing techniques for data classification, as shown by the comparative analysis between them. The outcomes show that the suggested method outperforms the KNN and Malware-GAN methods across the board. According to these findings, the proposed method performs data classification more effectively and efficiently than the KNN and Malware-GAN methods. The superiority of the suggested technique in handling data classification tasks is demonstrated by the higher throughput, transmission rate, accuracy, and MDA, along with better QoS and recall.

TABLE I. TABLE TYPE COMPARATIVE ANALYSIS OF PROPOSED AND EXISTING METHOD BASED ON NETWORK SECURITY AND DATA CLASSIFICATION

Techniques	Throughput	QoS	Transmission Rate	RMSE	Accuracy	Recall	Precision	Malicious Data Analysis
Case 1: Network security								
KNN	86	77	85	55	91	65	72	69
Malware_GAN	94	79	88	59	93	66	75	73
DPAD_NA_FANN_BCNN	96	83	89	61	95	69	79	75
Case 2: Data classification								
KNN	89	81	91	63	92	71	81	79
Malware_GAN	92	83	92	66	94	73	83	84

(a) (b)

Fig. 5. Comparative analysis between proposed and existing technique based on data classification: (a) comparison in terms of RMSE, transmission rate, QoS, and throughput; (b) comparison in terms of MDA, precision, recall, and accuracy.

We observe that our experimental analysis demonstrates the effectiveness of our proposed method in achieving high levels of network security and data classification performance. Our proposed technique outperforms the existing methods in terms of various parameters, including throughput, QoS, transmission rate, RMSE, accuracy, recall, precision, and malicious data analysis. The results indicate that our proposed method can significantly enhance the security and performance of wireless sensor networks.

Furthermore, the analysis of the Duchenne Smile Dataset, Product Dataset, and Sentiment Dataset reveals that our proposed method is robust and can be applied to various types of datasets. The high levels of accuracy, recall, and precision achieved by our proposed method indicate its potential for use in real-world applications, including in industries such as healthcare, e-commerce, and social media.

The results demonstrate the potential of our proposed method in enhancing the security and performance of wireless sensor networks and its ability to provide accurate and relevant results for data classification tasks. Further research can explore the use of our proposed method for other types of datasets and in different settings to evaluate its robustness and scalability.

The findings of this study highlight the effectiveness of the proposed technique in detecting and mitigating data poisoning attacks in intelligent networks. The achieved high levels of network security and accuracy in data detection demonstrate its practical value for network administrators, ensuring the protection of sensitive data and system integrity. The successful application of the technique contributes to advancements in network security and data analytics, while future research can focus on scalability and addressing potential vulnerabilities to further enhance its robustness. Overall, this study provides valuable insights for the implementation of secure and privacy-preserving intelligent networks.

V. Conclusion

This research proposes a novel technique for detecting data poisoning attacks based on deep learning, which combines

federated learning with adversarial neural networks. The proposed technique utilizes a Bayesian convolutional neural network to train the data analyzed by federated learning for detecting the presence of data poisoning attacks in the network. The experimental analysis is carried out based on network security and data classification, utilizing real-world datasets, such as the Duchenne Smile Dataset, Product Dataset, and Sentiment Dataset. The proposed technique outperforms the existing models in the literature, achieving high levels of performance in various parameters, including throughput, QoS, transmission rate, RMSE, accuracy, recall, precision, and malicious data analysis.

The results of this research indicate that the proposed technique can significantly enhance the security and performance of wireless sensor networks, contributing to a deeper understanding of data poisoning attacks and detection strategies in real-world contexts. Furthermore, this research contributes to the advancement of more effective outlier detection methods across a wider range of applications. Future work must address the challenge of preventing such attacks in a strengthened federated learning environment.

Overall, the proposed technique offers a promising approach to the detection of data poisoning attacks, which have become increasingly prevalent in wireless sensor networks. This research opens new avenues for future research in the field of wireless sensor networks, and the proposed technique holds potential for use in various industries, including healthcare, e-commerce, and social media.

Strengthening AES Security Through Key-Dependent ShiftRow and AddRoundKey Transformations Utilizing Permutation

Tran Thi Luong
Academy of Cryptography Techniques, No. 141 Chien Thang Road, Tan Trieu, Thanh Tri, Hanoi, Vietnam

***Abstract*—AES (Advanced Encryption Standard) is a widely applied block cipher standard in the United States, used in various security applications today. Currently, there are numerous research endeavors aimed at making AES block ciphers dynamic to improve their security against contemporary strong attacks. The most common dynamic approach involves the dynamization of AES block transformations, including SubByte, ShiftRow, AddRoundKey, and MixColumn operations. The combination of these transformations has also been explored and proposed. However, to the best of our knowledge, the dynamic combination of AddRoundKey and ShiftRow transformations remains unexplored. Therefore, in this paper we introduce algorithms for generating key-dependent AddRoundKey and ShiftRow transformations based on permutations. Subsequently, these key-dependent transformations are applied to AES to create dynamic AES block ciphers. Security analysis and evaluation of NIST's statistical criteria are performed, and the entropy of AES and dynamic AES is assessed. From our findings, it is evident that dynamic AES block ciphers can significantly enhance AES security and meet stringent randomness criteria, similar to AES.**

***Keywords*—AES; ShiftRow; AddRoundKey; dynamic AES; key-dependent**

I. Introduction

Along with the strong development of information technology, security risks and attacks are increasing in complexity. Therefore, cryptographic primitives are being widely used in various security domains nowadays [1, 2, 3]. Substitution-Permutation Network (SPN) block ciphers [4, 5, 6] represent a prevalent category of block ciphers extensively applied in contemporary cryptographic scenarios. An SPN block cipher comprises three primary components: the substitution layer, which typically employs S-boxes [7–10]; the diffusion layer, commonly utilizing MDS matrices [11–14] (matrices derived from maximum distance separable codes); and the key addition layer.

AES [15, 16] belongs to the class of SPN block ciphers and serves as a block cipher standard established by NIST in 2001, originating in the United States. The AES round function incorporates three operations, namely key addition, substitution, and linear transformations. AES, one of the world's most widely used encryption algorithms, faces potential vulnerabilities that could be exploited by cryptanalysts. The simplicity of AES's mathematical structure and the threat of attacks such as algebraic attacks [17], linear attacks [8, 18], and differential attacks [18, 19], make its security a concern. Moreover, the advent of supercomputers and quantum computing poses further risks, necessitating increased key lengths for maintaining security. Therefore, researching various approaches to enhance the security strength of AES is crucial in the current scenario.

To enhance the resilience of block ciphers against modern, potent attacks, extensive research has been conducted to animate these cryptographic algorithms. Specifically, with the AES block cipher, there is a variety of approaches to dynamize the AES block cipher to enhance its security. Some of these methods center on incorporating S-boxes in AES that depend on a secret key [20–25], while others work on creating key-dependent MixColumn transformations for AES [26–28]. Notably, there are studies exploring the dynamization of both AES's S-boxes and MixColumn [29], or the dynamization of all three transformations: S-Boxes, MixColumn, and ShiftRow, which have also received attention [30–32]. Another current research direction is to make the XOR operation dynamic in AES [33, 34].

For the dynamic S-box approach in AES, in their work [20], the authors introduced a method for generating S-boxes that depend on the encryption key and possess favorable algebraic characteristics, including non-linearity, BIC, and SAC. Furthermore, an alternative approach to produce S-boxes that rely on the encryption key in AES was introduced in [21]. This method entails establishing a novel arrangement for the S-box through the use of a simulated key expansion algorithm. In [22], the authors introduced an innovative method for creating variable S-boxes by rearranging the S-box of AES. These adaptable S-boxes rely on a secret key and utilize an affine constant and an unconventional polynomial. For each additional key bit, a fresh S-box with rearranged values is produced, thus enhancing the intricacy of the algorithm. In [23], the authors presented an approach to create S-boxes that vary with the encryption key, employing a evolving approach. The evaluative experimentation of these key-dependent S-boxes was conducted, focusing on characteristics such as achieving a SAC, BIC, balanced output, non-linearity, and probabilities related to linear and differential approximation. In [24], the authors introduced four straightforward procedures for producing key-influenced S-boxes. To assess the quality of these S-boxes, they introduced eight standardized dissimilarity measurements. The authors outlined four methods for generating key-influenced S-boxes and scrutinized eight normalized dissimilarity measurements

employed to appraise the effectiveness of these key-dependent generation techniques. Furthermore, in [25], Murphy et al. introduced an approach for the differential cryptanalysis of key-influenced S-boxes, elucidating methods for performing cryptanalysis with the utilization of these S-boxes.

For the dynamic Mixcolumn approach in AES, in [26], the authors proposed a MixColumn transformation that depends on the encryption key, derived from the AES MDS matrix, using scalar multiplication on the rows of the matrix along with an extra m-bit key. An idea presented in [27] includes the creation of a diffusion layer that relies on the encryption key, achieved through scalar multiplication and immediate exponentiation. In [28], the authors introduced a collection of $n \times n$ binary matrices that can be employed to create dynamic matrices resembling AES and recursive MDS matrices.

For the approach of making multiple transformations dynamic in AES, in [29], the authors introduced dynamic S-boxes and novel MixColumn matrices that preserve favorable cryptographic characteristics when developing dynamic AES. In [30], an image encryption method rooted in symmetric cryptography was introduced. It utilizes transformations like MixColumns, ShiftRows, and SubByte, which are dynamically influenced by the encryption key. In [31], the authors presented a dynamic block cipher based on AES, in which AES parameters vary for each unique key. More precisely, the ShiftRows, the SubBytes, and MixColumns transformations adapt according to the key, leading to distinct behavior for every key. Extensive testing has verified the security of the proposed algorithm. In [32], a fresh and efficient AES algorithm, which is dependent on the key, is introduced. The authors have put forward an innovative approach to enhance the advanced encryption standard algorithm by employing dynamic sub-byte, mix-column, and shift rows operations to ensure secure communication. This novel work exhibits superior avalanche and strict avalanche effects when compared to the conventional AES algorithm.

In [33, 34], the authors introduced innovative techniques that employ key-dependent XOR tables utilizing 3D chaotic maps. The authors utilized XOR tables that rely on the initial confidential parameters. In [34], they established a fresh MDS matrix, however, regrettably, this matrix does not qualify as an MDS matrix. Furthermore, their approaches in [31, 32] still exhibit numerous weaknesses and shortcomings.

Based on our review of related works, to the best of our knowledge, we haven't come across any research that investigates the combination of animating both the ShiftRow and AddRoundKey transformations of AES. In this paper, we introduce algorithms for generating key-dependent AddRoundKey and ShiftRow transformations based on permutations. Subsequently, we apply these key-dependent transformations to AES to create a dynamic AES block cipher. We conduct security analysis and evaluate NIST's statistical criteria, as well as assess the entropy of AES and dynamic AES. Consequently, it becomes evident that dynamic AES block ciphers can significantly enhance the security of AES and meet rigorous randomness criteria, similar to AES.

The structure of the remaining part of the paper is as follows: Section II provides preliminaries. Section III introduces algorithms for generating key-dependent ShiftRow and AddRoundKey transformations based on permutations. Section IV adapts the AES block cipher using key-dependent ShiftRow and AddRoundKey operations. Section V is conclusion.

II. PRELIMINARIES

A. Introduction to Hadamard Matrices

A Hadamard matrix [35] of dimension d, with the initial row elements represented as $h_0, h_1, \dots, h_d$, can be designated in the following manner.

$$H = had(h_0, h_1, \dots, h_d)$$

Furthermore, a Hadamard matrix of size $2d \times 2d$ has the following form.

$$H = \begin{pmatrix} A & B \\ B & A \end{pmatrix}$$

where A and B are $d \times d$ matrices, d is even.

B. ShiffRow and AddRoundKey Transformations in AES

The ShiftRow operation in AES processes the state by left rotating the last three rows of the state with a varying number of rotation. Row 1 of the state remains unchanged, row 2 of the state left rotates by 1 byte, row 3 of the state left rotates by 2 bytes, and row 4 of the state left rotates by 3 bytes.

The AddRoundKey operation in AES performs a bitwise XOR between the state and a round key. The AddRoundKey operation is represented by a 4-bit XOR table as described in Table I.

TABLE I. THE 4-BIT XOR TABLE IN AES

III. Proposing Algorithms to Generate Key-Dependent ShiftRow and AddRoundKey Transformations based on Permutation

A. Algorithm for Generating Key-Dependent ShiftRow

First, we analyze the diffusion capacity of active bytes (non-zero byte) through two rounds of AES. Fig. 1 represents the diffusion state of AES after the first round, with the initial state containing an active byte (indicated by the black cell).

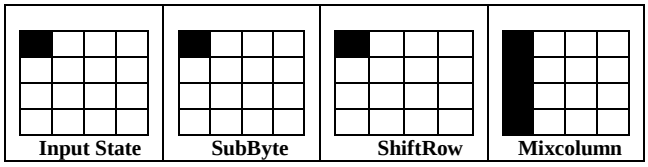

Fig. 1. Diffusion state of AES after the first round.

According to Fig. 1, after the SubByte and ShiftRow transformations in the first round, the number of active bytes in the state array remains at 1. Subsequently, during the MixColumn transformation, the number of active bytes becomes 4 due to the diffusion capabilities of the MDS matrix, and the number of active bytes is preserved when going through the AddRoundKey transformation. Thus, starting with 1 active byte, there will be 4 active bytes at the end of the first round.

Fig. 2 shows the diffusion state of AES after the second round.

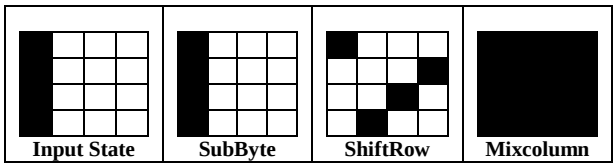

Fig. 2. Diffusion state of AES after the second round.

From Fig. 2, we can observe that the role of ShiftRow is extremely important in propagating active bytes from column 1 to all four columns of the state array. This allows, through the MixColumn transformation, the maximum number of active bytes to be achieved, which is 16 bytes in the state array.

Remark 1: The crucial point in designing the ShiftRow transformation is its capability to distribute active bytes from one column to all the remaining columns, ensuring that all four columns of the state array contain at least one active byte.

According to Fig. 2, the number of bytes rotated in each row of the state by the ShiftRow transformation in AES can be described as shown in Fig. 3.

Therefore, as long as the number of bytes rotated in each row is distinct and falls within the range [0, 3], active bytes will undoubtedly be propagated to all four columns of the state.

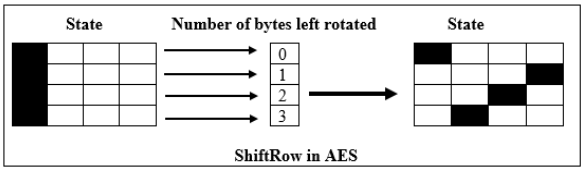

Fig. 3. The number of bytes rotated in each row of the state by the ShiftRow in AES.

Based on these observations, we propose the idea presented in Algorithm 1 to generate key-dependent ShiftRow transformations while ensuring the propagation of active bytes as described above.

Algorithm 1. Key-dependent ShiftRow Transformation Generation via Permutation

Input: A secret key K consists of k ($k \geq 128$) bits; A state S of size 4×4.

Output: The new ShiftRow operation for AES depends on the key K; A new state $\acute{S}$.

Step 1: Take the first two bits of the key K and convert them into an integer, denoted as a_0. Take the next two bits of K and convert them into an integer. If this integer is different from a_0, assign it to a_1; otherwise, shift the key K to the right by one bit until you obtain $a_1 \neq a_0$. Continue this process until you have four distinct integers: a_0, a_1, a_2, a_3.

Step 2: From the permutation (a_0, a_1, a_2, a_3) obtained in step 1, left rotate the rows of the state S as follows: left rotate a_0 bytes for row 1, left rotate a_1 bytes for row 2, left rotate a_2 bytes for row 3, left rotate a_3 bytes for row 4. The resulting state is denoted as $\acute{S}$.

Step 3: The left rotation operation as in step 2 is called *KD_ShiftRow*. The *KD_ShiftRow* operation will be used to replace the ShiftRow operation in AES.

Remark 2. Because there are 4! permutations of (0, 1, 2, 3), there will be $4! = 24$ key-dependent ShiftRow operations (*KD_ShiftRow*) that can be generated by Algorithm 1.

Example 1. If step 1 of Algorithm 1 results in the permutation $(a_0, a_1, a_2, a_3) = (2, 0, 3, 1)$, then the *KD_ShiftRow* operation obtained from Algorithm 1 will function as shown in Fig. 4.

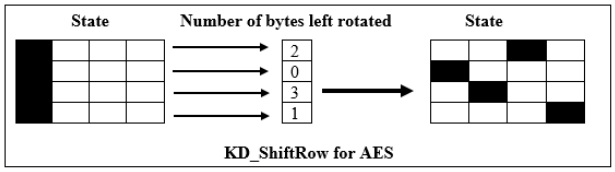

Fig. 4. An example of the KD_ShiftRow obtained from Algorithm 1.

B. Algorithm for Generating Key-Dependent AddRoundKey Transformations

From the original XOR table of AES (Table I), we have a remark regarding three essential Attributes that a XOR table must possess.

Remark 3. Three essential Attributes of an XOR table

- Attribute 1: Every row and column in the XOR table contains unique values within the range of 0 to 15.
- Attribute 2: The XOR table should exhibit symmetry along the principal diagonal, implying that $m\ XOR\ n = n\ XOR\ m$.
- Attribute 3: For any given m, n, and k elements within the XOR table where $m\ XOR\ n = k$, the following holds true: $m\ XOR\ k = n$ and $n\ XOR\ k = m$.

From the XOR table of AES, denote the 4×4 matrices as follows:

$$A_0 = \begin{pmatrix} 0 & 1 & 2 & 3 \\ 1 & 0 & 3 & 2 \\ 2 & 3 & 0 & 1 \\ 3 & 2 & 1 & 0 \end{pmatrix}, A_1 = \begin{pmatrix} 4 & 5 & 6 & 7 \\ 5 & 4 & 7 & 6 \\ 6 & 7 & 4 & 5 \\ 7 & 6 & 5 & 4 \end{pmatrix},$$

$$A_2 = \begin{pmatrix} 8 & 9 & 10 & 11 \\ 9 & 8 & 11 & 10 \\ 10 & 11 & 8 & 9 \\ 11 & 10 & 9 & 8 \end{pmatrix}, A_3 = \begin{pmatrix} 12 & 13 & 14 & 15 \\ 13 & 12 & 15 & 14 \\ 14 & 15 & 12 & 13 \\ 15 & 14 & 13 & 12 \end{pmatrix}.$$

$$\text{Set } \boldsymbol{A} = \begin{pmatrix} A_0 & A_1 & A_2 & A_3 \\ A_1 & A_0 & A_3 & A_2 \\ A_2 & A_3 & A_0 & A_1 \\ A_3 & A_2 & A_1 & A_0 \end{pmatrix}.$$

Remark 4. The matrices A_i $(0 \le i \le 3)$ are Hadamard matrices. And the matrix $\boldsymbol{A}$ is also a Hadamard matrix in the form $\boldsymbol{A} = had(0, 1, 2, \dots, 15)$. Therefore, the XOR table of AES is created from the Hadamard matrix $\boldsymbol{A}$, where **row 0** and **column 0** (bolded) of this XOR table are ordered according to the first row of matrix $\boldsymbol{A}$, meaning in the order 0, 1, 2, …, 15.

We can denote: $\boldsymbol{A} = had(A_0, A_1, A_2, A_3)$.

From Remark 4, it can be seen that by permuting the matrices A_i, new Hadamard matrices $\boldsymbol{A}$ can be generated. Based on this idea, we propose Algorithm 2 to generate a new XOR table and key-dependent AddRoundKey transformation by permuting the A_i matrices in matrix $\boldsymbol{A}$.

Algorithm 2. Generating a new 4-bit XOR table and key-dependent AddRoundKey transformation based on permutation.

Input: A secret key K consisting of k $(k \ge 128)$ bits, the original XOR table of AES.

Output: A new 4-bit XOR table; Key-dependent AddRoundKey operation.

Step 1: Take the first two bits of the secret key K and convert these two bits into an integer, denoted as x_0. Take the next two bits of K and convert them into an integer. If this integer is different from x_0, assign this integer to x_1; otherwise, shift the key K to the right by one bit until $x_1 \ne x_0$ is obtained. Do the same for the remaining bits until four distinct integers are obtained: x_0, x_1, x_2, x_3.

Step 2: Construct a permutation-based Hadamard matrix using the permutation (x_0, x_1, x_2, x_3) obtained in step 1, which has the form: $\hat{\boldsymbol{A}} = had(A_{x_0}, A_{x_1}, A_{x_2}, A_{x_3})$.

Step 3: Construct a new 4-bit XOR table based on the Hadamard matrix $\hat{\boldsymbol{A}}$ such that the elements in the first row and the first column of this new XOR table follow the order of elements in the first row of matrix $\hat{\boldsymbol{A}}$.

Step 4: Reorder the rows and columns of the new XOR table so that both row 0 and column 0 of the new XOR table follow an increasing order from 0 to 15.

Step 5: Replace the regular bitwise XOR operation in the AddRoundKey transformation of AES with the new XOR operation determined by the new XOR table created in step 4. The result is the *KD_AddRoundKey* operation, which is used in place of the AddRoundKey operation in AES.

Remark 5. Since there are 4! permutations of (0, 1, 2, 3), there will be a total of $4! = 24$ new XOR tables generated by Algorithm 2, corresponding to the number of *KD_AddRoundKey* operations obtained.

Example 2. Suppose that step 1 of Algorithm 2 yields the permutation $(x_0, x_1, x_2, x_3) = (3, 2, 0, 1)$. The resulting Hadamard matrix is as follows:

$$\hat{\boldsymbol{A}} = had(A_3, A_2, A_0, A_1) = \begin{pmatrix} A_3 & A_2 & A_0 & A_1 \\ A_2 & A_3 & A_1 & A_0 \\ A_0 & A_1 & A_3 & A_2 \\ A_1 & A_0 & A_2 & A_3 \end{pmatrix}$$

In that case, the resulting new XOR table after Algorithm 2 is presented in Table II.

TABLE II. THE NEW XOR TABLE GENERATED FROM ALGORITHM 1

From the three attributes of an XOR table as mentioned in Remark 3, we prove the accuracy of the new XOR table generated by Algorithm 1 with the following proposition.

Proposition 1. The new XOR table generated by Algorithm 1 satisfies the three necessary attributes of an XOR table.

Proof.

Since the Hadamard matrix $\hat{\boldsymbol{A}}$ is essentially a permutation of elements within a row of the original XOR table of AES, Atrribute 1 of the new XOR table is satisfied.

Matrix

$$\acute{\boldsymbol{A}} = had\left(A_{x_0}, A_{x_1}, A_{x_2}, A_{x_3}\right) = \begin{pmatrix} A_{x_0} & A_{x_1} & A_{x_2} & A_{x_3} \\ A_{x_1} & A_{x_0} & A_{x_3} & A_{x_2} \\ A_{x_2} & A_{x_3} & A_{x_0} & A_{x_1} \\ A_{x_3} & A_{x_2} & A_{x_1} & A_{x_0} \end{pmatrix}$$

is a Hadamard one, and the matrices $A_{x_i}(0 \le i \le 3)$ are also Hadamard matrices, so the matrix $\acute{\boldsymbol{A}}$ is symmetric across the main diagonal. Thus, Attribute 2 of the new XOR table is satisfied.

The matrix $\acute{\boldsymbol{A}}$ is denoted as follows: $\acute{\boldsymbol{A}} = had(a_0, a_1, \dots, a_{15})$.

Comparing with the original XOR table of AES, it can be observed that the elements of the new XOR table have been replaced by a one-to-one mapping as follows: $0 \to a_0$, $1 \to a_1$, …, $15 \to a_{15}$. This substitution is applied to all elements of the original XOR table, including both row 0 and column 0.

According to Attribute 3 of the original XOR table: if $i\ XOR\ l = j$, it always holds that $i\ XOR\ j = l$ and $l\ XOR\ j = i$.

From the replacement operation, we also have the corresponding relationship: if $a_i\ XOR\ a_l = a_j$, it always holds that $a_i\ XOR\ a_j = a_l$ and $a_l\ XOR\ a_j = a_i$. Therefore, Attribute 3 of the new XOR table is satisfied.

On the other hand, rearranging the order of rows and columns of the new XOR table so that row 0 and column 0 of that XOR table are in increasing order from 0 to 15 will not affect the values in the XOR table. Therefore, all three properties are satisfied for the new XOR table.

C. Proposing the Combined Algorithm

In this section, we will propose a combined algorithm to generate both the key-dependent ShiftRow and AddRoundKey transformations for the AES block cipher.

Algorithm 3. Generating key-dependent ShiftRow and AddRoundKey transformations.

Input: A secret key K consisting of k ($k \ge 128$) bits; The original XOR table of AES.

Output: A new 4-bit XOR table; New key-dependent ShiftRow and AddRoundKey transformations for AES.

Step 1: Take the first two bits of key K and convert these two bits into integers, denoted as a_0. Take the next two bits of K and convert them into integers. If this integer is different from a_0, assign it to a_1; otherwise, shift key K to the right by one bit until you obtain $a_1 \neq a_0$.. Repeat this process until you have four distinct integers: a_0, a_1, a_2, a_3.

Step 2: From the permutation (a_0, a_1, a_2, a_3) obtained in step 1, for any arbitrary state S, perform a left rotation on the rows of the state S as follows: rotate row 1 to the left by a_0 bytes, rotate row 2 to the left by a_1 bytes, rotate row 3 to the left by a_2 bytes, rotate row 3 to the left by a_2 bytes. This left rotating operation is named *KD_ShiftRow* and will be used to replace the ShiftRow operation in AES.

Step 3: Following the same procedure as in step 1, with the next bits of the secret key K after step 1, we obtain a permutation (x_0, x_1, x_2, x_3).

Step 4: Construct a Hadamard matrix based on the permutation (x_0, x_1, x_2, x_3) obtained in step 3, in the form of: $\acute{\boldsymbol{A}} = had(A_{x_0}, A_{x_1}, A_{x_2}, A_{x_3})$.

Step 5: Construct a new 4-bit XOR table based on the Hadamard matrix $\acute{\boldsymbol{A}}$, with the first row and column of the new XOR table containing elements in the same order as those in the first row of matrix $\acute{\boldsymbol{A}}$. Rearrange the rows and columns of the new XOR table so that the first row and column follow an increasing order from 0 to 15.

Step 6: Replace the usual bitwise XOR operation in the AddRoundKey transformation of AES with the new XOR operation defined by the XOR table generated in step 5. The result is the *KD_AddRoundKey* operation, which is used in place of AddRoundKey in AES.

IV. Adapt the AES Block Cipher by Incorporating the Key-Dependent ShiftRow and AddRoundKey Transformations

A. Implementation of Experiments

Execute the combined algorithm in Algorithm 3 to obtain two key-dependent transformations: *KD_ShiftRow* and *KD_AddRoundKey*. Then, use these two transformations to replace the original ShiftRow and AddRoundKey in AES. The resulting dynamic AES algorithm is denoted as *ShiftAES*. Fig. 5 illustrates the diagram of encryption/decryption rounds in the *ShiftAES* algorithm.

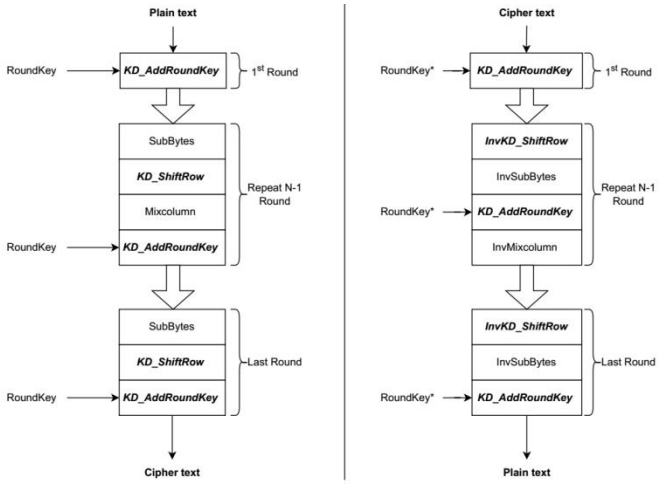

Fig. 5. Encryption / decryption round diagram of the ShiftAES algorithm.

For experiment, we select the AES-128 block cipher with a XOR table of 4-bit. This led to the development of a key-dependent dynamic block cipher algorithm, which we named ShiftAES-128 based on Algorithm 3. We implement these algorithms using C++ on an Asus K43SJ Laptop (Core i5-2430M, 500GB, HDD 6GB RAM, Nvidia Geforce GT 520M).

B. Security Analysis

In the realm of block ciphers, encompassing AES, the most potent threats manifest in the form of differential attacks [18, 19], linear attacks [18, 36], or their derivatives. In the case of differential attacks, attackers must rely on predefined differential patterns to execute their strategies. Our ShiftAES block cipher ensures the continuous alteration of differential patterns [17], contingent upon the encryption key. This

dynamic behavior significantly enhances the security of the ShiftAES block cipher, as it becomes exceedingly arduous for potential attackers to compute the differentials required for launching attacks.

The use of the key-dependent ShiftRow operation makes it considerably more challenging for attackers as it conceals the exact rotation values applied in AES's *KD_ShiftRow*, rendering decryption significantly more difficult. Moreover, the utilization of key-dependent AddRoundKey operations will heighten the intricacy of key-related attacks [37]. It disrupts the conventional property of XOR tables, where different inputs with the same difference yield an output difference of 0. The dynamic nature of the relationship between input differences, driven by the variable key, adds an additional layer of security to block ciphers that incorporate such elements.

Combining both KD_ShiftRow and KD_AddRoundKey makes the attacker's task significantly more challenging. In the case of AES, attackers know how ShiftRow and AddRoundKey work, they might collect a large number of plaintext/ciphertext pairs for differential or linear cryptanalysis attacks. This number of pairs could be very large, let's assume it's 2^{80}. However, with the *ShiftAES* algorithm, there can be 24 possibilities for *KD_ShiftRow* and 24 possibilities for dynamic XOR tables, which results in $24 \times 24 = 576$ possible combinations for ShiftRow and AddRoundKey used in *ShiftAES*. In this scenario, the number of plaintext/ciphertext pairs required for an attack is not just 2^{80} but 576×2^{80}. This number, at first glance, may not seem significantly larger, but in reality, it's extremely huge and has practical implications. So, for the dynamic AES block cipher, an attacker needs to collect plaintext/ciphertext pairs that are 576 times more than in the case of regular AES. This is not an easy task in practice. Furthermore, when the encryption/decryption switches to a different secret key, meaning different *KD_ShiftRow* and *KD_AddRoundKey* are used, the attacker might not have enough time to gather a sufficient number of plaintext/ciphertext pairs to carry out the attack.

Therefore, it can be seen that the proposed dynamic method can significantly increase the security of AES. Furthermore, as mentioned in the introduction, our proposed method is a novel approach, which may be highly beneficial for cryptography designers in designing secure dynamic SPN block ciphers.

C. Evaluating the Random Statistical Standards

In this section, we assess the random statistical standards according to NIST SP 800-22 [38] and Shannon Entropy criteria [39] of the AES and *ShiftAES* block cipher.

NIST SP 800-22 [38] has been developed to serve as the primary and extensively utilized means for evaluating the statistical randomness of random or pseudorandom number generators in the field of cryptography. NIST's set of randomness assessments encompasses a total of 15 tests, which are outlined below.

Random Excursions Test; Frequency Test within a Block; Test for the Longest Run of Ones in a Block; Approximate Entropy Test; Non-overlapping Template Matching Test; Binary Matrix Rank Test; Random Excursions Variant Test; Cumulative Sums (Cusum) Test; Frequency (Monobit) Test; Linear Complexity Test; Runs Test; Serial Test; Overlapping Template Matching Test; Discrete Fourier Transform (Spectral) Test; Maurer's "Universal Statistical" Test.

For a given input sequence, every test computes a respective p-value, which is then compared to the significance level $\alpha = 0.01$. Should $p_i \geq \alpha$, it is inferred that the sequence exhibits randomness, and conversely.

Entropy, also known as information entropy, is described as the degree of unpredictability concerning an individual's knowledge or the result of an experiment before it is observed, as well as the connected deterministic characteristics for forecasting its value. Higher entropy indicates increased uncertainty when forecasting an observation's value. Shannon entropy represents one category of information entropy developed by Shannon in [39].

1) Evaluate the shannon entropy change using the ENT tool: Shannon entropy is a vital indicator of randomness. In this section, we assess the alteration in Shannon entropy for the four datasets, namely LW, HW, AV1, and Rot, across each round of the DAES block cipher. This analysis aims to provide a comprehensive view of the randomness at each round. We utilized the ENT tool [40] to perform the evaluations and acquired the subsequent outcomes.

The results of the entropy evaluation are presented in Table III.

TABLE III. EVALUATION RESULTS OF ENTROPY FOR AES AND SHIFTAES

Rounds	AES	ShiftAES
1	4.994138	5.014244
2	7.077322	7.040298
3	8	7.999285
4	7.999989	7.999987
5	7.999990	7.999990
6	7.999989	7.999989
7	7.999990	7.999989
8	7.999990	7.999988
9	7.999989	7.999988
10	7.999989	7.999988

The entropy evaluation results show that after three rounds, the entropy of data encrypted by both original AES and ShiftAES is approximately 8 bits/byte. This implies that both block ciphers achieve randomness properties with three or more rounds.

2) The evaluation results according to NIST SP 800-22: We conducted an evaluation of the statistical tests for rounds 1, 2, ..., 10 of both AES and ShiftAES. Tables IV to VIII display the results of the randomness evaluation of AES and ShiftAES across 1, 2, 3, 4, and 10 rounds.

The results show that both the original AES and *ShiftAES* achieve randomness when they pass all the tests. For rounds fewer than four, both AES and *ShiftAES* still fail in some tests. From round 5 to round 10, both AES and *ShiftAES* block ciphers pass all tests. It means that the p-values of those tests are all greater than or equal to 0.01 from round 5 to round 10. Therefore, both block ciphers exhibit randomness when using four rounds or more.

Combining the evaluation results based on entropy and statistical tests from NIST SP 800-22, we conclude that the *ShiftAES* algorithm achieves randomness with a number of rounds greater than or equal to four and is equivalent to the original AES algorithm.

V. Conclusion

In this paper, we propose algorithms for generating key-dependent AddRoundKey and ShiftRow transformations based on permutations. Subsequently, we apply these key-dependent transformations to AES to create a dynamic AES block cipher. We conduct a security analysis and evaluate the statistical standards of NIST, assess the entropy of both AES and the dynamic AES (ShiftAES). Consequently, it is evident that the dynamic AES block cipher can significantly strengthen the security of AES and meets statistical randomness criteria similar to AES. This result is significant both in theory and practice, providing cryptographic researchers with a new method to improve block cipher security. Our future research direction involves further development of other dynamic algorithms to strengthen the resilience of SPN block ciphers against cryptanalysis.

Aeronautics Technology Research Center, National Research and Innovation Agency (BRIN), Jakarta, Indonesia[1]
Defense Science Doctoral Program, Republic of Indonesia Defence University, Jakarta, Indonesia[1, 2, 3, 4]

***Abstract*—Countries worldwide are attempting to acquire or create Class 3 unmanned aircraft as part of their armies' primary weapons systems. The development of medium altitude long endurance (MALE) unmanned aircraft in Indonesia forms part of the national strategic program. Based on documentation studies, three alternative MALE-class unmanned aircraft development models were identified. This study aims to determine the most appropriate unmanned aircraft development model for the MALE class for Indonesia's current situation. This will aid decision-making by the government and stakeholders related to the drone development model. The analytical hierarchy process (AHP) method was used to analyze the decision-making for the selection of an unmanned aircraft development model. The study began with a questionnaire survey of 11 experts from various institutions. The results show that the priority criterion should be the benefits obtained, followed by the opportunity and budget criteria, and, finally, the risk. The consortium model, which had the highest score of 0.548, is the most suitable for Indonesia's development of MALE-class unmanned aircraft. The results of the study are expected to provide useful input for AHP researchers, government institutions, and stakeholders.**

***Keywords*—Analytical Hierarchy Process (AHP); decision-making; development model; medium altitude long endurance (MALE); unmanned aircraft**

I. Introduction

Countries worldwide are attempting to acquire or create Class 3 unmanned aircraft as part of their armies' primary weapons systems. More and more nations are trying to compete in the race to create and offer ever-more advanced drones for sale on the international market. Long-simmering conflicts and rivalries are expected to change due to the emergence of a race for drones [1]. The primary rivalries in this arms race are between the United States of America, China, Russia, South Korea, and the European Union [2]. Unmanned aircraft are divided into three classes based on maximum take-off weight, namely Class 1 (<150 kg), Class 2 (150–600 kg), and Class 3 (>600 kg) [3]. Countries around Indonesia such as China, India, Pakistan, Singapore, and Thailand already have Class 3 unmanned aircraft. Meanwhile, countries that are growing and intend to obtain them include Australia, Bangladesh, Japan, Malaysia, the Philippines, South Korea, Taiwan, and Indonesia [4].

Examples of the deployment of unmanned aircraft in warfare include the United States of America's use of the Predator MQ-1 against Osama bin Laden in Afghanistan beginning in 2002. The Turkish military used Bayraktar TB2s against Syrian Army targets in March 2020 [5]. During the Nagorno–Karabakh war of 2020, Azerbaijan employed the Bayraktar TB2 against the Armed Forces of Armenia [6]. More recently, Russia has reduced the military power of Ukraine. Drones have played a significant role in the former's operations and Russia has improved the aiming speed for long-range indirect fire through the use of multiple drone types that fly at varying altitudes [7]. The conflict in Ukraine is swiftly bringing future trends for drone use into view [8]. The use of an Unmanned Aerial System (UAS) in a hostile environment reduces risk [9]. Drones can be used to solve a variety of problems related to the needs of the users, such as illegal fishing, illegal immigrants, piracy, floods, forest fires, terrorism, and military infiltration of other countries [10].

According to Presidential Regulation of the Republic of Indonesia, number 109 for the year 2020, numerous inventions and research projects are being executed efficiently to strengthen the country's technological independence. The national strategic program includes the development of medium altitude long endurance (MALE) unmanned aircraft in Indonesia. The Black Eagle unmanned aerial vehicle (UAV) system is part of several governmental research and innovation initiatives [11]. Based on documentation studies, three alternative development models for MALE-class unmanned aircraft have been identified, namely: 1) The BRIN model based on a letter from the Deputy for Research and Innovation Utilization of the National Research and Innovation Agency (BRIN) to the Secretary General of the Ministry of Defense dated 23-11-2021 regarding an explanation of the follow-up to the MALE UAV program, 2) A consortium model based on Minister of Research, Technology and Higher Education Regulation no. 38 of 2019 concerning the 2020-2024 national research program, the Agency for the Assessment and Application of Technology (BPPT) as coordinator of the combat PTTA development program, and based on a cooperation agreement (PKS) between the Ministry of Defense, Indonesian National Army Air Force (TNI AU), BPPT, Bandung Institute of Technology (ITB), PT Dirgantara Indonesia (PTDI), and PT LEN dated 08-21-2017, and 3) An international cooperation model based on the invitation letter and minutes of the coordination meeting for the implementation of the offset procurement of the Bayraktar TB2 UAV from the Director General of Defense Ministry of Defense dated 01-03-21.

The consortium-based MALE class UCAV development program started in 2017 but has been discontinued since 2020 due to the establishment of the National Research and Innovation Agency (BRIN). This study aims to determine the

most appropriate unmanned aircraft development model for the MALE class for Indonesia's current situation. This will aid decision-making by the government and stakeholders related to the drone development model. In this case, an analytical hierarchy process (AHP) based on the criteria provided for selecting current models can aid in making a superior choice.

The following section contains a literature review on UAV design, opportunities, product budgets, benefits, risks, and the AHP method. Section III presents the methodology: system design, the AHP method, sampling and data collection, research instruments and measurements, and methods of analysis. The findings of the analysis are discussed in Section IV. Finally, the study will end with conclusions and recommendations for future research in Section V.

II. Literature Review

Manned aircraft and UAV designs share certain similarities and contrasts. They both consist of a design procedure, limitations, and core UAV parts (autopilot, ground station, communication, sensors, and payload). A UAV designer must be well versed in the most recent UAV advancements, modern technologies, the lessons learned from previous failures, and the diversity of UAV design possibilities, and they must understand the environment, the requirements, and the design problems, as well as how to integrate complex, multi-disciplinary systems [12]. A step-by-step layout design study was conducted using precision tools and computational simulations to define the essential layout parameters and choose the ideal airframe-engine combination [13].

When Inertial Navigation System data are not sufficiently precise to minimize drift from a planned trajectory, Synthetic Aperture Radar (SAR) can assist in UAV navigation [14]; [15]. Stability and maneuverability are key trade-offs in aircraft construction for civil or military use. The UAV and its handling characteristics are both addressed in the design of the flight control system [16]. While every technological product carries the risk of malfunction or operational error, pilots can respond to a failure by using the best mitigation that has been designed, such as by disabling automatic power control or completing the operation manually [17].

The initial model in the B787 Dreamliner program represented a disruptive technology product innovation within the industry. The program fundamentally altered the supply chain of the industry partnership model [18]. Many strategies and thematic lenses have arisen in the academic community to address various questions in innovation management [19]. Similarities exist in the new product development innovation process within the stages of identifying issues and opportunities, creating and processing ideas, market projections, business analysis, visualization, and execution, as well as expressing the model in service organizations [20]. The current research contains various outstanding challenges concerning the discovery of technology opportunities [21]. Only an appropriate product structure will allow the benefits of product portfolio management to be fully realized [22]. With a restricted budget, a government could determine the appropriate level of subsidy to boost the sales of remanufactured products. The best subsidy is offered when a budget is limited [23]. The creation of a project selection and evaluation tool may potentially be applied to a wide range of research, technology, and investment decisions [24].

An organization that creates a new product invests time and money in the hope that the product will provide a sufficient return on investment. An effective and efficient risk management strategy must be selected to match the specific product development case. Firms that develop products use risk identification, assessment, and mitigation to support their risk management procedures and decision-making [25], where the risks are detectable and manageable. Product development industries are also assisted in incorporating sustainability into strategic, tactical, and operational decision-making [26].

The AHP method is effective for analyzing a complex problem involving the selection of an alternative as a decision from several choices. A problem's complexity stems partially from the presence of numerous influencing criteria. AHP offers a means of breaking down a complicated unstructured scenario into multiple components in a hierarchical order by assigning a subjective value to the relative relevance of each variable and identifying which variable has the highest priority in terms of impacting the outcome of the situation [27]. The AHP method developed by Professor Thomas L. Saaty is widely used for business purposes in companies, government interests, and research.

The AHP method has been widely used in several research fields, for example: The AHP method enables for the evaluation and rating of the device's design elements, resulting in a more reasonable and comprehensive device design [28], The VAHP model is a helpful decision-making tool for transportation planners, policymakers, and other stakeholders in the industry [29].

III. Methodology

The research method employed in this study combined the survey method by distributing questionnaires to experts in the field of UAV development with the AHP method to determine the global priority of the alternatives offered. The research flow is shown in Fig. 1. A literature review was conducted in step one, the criteria for the alternatives presented were determined in step two, a questionnaire was developed in step three and distributed to expert respondents in step four, the data were analyzed in step five, and conclusions were drawn from the research findings in step six. The research questionnaire can be seen in Appendix 1.

A. System Design

In this study, four important criteria were determined, namely: 1) Opportunity (Op): With government policies, sufficient and qualified human resources, and infrastructure for product development, the opportunity is enormous, 2) Budget (Bu): Budgets are needed for initial investment, expert and employee salaries, tool and material purchases, and testing costs, 3) Benefits (B): These include speedier technological mastery, achieving defense industry independence, avoiding embargoes, creating jobs, and producing foreign exchange, and 4) Risk (Ri): The identified risks would manifest in forms such as the program not running smoothly, the goal time being delayed, the product failing, or there being no partner. Fig. 2

shows the AHP structure chart with the existing goals, criteria, and alternatives.

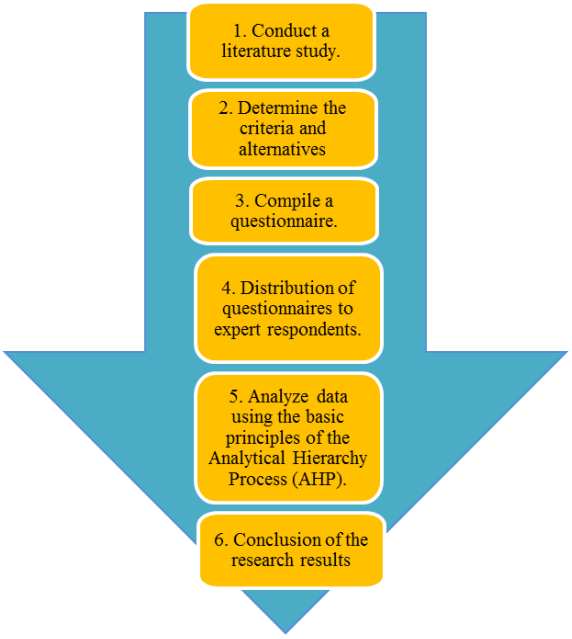

Fig. 1. Research flow.

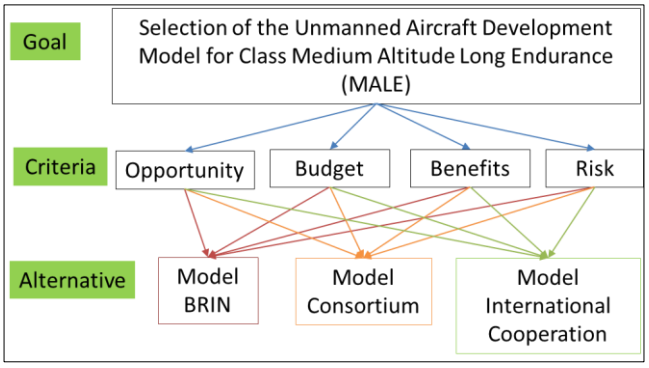

Fig. 2. AHP structure chart.

B. Sampling and Data Collection

The population in this study comprised individuals involved in national research and development on MALE-class drones and their use on the territory of the Republic of Indonesia. Samples were selected by purposive sampling, which is a technique suitable for data sources with specific considerations, such as identifying the person considered to be the most knowledgeable in the area under consideration [30]. Some questionnaires were distributed online to respondents while other respondents were visited face to face. The data were collected from July to August 2022. While the AHP method has no specific formulation for the number of respondents, it must include a minimum of two. The priority in applying the AHP method is the quality of the data derived from the respondents, not the quantity. The respondents in AHP assessments must be experts in order to decide between the alternatives proposed. The experts in this case were competent individuals who had truly mastered and comprehended the situation, influenced policymaking, or knew the information needed.

Table I contains the characteristics of the respondents and shows that 36.4% had undergraduate or diploma degrees while 63.6% had postgraduate degrees, thus indicating a group of participants with a high level of education. In terms of the respondents' age, 18.2% of the population were aged between 41 and 50, 63.6% were aged between 51 and 60, and 9.1% were aged between 61 and 75.

TABLE I. CHARACTERISTICS OF THE RESPONDENTS

Respondent	Age (years)	Education level	Institutions
1	51–60	S3	Head of Aeronautics Technology Research Center, Nasional Research and Innovation Agency (BRIN)
2	51–60	S3	Member of the House Of Representatives - Commission VII (Energy, Mineral Resources, Research and Technology, Environmental Affairs)
3	51–60	S2	Secretary General of Indonesian Aeronautical Engineering Center (IAEC)
4	41–50	S1	Chairman of Unmanned Technology Systems Association (ASTTA) and Director of PT Aeroterra Indonesia
5	31–40	S1	Senior Vice President (SVP) Technology and Research Development Centre of PT LEN Industry
6	51–60	S2	Director of Commerce, Technology, and Development of PT. Dirgantara Indonesia (Indonesian aircraft industries)
7	51–60	S1	Head of Combat Power Division, Research, and Development Agency of the Ministry of Defense
8	51–60	S3	Head of sub-directorate Europe and Africa, Directorate of Defense International Cooperation, Directorate General of Defense Strategy Ministry of Defense
9	41–50	S3	Lecturer at the Faculty of Mechanical and Aerospace Engineering and Head of the Center for Unmanned Studies, Bandung Institute of Technology (ITB)
10	61–75	S3	Head of Technology Transfer and Offset Defense Industry Policy Committee
11	51–60	S1	Head of the Indonesian Air Force's Research and Development Department

C. Research Instruments and Measurements

The research instrument used was a questionnaire with a comparison matrix between the criteria (four criteria) and a comparison matrix between the alternatives (three alternatives) based on the four existing criteria. This study used the nine-point Saaty scale, where 1: equal importance, 3: moderate importance, 5: high importance, 7: very high importance, 9: extreme importance, and 2, 4, 6, 8: intermediate values. In addition, demographic questions were asked, such as age, education, and employment institutions. The research questionnaire is shown in Appendix 1. The researcher then inputted data from the questionnaire results

into a matrix table in Excel software based on the stages in the AHP method (see Appendices 2 to 6).

D. Methods of Analysis

Fig. 3 illustrates the 11 main steps used to obtain the priorities for the unmanned aircraft development model evaluation using AHP, as in [31]; [32]. The study in [33] has written that The AHP is sufficient for decision-making.

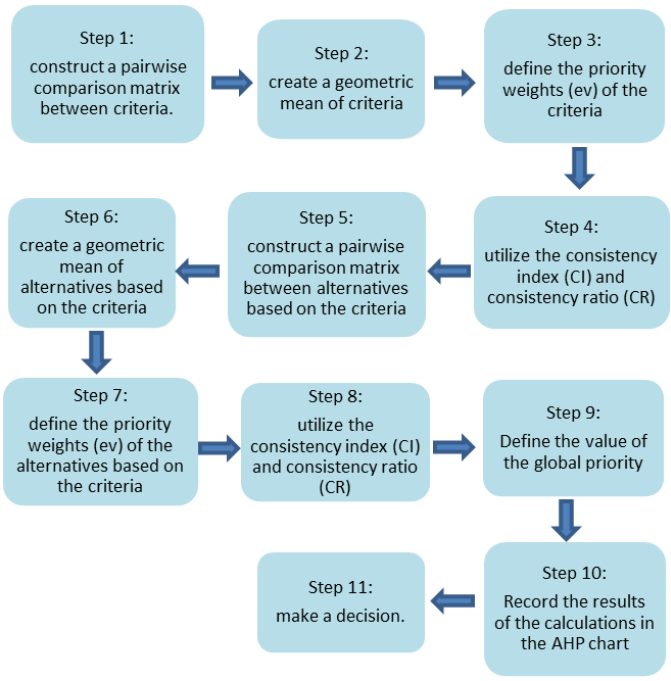

Fig. 3. The main steps used to obtain the global priority.

1) Step 1: Construct a pairwise comparison matrix between the criteria.

Given that there are m responders, there are m pairwise comparison matrixes with n criteria, as shown in Table II below, where, R denotes Respondent:

TABLE II. PAIRWISE COMPARISON MATRIX BETWEEN CRITERIA: INPUT ANSWERS FROM ALL RESPONDENTS

R1	C1	C2	...	Cn		Rm	C1	C2	...	Cn
C1	1	X_{12}	...	X_{1n}		C1	1	X_{12}	...	X_{1n}
C2	$1/X_{12}$	1	...	X_{2n}		C2	$1/X_{12}$	1	...	X_{2n}
...	...	...	1	...		...	...	...	1	...
Cn	$1/X_{1n}$	$1/X_{2n}$	...	1		Cn	$1/X_{1n}$	$1/X_{2n}$	...	1

2) Step 2: Create a geometric mean of criteria

After entering the comparative assessment into the matrix above, an average measurement using the geometric mean (see Appendix 7) (GM) of the m respondents' replies was entered using the formula below, with the values shown in Table III:

$$GM_{12} = \sqrt[m]{X_{12(R1)} * X_{12(R2)} * X_{12(R3)} * \dots\dots * X_{12(Rm)}} \quad (1)$$

$$GM_{21} = \sqrt[m]{X_{21(R1)} * X_{21(R2)} * X_{21(R3)} * \dots\dots * X_{21(Rm)}} \quad (2)$$

$$GM_{n1} = \sqrt[m]{X_{n1(R1)} * X_{n1(R2)} * X_{n1(R3)} * \dots\dots * X_{n1(Rm)}} \quad (3)$$

$$GM_{1n} = \sqrt[m]{X_{1n(R1)} * X_{1n(R2)} * X_{1n(R3)} * \dots\dots * X_{1n(Rm)}} \quad (4)$$

TABLE III. GEOMETRIC MEAN OF M MATRIX OF RESPONDENTS' ANSWERS

GM	C1	C2	...	Cn
C1	1	GM_{12}	...	GM_{1n}
C2	GM_{21}	1	...	GM_{2n}
...	...	...	1	...
Cn	GM_{n1}	GM_{n2}	...	1

3) Step 3: Define the priority weights (ev) of the criteria

Formulas (5) and (6) below were used to calculate and assign the priority weights:

$$\begin{bmatrix} 1 & GM12 & \dots & GM1n \\ GM21 & 1 & \dots & GM2n \\ \dots & \dots & 1 & \dots \\ GMn1 & GMn2 & \dots & 1 \end{bmatrix} \times \begin{bmatrix} 1 & GM12 & \dots & GM1n \\ GM21 & 1 & \dots & GM2n \\ \dots & \dots & 1 & \dots \\ GMn1 & GMn2 & \dots & 1 \end{bmatrix} = \begin{bmatrix} Z11 & Z12 & \dots & Z1n \\ Z21 & Z22 & \dots & Z2n \\ \dots & \dots & \dots & \dots \\ Zn1 & Zn2 & \dots & Znn \end{bmatrix} \quad (5)$$

the GM sum in the 1 row	priority weights	criterion or alternative
Y1 = Z11 + Z12 + ... + Z1n	ev1 = Y1 / Q	C1 or A1
Y2 = Z21 + Z22 + ... + Z2n	ev2 = Y2 / Q	C2 or A2
Y... = Z.... + Z.... + ... + Z...n	ev...= Y.../ Q	....
Yn = Zn1 + Zn2 + ... + Znn	Evn = Yn / Q	Cn or An
total: Q = Y1 + Y2 + Y... + Yn		

(6)

4) Step 4: Utilize the consistency index (CI) and consistency ratio (CR) to evaluate logical consistency via the following steps:

a) Calculate the value of Vector [A]; Multiplication of the geometric mean (GM) matrix with the weight matrix priority (ev) = Vector [A]:

$$\begin{bmatrix} 1 & GM12 & \dots & GM1n \\ GM21 & 1 & \dots & GM2n \\ \dots & \dots & 1 & \dots \\ GMn1 & GMn2 & \dots & 1 \end{bmatrix} * \begin{bmatrix} ev1 \\ ev2 \\ \dots \\ evn \end{bmatrix} = \begin{bmatrix} A1 \\ A2 \\ \dots \\ An \end{bmatrix} \quad (7)$$

b) Calculate the value of Vector [B];

$$Vector\ |B| = \left| \frac{A1}{ev1} \quad \frac{A2}{ev2} \quad \frac{\dots}{\dots} \quad \frac{An}{evn} \right| \quad (8)$$

c) Calculate the maximum Eigenvalue:

$$\lambda_{max} = \frac{summary\ of\ the\ value\ of\ Vector\ B}{number\ of\ criteria\ (n)} \quad (9)$$

d) Calculate CI:

$$CI = \frac{\lambda_{max} - n}{n-1} \quad (10)$$

e) Determine the Random consistency index (RCI):

n (criteria)	1	2	3	4	5	6	7	8	9	10
RCI	0	0	0.58	0.9	1.12	1.24	1.32	1.41	1.45	1.49

f) Calculate CR:

$$CR = \frac{CI}{RCI} \quad (11)$$

If the CR value does not exceed 10% or < 0.1, then the pairwise comparisons between criteria data are consistent/valid.

5) Step 5: Construct a pairwise comparison matrix between alternatives based on the criteria

6) Step 6: Create GM of alternatives based on the criteria

7) Step 7: Define the priority weights (ev) of alternatives based *on the criteria*

8) Step 8: Utilize the consistency index (CI) and consistency ratio (CR) to evaluate logical consistency; The processes in steps 5 to 8 are the same as in steps 1 to 4.

9) Step 9: Define the value of the global priority; Global priority = priority weight of each alternative multiplied by the priority weight of the criteria.

*10)*Step 10: Record the results of the calculations in the AHP *structure chart; and finally*

11)Step 11: Make a decision.

IV. Results And Discussion

A. Priority Weights of Criteria

Table IV shows the priority weights of the criteria. The benefits criterion obtained the highest ratings with a priority weight value of 0.471. This was followed by opportunity, budget, and risk, respectively. Meanwhile, the risk criterion has a very small priority weight, namely 8.8%. The development of MALE-class drones will have significant benefits for the nation, including speedier technological mastery, defense industry independence, and the avoidance of embargoes, job creation, and foreign exchange production.

TABLE IV. Priority Weights of the Criteria

	Op	Bu	Be	Ri	Sum	Priority weight (ev)	Rank
Op	0.255	0.179	0.278	0.338	1.050	0.262	2
Bu	0.243	0.171	0.149	0.148	0.711	0.178	3
Be	0.436	0.548	0.476	0.426	1.885	0.471	1
Ri	0.066	0.102	0.098	0.088	0.354	0.088	4
Sum	1	1	1	1	4	1	

B. Priority Weights of Alternatives Based on the Opportunity Criterion

Based on the calculations in Table V, the following priorities among the alternatives were obtained regarding the opportunity criterion: 1) The consortium (CO) model with a priority weight value of 0.595, 2) The international cooperation (IC) model with a priority weight value of 0.240, and 3) The BRIN (BR) model with a priority weight value of 0.165. A CO model for the development of MALE-class drones has a better chance of success, with the smallest opportunity for the BRIN model.

C. Priority Weights of Alternatives Based on the Budget Criterion

Using the calculations in Table VI, the following priorities among the alternatives were obtained based on the budget criterion: 1) The CO model with a priority weight value of 0.483, 2) The IC model with a priority weight value of 0.357, and 3) The BR model with a priority weight value of 0.160. A larger budget is required to develop the MALE-class drone using a CO model. Budgets are required for initial investment, tool and material purchases, and testing costs. The BRIN model requires the smallest budget.

TABLE V. Priority Weights Of Alternatives Based On The Opportunity Criterion

	BR	CO	IC	Sum	Priority weight (ev)	Rank
BR	0.158	0.148	0.189	0.495	0.165	3
CO	0.633	0.590	0.562	1.785	0.595	1
IC	0.209	0.262	0.249	0.720	0.240	2
Sum	1	1	1	3	1	

TABLE VI. Priority Weights of Alternatives based on the Budget Criterion

	BR	CO	IC	Sum	Priority weight (ev)	Rank
BR	0.158	0.147	0.175	0.479	0.160	3
CO	0.512	0.476	0.460	1.449	0.483	1
IC	0.330	0.377	0.365	1.072	0.357	2
Sum	1	1	1	3	1	

D. Priority Weight of Alternatives Based on the Benefits Criterion

Based on the results of the calculations in Table VII, the following alternative priorities were obtained when considering the benefits criterion: 1) The CO model with a priority weight value of 0.588, 2) The IC model with a priority weight value of 0.260, and 3) The BR model with a priority weight value of 0.152. As such, the use of the CO model when developing the MALE-class drone would yield greater benefits, with the BRIN model providing the lowest benefits.

TABLE VII. Priority Weights of Alternatives based on the Benefits Criterion

	BR	CO	IC	Sum	Priority weight (ev)	Rank
BR	0.143	0.129	0.183	0.456	0.152	3
CO	0.642	0.579	0.543	1.764	0.588	1
IC	0.214	0.292	0.274	0.780	0.260	2
Sum	1	1	1	3	1	

E. Priority Weights of Alternatives Based on the Risk Criterion

The calculation results in Table VIII show that the risk criterion produced the alternative priorities as follows: 1) The IC model with a priority weight value of 0.453, 2) The CO

model with a priority weight value of 0.326, and 3) The BR model with a priority weight value of 0.221. The development of a MALE-class drone with an IC model would carry greater risk, such as the program not running smoothly, a delayed goal time, and product failure. In contrast, the lowest risk is with the BRIN model.

TABLE VIII. PRIORITY WEIGHTS OF ALTERNATIVES BASED ON THE RISK CRITERION

	BR	CO	IC	Sum	Priority weight (ev)	Rank
BR	0.221	0.228	0.216	0.664	0.221	3
CO	0.317	0.328	0.333	0.978	0.326	2
IC	0.462	0.444	0.451	1.358	0.453	1
Sum	1	1	1	3	1	

F. Verify the CR

Tables IX and X show the results obtained from using the CR of the criteria and the alternatives. A CR value < 0.1 indicates that both the pairwise comparison data between the criteria and the pairwise comparisons between the alternatives are consistent or valid.

TABLE IX. RESULT OF UTILIZING THE CONSISTENCY RATIO (CR) OF CRITERIA

Vector [A]	Vector [B]	λ_{max}	CI	RCI	CR
$\begin{bmatrix}1.063\\0.725\\1.920\\0.359\end{bmatrix}$	|4.057 4.073 4.076 4.080|	4.0715	0.0238	0.9	0.0264

Risk	$\begin{bmatrix}0.664\\0.978\\1.358\end{bmatrix}$	|3.001 3.001 3.00	3.001	0.0003	0.58	0.0005

G. Global Priority

Table XI shows that the CO model is the top priority with a score of 0.548, followed by the IC model with a value of 0.289, and, finally, the BR model with a value of 0.163. Fig. 4 shows the AHP structure chart with the priority weights of the criteria and the global priority for the development model of MALE-class unmanned aircraft.

A consortium is a collective structure, collaboration, or cooperation of individuals or institutions. Previous studies have reported its use in a variety of fields, including the tourism market [34], electronic products [35], new medical product development for transplant patients [36], and in the form of an agricultural industrialization consortium in low carbon agriculture [37].

TABLE XI. GLOBAL PRIORITY

	Priority weight (ev) of alternatives					Priority weight (ev) of criteria		Global priority
	Op	Bu	Be	Ri				
Br	0.165	0.160	0.152	0.221		0.262		0.163
CO	0.595	0.483	0.588	0.326	X	0.178	=	0.548
IC	0.240	0.357	0.260	0.453		0.471		0.289
						0.088		

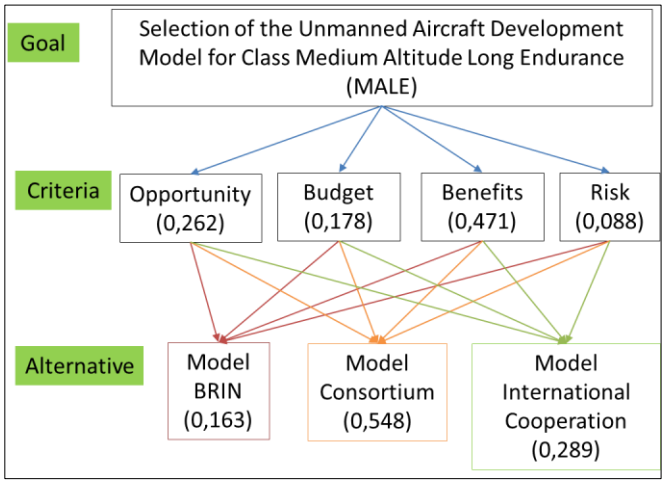

Fig. 4. AHP structure chart with priority weights of criteria and global priority.

V. CONCLUSION

This study sought to identify the most appropriate development model for the MALE class of unmanned aircraft using the AHP method. Based on the four criteria examined, the results show that the alternatives should be considered in the following order of priority: the benefits obtained, the opportunity, the budget required, and, finally, the risk that will arise. The results of the global priority calculation show that the consortium model has the highest value, at 0.548. It can therefore be concluded that the consortium model is the most suitable for the development of MALE-class unmanned aircraft in Indonesia.

A. Limitation

This study focused on respondents who were involved in national research and development for MALE-class drones, as well as their application in the Republic of Indonesia. The sample may thus differ from that of other countries and the findings of the study may not apply to all countries.

B. Recommendations for Future Research

It is recommended that future studies continue to examine the consortium model by studying and exploring the benefits and drawbacks of current such programs. It is hoped that this will provide input and guidance for implementing the next consortium program and help to ensure that the MALE-class

unmanned aircraft development program runs smoothly and as expected.

ACKNOWLEDGMENT

This study was supported by the Republic of Indonesia Defense University, and the National Research and Innovation Agency (BRIN). We are grateful to the director of the doctoral program, and the head of the Aeronautics Technology Research Center, for their assistance with this paper.

***Abstract*—The diagnosis of Autism Spectrum Disorder (ASD) is a crucial, drawn-out, and sometimes subjective procedure that calls for a high level of knowledge. Automation of this diagnostic procedure appears to be possible because to recent developments in machine learning techniques. This paper presents a unique method for improving the performance of a Recurrent Neural Network with a Bidirectional Long Short-Term Memory (RNN-BiLSTM) model for ASD diagnosis by utilizing the power of Artificial Bee Colony (ABC) optimization. Because Python software is used to carry out the implementation, accessibility and adaptability in clinical contexts are guaranteed. The suggested approach is thoroughly contrasted with current techniques, such as ABC optimization for feature extraction, Convolutional Neural Networks (CNN), Long Short-Term Memory (LSTM) models, and Transfer Learning, in order to highlight its effectiveness. The outcomes demonstrate the superiority of the RNN-BiLSTM over other methods, with much greater accuracy and precision. Combining RNN-BiLSTM with ABC optimization demonstrates not just cutting-edge accuracy but also excellent interpretability. By using this sophisticated model's capabilities, an outstanding diagnosis accuracy of 99.12% is attained, which is 2.77% higher than previous approaches. The model helps physicians comprehend the diagnosis process by highlighting important characteristics and trends that influence its conclusion. Additionally, it lessens the subjectivity and unpredictability involved in human diagnosis, which may result in quicker and more accurate diagnoses of ASD. The research emphasizes how well the Artificial Bee Colony optimized RNN-BiLSTM model diagnoses autism spectrum disorder. By integrating AI-driven diagnostic tools into clinical practice, this research improves early diagnosis and intervention for ASD.**

Keywords*—Autism spectrum disorder; artificial bee colony; recurrent neural network; bidirectional long short-term network; artificial intelligence

I. INTRODUCTION

ASD is a neurodevelopmental disorder that is widespread and complicated that has a big influence on how people behave, communicate, and connect with others [1]. It affects people of different ages, genders, and backgrounds and spans a spectrum of symptoms, from moderate to severe. Since ASD was first discovered in the early 20th century, our knowledge of it has grown significantly, resulting in better diagnostic methods and criteria. Making an ASD diagnosis is a difficult, interdisciplinary process [2]. To ascertain the existence and severity of the condition, a variety of behavioral, developmental, and medical traits are usually evaluated. Many times, the diagnosis procedure is a drawn-out and intricate process that greatly depends on the knowledge and skills of clinicians, psychologists, speech therapists, and other medical specialists [3]. A person's quality of life and social integration can be greatly improved by early intervention and customized assistance, both of which are made possible by an accurate and timely diagnosis.

The Diagnostic and Statistical Manual of Mental Disorders and the International Classification of Diseases provide the most current and generally recognized classification of ASD, while there have been previous updates to the diagnostic criteria. These criteria take into account social communication impairments, the existence of repetitive and limited behaviors, and the requirement to evaluate the severity of symptoms in order to make a formal diagnosis [4].

Standardized observation, organized clinical interviews, and gathering comprehensive developmental histories from parents or carers are all common components of the evaluation process [5]. There is some subjectivity in the diagnosis process since these approaches rely on the experience and judgment of specialists to evaluate the behavioral and developmental data. Artificial intelligence combined with contemporary technology has demonstrated significant

potential in aiding in the diagnosis of ASD in recent years. More objective and effective diagnostic tools have been made possible by advances in machine learning algorithms, data analytics, and improved imaging techniques.

These cutting-edge methods seek to decrease subjectivity, increase accuracy, and speed up the diagnosis procedure all of which will eventually help people with ASD and their families. This lays the groundwork for an in-depth examination of the several tools and techniques utilized in the diagnosis of ASD. It will examine conventional diagnostic techniques, the changing digital tool market, and the possible revolution in the sector that AI and ML may bring about. The continuous search for more accurate, trustworthy, and approachable ways to diagnose ASD is a testament to the unrelenting dedication of scholars, medical professionals, and activists to helping individuals impacted by this intricate and varied disorder [6].

Since ASD is a complicated neurodevelopmental disorder that affects people differently, diagnosing it may be difficult and frequently subjective [7]. The long-term results for those with ASD are greatly improved by prompt intervention and specialized assistance, which are made possible by an early and precise diagnosis of the illness. Integrating cutting-edge technologies, including -BC optimization and RNN with BiLSTM, has emerged as a viable way to improve the diagnostic process in response to the urgent demand for more accurate and dependable diagnostic tools [8]. Traditionally, the ability of clinicians, psychologists, and other medical experts to evaluate behavioral observations, developmental histories, and clinical evaluations has been crucial in the diagnosis of ASD. However, as this procedure is fundamentally subjective, there may be differences in the accuracy of the diagnosis and possible delays.

Improving diagnosis techniques is crucial because of the complexity, heterogeneity, and early intervention requirements of ASD. The application of AI and ML in healthcare has created new opportunities to enhance and automate the diagnostic procedure. Large-scale dataset analysis, pattern recognition, and prediction are all impressive skills of machine learning algorithms. Complex temporal patterns and relationships in ASD-related data, such as behavioral observations and patient history, may be captured by RNN-BiLSTM, a recurrent and deep learning model combination [9].

Simultaneously, ML models perform better when nature-inspired optimization methods like ABC optimization are included. ABC optimization finds the best answers by simulating honeybee foraging behavior. It adjusts the hyper parameters of the RNN-BiLSTM model, improving the diagnostic efficiency and accuracy of ASD. In order to solve the difficulties in diagnosing ASD, this research aims to maximize the synergy between cutting-edge AI methodology and optimization strategies [10]. The purpose of this work is to speed the diagnosis of ASD, decrease subjectivity, and improve diagnostic accuracy by presenting the idea of ABC optimized RNN-BiLSTM. These developments might lessen the load on medical staff and the larger healthcare system in addition to enhancing the quality of life for people with ASD and their families. It will examine the technique, findings, and consequences of this novel approach as we dig into the next parts, showing how it advances the continuing search for more accurate and dependable instruments in the field of autism diagnosis.

ASD is a multifaceted neurodevelopmental disorder that manifests as a wide range of symptoms, including as limited interests, repetitive behaviors, and issues with socialization and communication. Improving the long-term results for people with ASD requires early identification and intervention. But making an accurate diagnosis of ASD is a difficult process that frequently depends on the expert opinion of physicians and other professionals. It is crucial to investigate and utilize the potential of cutting-edge technology to improve the diagnosis process since subjectivity can result in variances in diagnostic accuracy. Artificial intelligence and machine learning have advanced significantly in the last several years, with a number of applications including healthcare. With the availability of more impartial, reliable, and consistent evaluation instruments, these developments hold the potential to completely transform the diagnosis of ASD. RNNs and BiLSTMs are two of the many AI approaches that have shown to be effective at processing sequential data. This makes them especially suitable for the study of behavioral and clinical data related to ASD.

Finding the cause of an ASD diagnosis is crucial for impacted individuals as well as their families, teachers, and the general public [11]. ASD is a multifaceted neurodevelopmental disorder that presents with a wide range of symptoms and problems, including trouble with social communication, repetitive behaviors, and narrow interests. Effective ASD diagnostic methods and procedures are desperately needed for a number of compelling reasons, including the need of timely and accurate diagnosis. First and foremost, early action is made possible by early diagnosis. Although ASD is a lifelong illness, people on the spectrum can greatly enhance their quality of life and long-term results by receiving the right therapies and interventions at an early age.

When ASD is discovered early on, it is easier to start behavioral and educational treatments, speech and occupational therapy, and social skill development. Early diagnosis also makes it possible for families to better comprehend and assist their loved ones who have ASD. It facilitates the development of a more accepting and inclusive environment for people with ASD by assisting parents and other carers in navigating the difficulties and special requirements related to the disease. Early diagnosis allows families to get in touch with advocacy and support groups, giving them access to important tools and advice [12].

In the field of education, prompt diagnosis is essential to deliver customized and relevant curricula. Individualized Education Plans (IEPs) and accommodations can be implemented by educators and schools to make sure that kids with ASD get the help they need to succeed in the classroom. Fostering a student's intellectual and social growth requires an understanding of their unique strengths and difficulties. Additionally, the identification of ASD is essential for

resource allocation and public health planning. Healthcare systems can anticipate the demands on resources and services needed to serve people with ASD when they have accurate prevalence data. Governments and healthcare professionals need to know the extent of the problem in order to deploy resources wisely, as the incidence of ASD has been rising. Finally, early diagnosis also helps to lessen the long-term potential strain on the social assistance and healthcare systems.

People with ASD are more likely to acquire the skills required for independent functioning when early treatments and assistance are provided, which lessens their long-term dependency on intensive support services. These strong arguments make it more important than ever to have trustworthy, easily available, and effective ASD diagnosis methods. In order to guarantee that people with ASD receive the support and opportunities they deserve, researchers, clinicians, and the larger healthcare community are always striving to improve and innovate diagnostic methodologies. By doing this, they are making significant progress towards a society that is more accepting and understanding of one another.

In order to fully realize the promise of ABC optimization, this research explores a novel strategy that blends the advantages of AI with optimization methods inspired by nature. The goal of the RNN-BiLSTM model's integration of ABC optimization is to improve the precision and effectiveness of ASD diagnosis. We want to reduce the subjectivity present in conventional diagnostic approaches by improving the diagnostic capabilities of the model through hyper parameter optimization. This research project not only satisfies the urgent demand for more impartial and trustworthy ASD diagnosis instruments, but it also serves as an example of how AI and optimization techniques may work together in the healthcare industry.. Combining RNN-BiLSTM with ABC optimization presents a viable way to diagnose ASD more quickly, which might help affected individuals, carers, and physicians better understand the illness and enable early intervention.

The key contributions of the article is:

- By fusing two potent machine learning techniques BiLSTM and ABC optimization the research presents a novel diagnostic strategy. By combining the best features of both approaches, this innovative approach develops a strong foundation for diagnosing ASD.
- The investigation demonstrates the adaptability of ABC optimization in optimizing hyper parameters and also its efficacy in selecting the most useful features for precise diagnosis of ASD by integrating it into the feature extraction process.
- By employing Python software to construct the suggested paradigm, the study demonstrates its clinical usefulness. This guarantees flexibility and accessibility in actual clinical situations, which makes it a useful tool for medical practitioners.
- The study's impressive 99.12% diagnosis accuracy demonstrates the potential of the suggested RNN-BiLSTM model that has been optimized using ABC. This degree of precision is a major advancement over current techniques, lowering the possibility of false positives and boosting the procedure' dependability.

The remaining content of this article is arranged as follows: A synopsis of relevant research is given in Section II. The problem statement is provided in Section III. The article's Section IV explains the architecture and methodology of the recommended approach. Section V discusses the results and the debate that followed. Section VI discusses the conclusion.

II. Related Works

The need for efficient and effective medical diagnostic systems in the context of ASD detection and treatment is paramount [13]. Healthcare professionals often spend considerable time documenting and processing extensive remarks related to patient behavioral assessments. Early identification of ASD is vital for ensuring individuals receive appropriate care and treatment, ultimately improving their quality of life. Machine learning models present a promising avenue to explore the feasibility of identifying essential features and accurately assessing the presence or absence of autism. In this study, the objective is to create a recommendation model that leverages multiple classifiers to enhance the precision of ASD prediction. This study conduct experiments with a range of machine learning algorithms to assess the model's performance. The results indicate that, when considering evaluation metrics such as accuracy, precision, recall, and F1-score, Decision Trees and Random Forests outperform other algorithms.

Through the analysis of children's abnormal social patterns, behavioral observation is crucial in the diagnosis of ASD [14]. Even now, a significant portion of this procedure still depends on clinical observations, questionnaire surveys, or retrospective video analysis, which drives up the demand for experts and drives up labor costs. This work suggests a standardized platform for applying computer-aided ASD diagnosis to human behavioral data collection, analysis, modelling, and interpretation. The suggested system could automatically assess children's various social interaction abilities utilizing the recorded audio-visual data through an organized evaluation process, and it could additionally provide the ultimate diagnostic recommendations. During the research at a Chinese hospital, data was gathered from both ASD-afflicted (72 individuals) and non-ASD (24 individuals) patients, totaling 95 participants. According to the clinical database, the newly created computer software designed to aid in the identification of ASD in children has achieved an 88% accuracy rate. 42% accurate it works well with children who are around two years old and is as good as experienced doctors in diagnosing ASD. This solution can be easily shared and used in areas with fewer medical resources.

ASD is a neurodevelopmental disorder that impacts the way the brain forms and involves struggles in perceiving and responding to stimuli [15]. The challenges encountered in understanding their senses may hinder their ability to act appropriately and impede their cognitive and educational

development. The goal of this study was to see how the nervous system of children with autism and children without autism responds to sounds, images, and just sounds using a method called EEG. In this research, they looked at 20 children with ASD and 20 children with TD (typical development) to see how their brains work differently. The way the brain behaves can be studied by analyzing the EEG signal using non-linear methods. In this research, RQA is used to understand the hidden patterns in EEG data that are not linear. The RQA measures were studied by making different changes to the parameters used in the RQA calculations. In this research, our focus was on the cosine distance metric as it exhibits proficiency in information retrieval, and we contrasted different distance metrics to ascertain the most suitable biomarker. It examined and talked about every combination of the RQA measure and the corresponding channel. To determine if someone has autism or not, it used the features generated by a technique called RQA. These features were then inputted into a special type of neural network called BiLSTM. It tested how accurately we could classify the channels for each combination. When it comes to distinguishing between ASD and TD, the combination of T3 and T5 channels, along with selecting a fixed number of nearby neighbors and utilizing cosine as the distance measurement method, is widely regarded as the most successful, achieving an accuracy rate of 91.86%.

Stoddard et al. [16] critically examined the internal consistency of the Aberrant Behavior Checklist (ABC), Irritability Subscale (ABC-I), and its connection with additional indicators of irritability in 758 psychiatrically hospitalized youth with autism spectrum disorder, given its frequent use in clinical outcome research. Research performed factor and factor analysis in both confirmatory and exploratory datasets to characterize the ABC-I's internal structure. Based on factor analysis, a general factor suggests that the ABC-I represents approximately a one-dimensional idea of irritation. Apart from irritability, tantrums, verbal outbursts, self-harm, and poor affect are also shown as subordinate components. Notably, independent of irritation, self-harm factors account for a significant percentage of variance. As such, their input into studies of treatment effects ought to be taken into account. In therapy trials addressing irritability in ASD, more research or revisions to the ABC-I may enhance convergent validity with transdiagnostic formulations of irritation and avoid confounding from self-harm.

Due to the limited therapy available for ASD, the adoption of alternative interventions, such as gluten-free and casein-free (GFCF) diets, is common [17]. Objectives were to ascertain the impact of a GFCF diet on behavioral issues in kids and teens with ASD diagnoses and any possible correlation with urine beta-casomorphin levels. For this crossover trial, thirty-seven participants were enrolled. Every patient had a regular diet for six months, which included casein and gluten, and then a GFCF diet for an additional six months. The intervention's sequence beginning with the GFCF diet or the regular diet was decided at random. Three time points were assessed for the patients: before the trial started, following a regular diet, and following a GFCF diet. At each time point, urine beta-casomorphin concentrations were measured and questionnaires about diet compliance, behavior, and autism were filled out. Following the GFCF diet, there were no discernible behavioral alterations and no correlation with urine beta-casomorphin contents. Urinary beta-casomorphin concentrations and behavioral signs of autism do not significantly change after six months on the GFCF diet. More research with a lengthy follow-up period, comparable to ours, including components of blinding and placebo are required to more accurately identify those who responded to GFCF diets.

The diagnosis of ASD in children relies on several parameters, including social skills, repetitive behaviors, speech, and nonverbal communication [18]. Repetitive behavior is a crucial indicator for physicians when determining drug dosages, particularly in cases where the child exhibits increased aggressiveness as a symptom of the disorder's progression. To address the need for continuous monitoring and to replace the somewhat subjective measurement of repetitive behavior using the Aberrant Behavior Checklist, the paper introduces an innovative solution through the utilization of the IP Webcam app for ASD recognition. The proposed method employs activity detection to recognize changes in the behavior of autistic children, specifically in response to medication overdosages. This hybrid framework incorporates training a deep CNN model, utilizing the Autismdata.Net dataset, to monitor ASD children in their natural environment. Furthermore, transfer learning is employed to mitigate overfitting issues associated with the relatively small Autismdata.Net dataset when assessing the severity of the child's condition. The ASD children's behavior is evaluated using the Autismdata.Net dataset and validated by examining the thermoregulation of autistic children in response to medication. The proposed method demonstrates significantly improved action recognition accuracy compared to traditional clinical analysis or therapist observations. Ultimately, this system offers valuable support to physicians in regulating drug dosages for children with ASD.

The literature review emphasizes how important it is to have reliable and efficient medical diagnostic procedures in order to identify and treat ASD. It highlights how crucial early detection of ASD is to better patient treatment and overall quality of life. An intriguing strategy to improve the prediction accuracy of ASD is the exploration of machine learning models. The use of several machine learning algorithms is covered in the review, with DT and RF emerging as the best options. It also emphasizes the value of computer-aided diagnosis, especially when examining behavioral data, and provides a common platform for evaluating children's social interaction skills. Remarkably, an investigation conducted in a Chinese hospital identified ASD in youngsters with 88% accuracy, even surpassing that of board-certified physicians. The article also explores how EEG data processing is used to study how children with ASD's neurological systems react to stimuli differently. This study uses neural networks and other non-linear techniques, such as RQA, to categorize people with a 91.86% accuracy rate. The review also addresses the Aberrant Behavior Checklist's internal coherence and applicability to the topic of irritability in ASD. Lastly, it discusses the use of casein- and gluten-free diets as substitute

therapies for ASD and emphasizes the need for more study in this field. Overall, the study emphasizes how important cutting-edge methods are for diagnosing and treating ASD, such as ML, EEG analysis, and nutritional therapies.

As part of the review of literature, a thorough analysis is carried out to evaluate the technologies and procedures that are currently being used in the field of diagnosing ASD, providing a background for the current research. An analysis of previous research reveals a range of methodologies, each with unique advantages and disadvantages. Notably, some approaches show excellent diagnostic accuracy, but their practical use in clinical settings is hampered by their lack of interpretability. On the other hand, other studies rely on assumptions that can be viewed as unjustified or fail to take into account the subtle differences that exist across various demographic groups. This review of the literature highlights the contributions made by earlier researchers while also pointing out the shortcomings and gaps that have been found and are being addressed by current research. This nuanced view emphasizes how important it is to build on past successes and make new contributions that are specifically designed to address weaknesses in order to further the development of ASD diagnosis techniques.

III. Problem Statement

From the above discussed literatures, it states the diagnosis of ASD presents a significant difficulty due to its deep subjectivity and intrinsic heterogeneity in evaluation, which can lead to premature treatments. The subjective knowledge of doctors plays a major role in current diagnostic techniques, which introduces significant swings in diagnostic accuracy. This research project introduces a novel method that makes use of ABC optimization to address the urgent problem of improving ASD diagnosis. It carefully adjusts an RNN-BiLSTM architecture's hyper parameters, solving the fundamental problem of the pressing need for an ASD diagnosis tool that is more streamlined, accurate, and objective. This innovation has the potential to improve early interventions by reducing subjectivity and expediting the diagnostic process. This will ultimately benefit the lives of individuals on the autism spectrum and their families, who are working towards a future that is more accepting and helpful [19].

IV. Proposed ABC-RNN-BiLSTM Framework

This study's technique focuses on improving the diagnosis of ASD by applying ABC optimization to an RNN-BiLSTM. The first step of the procedure is gathering and preparing a large dataset. It then applies the ABC optimization approach to adjust the RNN-BiLSTM model's hyper parameters. For smooth implementation and accessibility in clinical settings, Python software is used.

The suggested RNN-BiLSTM is then compared with other widely used techniques in a comparative study. Feature extraction makes advantage of ABC optimization. The study assesses the model's interpretability and diagnostic accuracy, emphasizing its capacity to mitigate the subjectivity and unpredictability that come with human diagnosis while illuminating significant traits and patterns impacting the diagnostic process. It is depicted in Fig. 1.

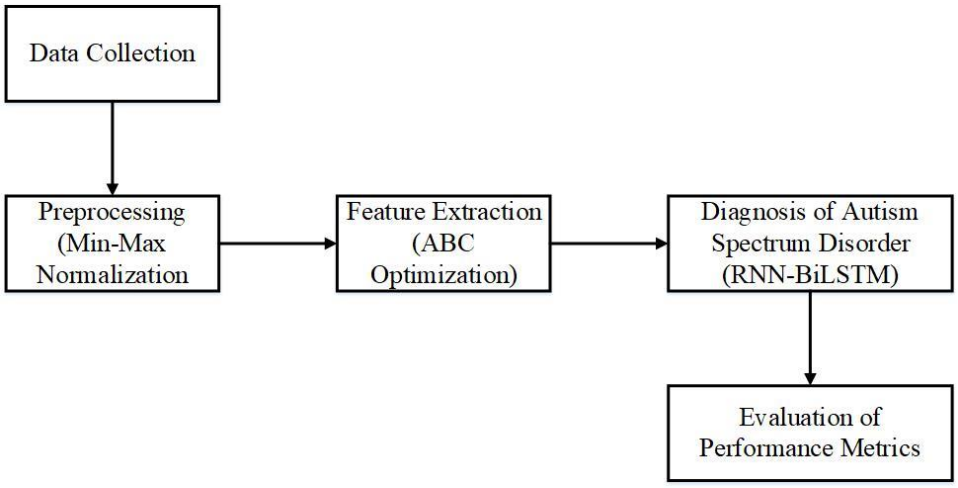

Fig. 1. Proposed ABC-RNN-BiLSTM framework.

A. Data Collection

The dataset used in this study was downloaded from Kaggle and consists of survey answers from people who filled out an application, labelled with whether or not the person was diagnosed with autism. This dataset provides insights into the traits and attributes that may be suggestive of ASD in individuals, making it an invaluable tool for research on ASD and its diagnosis. Using this dataset, the study intends to investigate how machine learning and AI methods, such as feature selection and classification algorithms, can enhance the precision and efficacy of ASD diagnosis, leading to improved early intervention and assistance for people on the autism spectrum [20]

B. Min-Max Normalization for Preprocessing

Preprocessing is a crucial first step that carefully plans data optimization in the goal of diagnosing autism. The application of Min-Max Normalization, a reliable approach that helps to harmonize the several data sources obtained from the patients, is key to this procedure. In order to guarantee that

each contributor has an equal weight inside the model, Min-Max Normalization expertly scales and standardizes these varied data inputs to a consistent range between 0 and 1. This harmonization reduces any unwanted effects brought on by data discrepancies, creating a setting that supports the RNN-BiLSTM increased accuracy. In addition to strengthening the resilience and preparedness of the early warning system, this standardized data bedrock serves as the cornerstone of more precise autism diagnosis. The actual data n is transformed linearly by Min-Max Normalization into the desired interval min_{new}, max_{new}.

$$n = min_{new} + (max_{new} - min_{new}) * (\frac{n - min_x}{max_x - min_x}) \quad (1)$$

The process has the advantage of appropriately preserving all links between the data bits. The data won't undergo any unfavorable alterations.

C. Feature Extraction using Artificial Bee Colony

The traditional ABC method, introduced by Karaboga in 2005, is a swarm-based artificial algorithm inspired by the foraging behavior of bee populations. During their foraging activities, honeybees are categorized into three distinct groups: employed bees, onlookers, and explorers. The employed bees are responsible for collecting nectar and exchanging information, the explorers are tasked with discovering new food sources, and the onlookers play a crucial role in determining the most efficient flight paths. Explorers seek out food resources based on their past experiences or sometimes by venturing randomly, and they may recruit fellow hive members to gather pollen while retaining valuable information about the food sources they encounter.

The conventional ABC approach, founded on simulating bee foraging behavior, serves as a swarm intelligence algorithm introduced by Karaboga in 2005 [21]. In this approach, honeybees are divided into three roles: employed bees, onlookers, and explorers, with each group contributing to the collective foraging success of the colony. Conversely, on the flip side, the onlookers' selection of the most efficient pollen-gathering path is influenced by their knowledge of food resources obtained initially and their decision to abandon those with lower nectar reserves.

In the conventional ABC technique, the number of explorers and the accuracy of information retained by employed honeybees regarding food sources have a significant impact on the tracking speed and overall effectiveness. According to various references in the conventional ABC method, if inaccurate data is incorporated, it can lead to suboptimal path optimization by onlookers, ultimately slowing down the tracking speed in later stages. Consequently, there is a need to implement novel strategies aimed at enhancing tracking performance [22].

As the number of bee's increases, the precision of tracking also improves. On the contrary, reducing the number of pollinators can lead to a shorter procedure duration, although it can pose challenges in pinpointing the optimal solution. This is because the method executed using a microcontroller has a search duration that directly correlates with the bee population size, resulting in a longer procedure time for a larger population. As a result, to address the challenge of attaining the global optimum within a limited number of iterations due to a reduced number of bees, an enhanced approach employing an ABC method with a minimal number of pollinators in conjunction with the RNN-Bi-LSTM technique is introduced and applied to forecast ASD.

The paper introduces an optimized RNN-Bi-LSTM hybrid network model, which is enhanced using the ABC algorithm to improve the reliability of forecasts. During the search phase, the algorithm aims to find a globally optimal solution to enhance the resolution. The equation being sought is as follows:

$$B_{uv}^{new} = B_{uv} + r_1 \times (B_{uv} - B_{neighbour,v}) + r_2(O_v - H_{uv}) \quad (2)$$

When presenting the global best solution, the ABC approach prioritizes honey sources that exhibit high adaptability while reducing the diversity within the bee colony. This can lead to the issue of early convergence, resulting in the emergence of localized optima. To address this, the enhanced ABC algorithm incorporates flexible parameter adjustments that help maintain the convergence rate and population characteristics. The search equation for this improved ABC algorithm is then derived:

$$B_{uv}^{new} = F_1 \times B_{uv} + F_1 \times r_1 \times \left(B_{uv} - B_{neighbour,v}\right) + F_2 \times r_2(O_v - H_{uv}) \quad (3)$$

$$F_1 = F_{max} - (2 - e^{\frac{iterate}{\max cycle} ln2})(F_{max} - F_{min}) \quad (4)$$

$$F_2 = F_{min} - (2 - e^{\frac{iterate}{\max cycle} ln2})(F_{max} - F_{min}) \quad (5)$$

$$Q_i = \frac{1/Fitness_i}{\sum_{j=1}^{n} 1/Fitness_j} \quad (6)$$

Due to the utilization of the reverse martingale feature selection method, the subsequent bees will place a higher emphasis on searching for nectar resources with limited adaptability during the initial phases of the process.

$$\propto = e^{\frac{iterate}{\max cycle} ln2} - 1 \quad (7)$$

Q_i equation and solutions B_i are optimized as follows:

$$Q_i = \begin{cases} \frac{\boldsymbol{Fitness_i}}{\sum_{j=1}^{n} \boldsymbol{fitness_j}} & , \boldsymbol{random} > \propto \\ \frac{\boldsymbol{1/Fitness_i}}{\sum_{j=1}^{n} \boldsymbol{1/Fitness_j}} & , \boldsymbol{random} < \propto \end{cases} \quad (8)$$

A colony of artificial bees are employed in iterative phases to represent dataset features as food sources in the adaption of the ABC algorithm for feature extraction in the diagnosis of ASD. These bees investigate feature subsets and assess their quality using a fitness function during the employed bees phase. Based on the findings of the employed bees, onlooker bees choose feature subsets, and if no progress is observed, scout bees investigate completely new subsets. Utilizing dynamic parameter adjustments, the ABC algorithm balances exploration and exploitation to optimize feature selection. Through effective feature selection and search, reduction of noise and redundancy, and improved ASD categorization, this strategy improves diagnosis accuracy.

D. RNN-BiLSTM for the Diagnosis of Autism Spectrum Disorder

There is a lot of potential in using an RNN-BiLSTM architecture to diagnose ASD. The diagnosis of Autism Spectrum Disorder is a complex task that necessitates the examination of large amounts of behavioral data, frequently spanning many time periods. RNN-BiLSTM's special benefit is its remarkable capacity to represent time relationships in this data. Complex time-dependent trends in behavioral observations are captured by the BiLSTM component by taking into account both past and future context in the sequences. This is especially important to consider when evaluating developmental milestones, social interactions, and repeated behaviors, all of which change with time. The ability to identify minute alterations and abnormalities that might be crucial markers of ASD is provided by the use of RNN-BiLSTM in the diagnostic procedure, which improves the precision and accuracy of the diagnosis.

The diagnostic procedure gains interpretability thanks to the RNN-BiLSTM model. It pinpoints important characteristics and trends that influence its diagnostic judgments, which may be extremely helpful for medical professionals in comprehending the elements influencing the diagnosis. This openness can help in the creation of more specialized and focused therapies for people with ASD. RNN-BiLSTM plays a critical role in enhancing ASD diagnosis by giving medical professionals a better understanding of the diagnostic procedure and the tools they need to make wise judgments. It is a major advancement in the direction of more dependable and effective diagnostic instruments that can hasten early intervention and improve the quality of life for people on the autism spectrum and their families.

An excellent tool in many domains, from time series analysis to natural language processing, are RNNs, a family of ANN that specialize in modelling sequential data. The fundamental function of RNNs is to process data having a time-based or sequentially structure, in which inputs are handled in connection to one another rather than separately from one another. A hidden state that changes over time and retains data from previous observations is a key component of an RNN's basic design. RNNs are particularly well-suited for tasks like speech recognition, language production, and sentiment analysis because of their dynamic memory mechanism, which enables them to identify and remember patterns within sequential data.

Traditional RNNs do have certain drawbacks, though, particularly when it comes to managing long-range dependencies. The vanishing gradient issue can make it difficult for deep RNNs to learn and retain information over long sequences. Variants with more intricate gating mechanisms, such as LSTM, were developed to meet this problem. These architectures improve RNNs' capacity to learn and retain important information over long sequences, which makes them a key component of contemporary machine learning for a variety of uses, such as speech recognition, machine translation, and even the diagnosis of conditions like ASD, where it is crucial to model the behavioral data's time frame evolution.

$$y_{in}=\partial(WE^{iny}x_{in}+WE^{hy}h_{im-1}) \quad (9)$$

$$rg_{in}=(WE^{inrg}y_{in}+WE^{hrg}h_{in-1}) \quad (10)$$

Here, the weight metrics WE_{RMM} are indicated as WE^{iny}, WE^{inrg},and WE^{hrg},

The logistic sigmoid function is termed as ∂: In the hidden unit, the candidate state is formulated in,

$$\check{h}_{in}=\tan(WE^{inh}\ y_{in}+WE^{hy}(h_{in-1}\otimes rg_{in})) \quad (11)$$

Here, the element wise multiplication is termed as,

$$\text{While } h_{in}=(1-y_{in})\otimes\hat{h}_{in}+y_{in}\otimes h_{in-1}h_{in} \quad (12)$$

$$=(\ (1-y_{in})\otimes\hat{h}_{in}+y_{in}\otimes\ h_{in-1}h_{in} \quad (13)$$

The reset gate essentially makes the device behave as though it is examining the power source first representation of a feedback sequence when it is closest to 0, enabling it to forget the previously established state.

Adaptable and dynamic, BiLSTM is a deep learning architecture that can handle jobs involving sequential data processing. It is a development of the classic LSTM model that improves on its ability to identify dependencies in sequential data. The primary novelty of BiLSTM is its directionality, which enables it to analyze sequences taking into account context from both the past and the future. Through the use of two distinct LSTM networks one for forwarding data and the other for backwards BiLSTM is able to fully comprehend the temporal correlations present in the data. This bidirectional analysis is particularly helpful in situations when a data point's interpretation heavily depends on observations from the past and the future. As a result, BiLSTM performs exceptionally well in a variety of fields, including as voice recognition, natural language processing, and time series analysis, where the ability to comprehend context is crucial for making precise predictions.

The vanishing gradient problem, one of the main issues with conventional RNNs, is lessened by BiLSTM. Standard RNN gradients can get very tiny in deep sequences, which hinders learning and makes it difficult for the model to capture long-range relationships. By ensuring that information moves more freely across the network, the gating methods of the BiLSTM enable it to represent lengthy sequences efficiently and avoid running into the vanishing gradient problem.

In applications like as machine translation, where the link between words or symbols may span the whole phrase, its ability to simulate long-range dependencies is very significant. Therefore, by addressing the difficulties of comprehending and interpreting sequential information, BiLSTM's improved capacity to handle sequential data with both short- and long-term dependencies makes it a fundamental building block in many contemporary deep learning applications, empowering advancements in diverse fields.

An effective and adaptable deep learning model, the combined RNN-BiLSTM architecture is well-suited for sequential data processing. The advantages of both classic

RNNs which are excellent at capturing temporal dependencies and BiLSTM which takes into account both past and future are combined in this hybrid technique. As a consequence, the model gains a thorough knowledge of sequential information, which helps it identify complex patterns and relationships in any type of data be it behavioral observations, time series data, or natural language text.

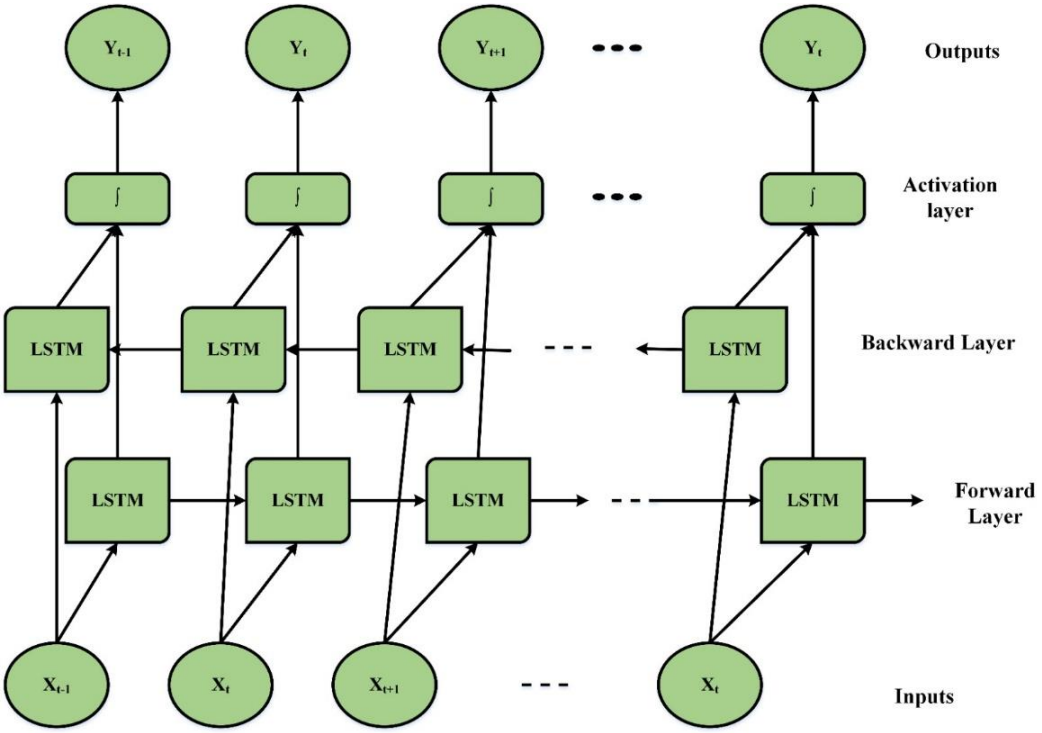

Fig. 2. Architecture of RNN-BiLSTM.

BiLSTM allows for a more sophisticated understanding of the context inside sequences, which is especially useful for applications like voice recognition, sentiment analysis, and, most importantly, the diagnosis of complex disorders like ASD. This hybrid architecture is a key component of state-of-the-art machine learning systems because of its capacity to extract both short- and long-range relationships from data. Fig. 2 shows the architecture of RNN-BiLSTM.

V. Results and Discussion

Through the use of ABC optimization, an RNN-BiLSTM is optimized in this study to improve the diagnosis of ASD. A thorough dataset is gathered and preprocessed at the start of the procedure. The RNN-BiLSTM model's hyper parameters are then adjusted using the ABC optimization approach. The use of Python software facilitates implementation and ensures accessibility in medical contexts. Next, a comparative study is carried out, whereby the suggested RNN-BiLSTM is contrasted with other widely used techniques. For feature extraction, ABC optimization is employed. The study assesses the model's diagnostic accuracy and interpretability, emphasizing its capacity to clarify significant traits and patterns impacting the diagnostic procedure while reducing the subjectivity and unpredictability inherent in human diagnosis.

Model accuracy, which shows the percentage of properly predicted instances among all the instances in a dataset, is a crucial performance statistic in machine learning and predictive modelling. It measures how well the model can predict the future and shows how closely the model's output matches the real results or the ground truth. Accuracy is a percentage that indicates how well the model performs overall in categorizing or forecasting results; higher accuracy values indicate a stronger ability to generate accurate predictions. Although accuracy offers a comprehensible and transparent indicator of a model's efficacy, it is crucial to take into account the particular problem context and possible class disparities, since a model's exceptionally high accuracy may not necessarily indicate that it can generalize well across various datasets or conditions. The model accuracy of the proposed method is depicted in Fig. 3.

Model loss, also known as the objective function or loss function, is a crucial parameter in deep learning and machine learning that measures how different the model's predictions are from the real target values. It calculates the prediction error, or loss, of the model and provides the foundation for fine-tuning its parameters as it is being trained. The main objective is to minimize the loss, a sign that the real values and the model's predictions are quite near. There are several different types of loss functions, such as cross-entropy for classification tasks and mean squared error for regression tasks. In order to guarantee that machine learning models provide precise and accurate predictions, monitoring and minimizing the loss function is essential during the training process. This will eventually improve the models' performance and predicted. It is depicted in Fig. 4.

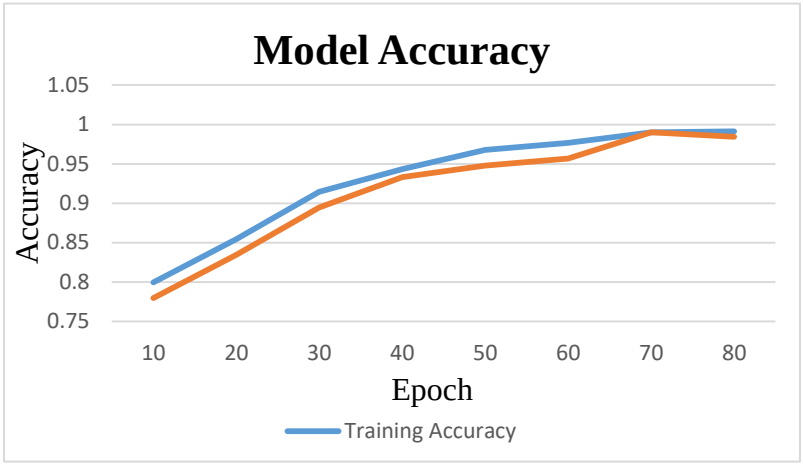

Fig. 3. Model accuracy.

Fig. 4. Model loss.

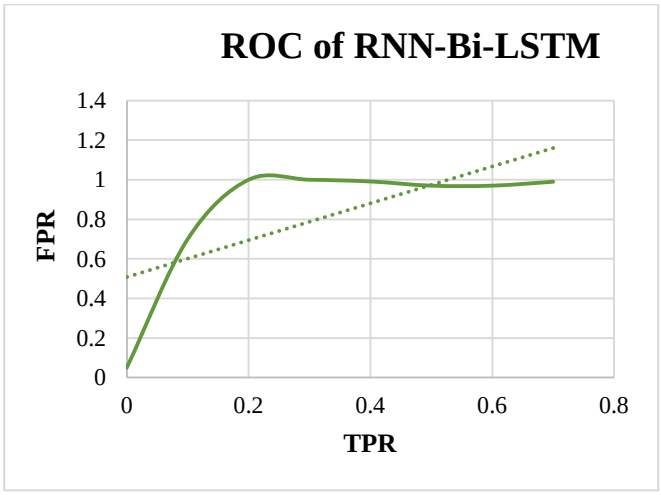

Fig. 5. ROC curve.

A thorough assessment has been conducted on the effectiveness of the suggested method, which diagnoses ASD by combining the RNN-Bi-LSTM with the ABC algorithm. The Receiver Operating Characteristic (ROC) curve is a useful tool for evaluating the diagnostic performance of classification models and is one of the primary metrics demonstrating the efficacy of the system. The ROC curve for the suggested system, which has attained an exceptional diagnostic accuracy of 99.12% in the context of ASD diagnosis, is presented in this analysis. Fig. 5 illustrates the graphical depiction of a classifier's capacity to discern between positive and negative situation is called a ROC curve. Across various categorization thresholds, it compares the True Positive Rate (Sensitivity) against the False Positive Rate (1-Specificity). One widely used statistic to measure a model's discriminatory capacity is the area under the ROC curve (AUC). An AUC of 1 would indicate a flawless model, whereas an AUC of 0.5 would indicate a random estimate.

A. Fitness Assessment of the Proposed System

The suggested method, which combines RNN-Bi-LSTM with the ABC algorithm for diagnosing ASD, is being evaluated for its fitness using a wide range of criteria, including accuracy of diagnosis, relevance of feature selection, generalization to new cases, computational efficiency, robustness to noisy data, interpretability of results, comparison with other proven diagnostic techniques, practical application in clinical settings, optimization of model hyper parameters specify In light of the particular nuances and difficulties associated with diagnosing ASD, this evaluation seeks to ascertain the system's efficacy in accurately diagnosing the disorder, as well as its capacity to identify the most informative features, generalize findings to a range of patient profiles, and provide useful assistance to clinicians. The suggested ABC method's fitness assessment is graphically represented in Fig. 6.

The overall performance of the system model is assessed using accuracy. The core idea behind it is that every encounter can be accurately predicted. Eq. (14) is utilized to provide the accuracy.

$$Accuracy = \frac{T_{Pos} + T_{Neg}}{T_{Pos} + T_{Neg} + F_{Pos} + F_{Neg}} \quad (14)$$

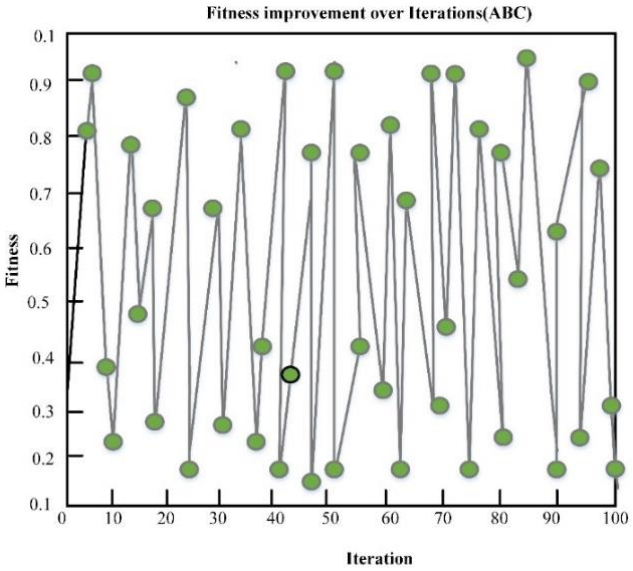

Fig. 6. Fitness assessment of ABC.

In addition to being accurate, precision also characterizes how similar two or more computations are to one another. The relationship between precision and accuracy demonstrates how frequently viewpoints can shift. It is brought up in Eq. (15).

$$P = \frac{T_{Pos}}{T_{Pos} + F_{Pos}} \tag{15}$$

Recall is the proportion of all relevant findings that were successfully sorted using the approaches. For these numbers, the appropriate positive is obtained by dividing the true positive by the falsely negative values. In Eq. (16), the phrase is mentioned.

$$R = \frac{T_{Pos}}{T_{Pos} + F_{Neg}} \tag{16}$$

Accuracy and recall are combined in the F1-Score calculation. Apply Eq. (17), which divides the recall by the accuracy to find the F1-Score.

$$F1 - score = \frac{2 \times precision \times recall}{precision + recall} \tag{17}$$

A comparison of several techniques for diagnosing ASD is shown in Table I, with an emphasis on important performance indicators such as F1-Score, Accuracy, Precision, and Recall. Remarkably, the outcomes show that the Proposed RNN-BiLSTM approach performs better than the other methods, with an F1-Score of 98.11% and remarkable results of 99.12% accuracy, 99% precision, and 98.99% recall. This suggests that the RNN-BiLSTM model has excellent diagnostic performance and can predict ASD with a high degree of accuracy. Although the Transfer Learning method also performs exceptionally well, its accuracy and recall are somewhat worse than those of the RNN-BiLSTM model. However, although still producing excellent results, the conventional CNN and LSTM models are inferior to the suggested RNN-BiLSTM in every metric. The RNN-BiLSTM's remarkable performance highlights its promise as a robust diagnostic tool for ASD, lowering subjectivity and improving the precision and dependability of early treatments and support for people on the spectrum. These results imply that cutting-edge deep learning methods, like the RNN-BiLSTM model, have enormous potential for use in healthcare and greatly enhance the ability to diagnose difficult neurodevelopmental disorders like ASD. In Fig. 7, it is shown.

TABLE I. COMPARISON OF PERFORMANCE METRICS

Methods	Accuracy (%)	Precision (%)	Recall (%)	F1-Score (%)
CNN	95	92.35	98.91	97.89
LSTM	96.77	97.34	96.36	97.12
Transfer Learning	97.57	98.52	97.56	95.56
Proposed RNN-BiLSTM	99.12	99	98.99	98.11

B. Discussion

The study's results provide strong evidence for the usefulness of the suggested ABC-optimized RNN-BiLSTM model for diagnosing ASD. The diagnostic accuracy of 99.12% is an amazing result that puts the model well ahead of current approaches, outperforming them by 2.77%. This result emphasizes the model's ability to produce extremely precise and dependable predictions, which is critical in lowering the subjectivity and ambiguity that are frequently connected to human diagnosis [4]. Additionally, the interpretability of the model gives medical professionals a better grasp of the diagnostic procedure, increasing openness and confidence in its predictions. A significant achievement in the area, the decrease in subjectivity and unpredictability may hasten the diagnosis and treatment of ASD in persons on the spectrum and their families, therefore enhancing their quality of life. These findings demonstrate the enormous promise of AI-driven diagnostic tools and represent a significant advancement in the accuracy and effectiveness of ASD diagnosis in clinical settings [5].

The obtained findings demonstrate the extraordinary accuracy and interpretability of the suggested ABC optimized RNN-BiLSTM model, and have important implications for the field of ASD diagnosis. In addition to demonstrating the model's effectiveness, its exceptionally high diagnosis accuracy of 99.12% raises the possibility of its use as a useful tool in clinical settings. By giving physicians insights into the elements impacting the diagnostic process, the model's interpretability improves its value and promotes a collaborative and educated approach to ASD diagnosis. But it's important to recognize some boundaries. The study primarily examines the model's diagnostic accuracy; however, in order to give a more thorough assessment, future research may explore other performance metrics, such as sensitivity and specificity. It is also important to evaluate the model's performance across a variety of demographic and population groupings in order to guarantee equal application and gauge its generalizability.

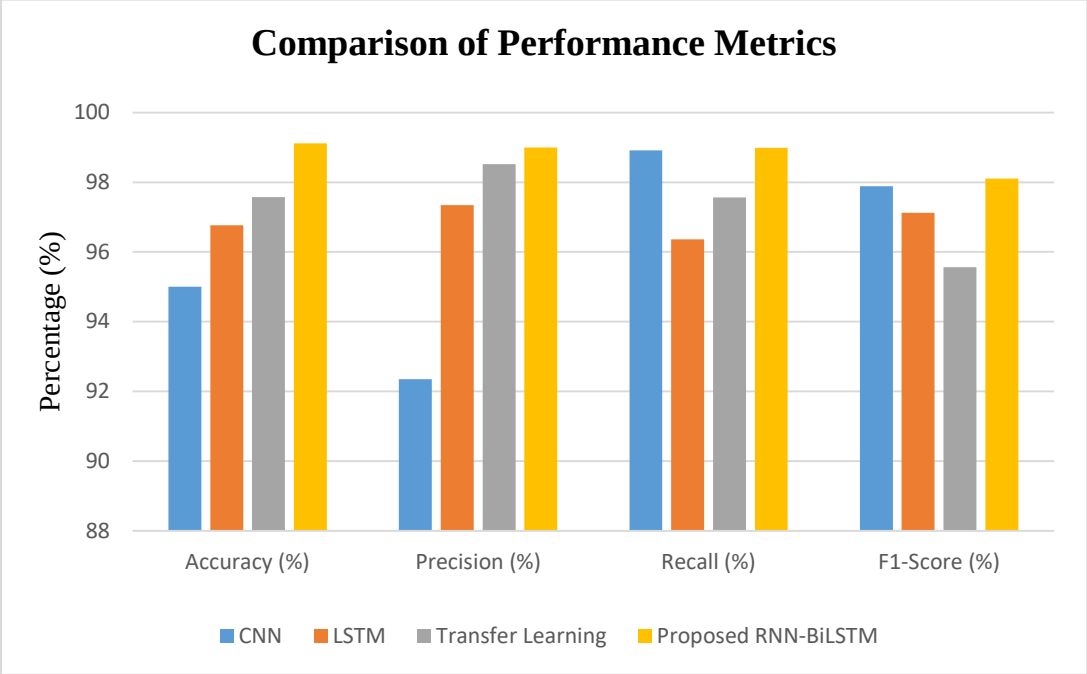

Fig. 7. Comparison of performance metrics.

Future research might improve the comprehension of the intricate elements of ASD by extending the model's applicability to multi-modal data, such as genetic and neuroimaging data. It is crucial to look at the privacy issues, ethical issues, and potential biases related to using AI-driven diagnostic tools in actual healthcare settings. Furthermore, investigating methods to smoothly incorporate the suggested model into current healthcare processes and systems will help make it more feasible to put it into practice. Even if the study makes a substantial contribution to the diagnosis of ASD, addressing these issues in subsequent research projects will increase the model's usefulness and clear the path for its effective incorporation into standard clinical procedures.

Enhancing the applicability of the suggested approach requires identifying possible generalization routes to more complicated scenarios. One approach is to carry out focused studies to evaluate the model's efficacy in a wide range of neurodevelopmental diseases other than ASD. Adding more examples of similar disorders to the dataset like Attention-Deficit/Hyperactivity Disorder (ADHD) or intellectual disabilities will help us better understand how adaptive the model is to more complex diagnostic problems. Furthermore, determining the model's generalizability requires examining its resilience across other age groups, and demographic groupings. The model's ability to generalize to complex and diverse clinical circumstances might be further improved by utilizing multi-modal data, such as genetic or neuroimaging information, and applying transfer learning techniques. These factors highlight the significance of methodically investigating and verifying the model's functionality in more complicated circumstances, offering a path for its incorporation into a more thorough framework for diagnosing neurodevelopmental disorders.

VI. Conclusion and Future Works

This study represents a major advancement in the diagnosis of ASD. A remarkable 99.12% diagnosis accuracy is achieved by using an ABC optimized RNN-BiLSTM architecture. This accomplishment highlights the potential of the suggested technique to lessen subjectivity and improve the accuracy of ASD diagnosis in addition to demonstrating its effectiveness. Clinicians can get important insights from the interpretability of the model, which enhances their comprehension of the diagnostic procedure. Moreover, this decrease in subjectivity speeds up early intervention, which is a vital component in enhancing the lives of people with autism spectrum disorders and their families. Furthermore, the elimination of subjectivity expedites the early intervention procedure, and the interpretability of the model aids healthcare practitioners in understanding the diagnostic process. Subsequent paths might entail implementing this model in therapeutic environments, carrying out extensive experiments, and broadening its relevance to encompass a range of neurodevelopmental conditions. Furthermore, investigating the possibilities of transfer learning and incorporating multi-modal data may improve diagnostic accuracy even more and increase the research's impact on the field of medical diagnosis.

***Abstract*—Pregnancy monitoring plays a pivotal role in ensuring the well-being of both the mother and the fetus. Accurate and timely classification of fetal health is essential for early intervention and appropriate medical care. This work presents a novel method for classifying fetal health optimally by combining the Bat Algorithm (BA) in an effective manner with a hybrid model that combines Recurrent Neural Networks (RNN) and Extreme Gradient Boosting (XGB). The Bat Algorithm, inspired by the echolocation behaviour of bats, is employed to optimize the hyperparameters of the XGB-RNN hybrid model. This enables the model to adapt dynamically to the complexities of fetal health data, enhancing its performance and predictive accuracy. The XGB-RNN hybrid model is designed to capitalize on the strengths of both algorithms. XGB provides superior feature selection and gradient boosting capabilities, while RNN excels in capturing temporal dependencies in the data. This approach effectively deals with the difficulties involved in classifying fetal health in the context of pregnancy monitoring by combining these approaches. Python is used to implement the proposed framework. To validate the performance of the proposed approach, extensive experiments were conducted on a comprehensive dataset comprising a wide range of physiological parameters related to fetal health. When it comes to fetal health, BAT Algorithm's XGB-RNN (BARXG) performs outstandingly, greater than other classifiers in terms of accuracy, sensitivity, and specificity. The proposed BARXG model has greater accuracy (98.2%) than existing techniques, which include SVM, Random Forest Classifier, LGBM, Voting Classifier, and EHG.**

Keywords*—BAT; fetal health; pregnancy monitoring; RNN; XGBoost

I. Introduction

Embryogenesis and maternity are essential components for human life and fertility. Whenever the fertilized egg, also called as a zygote, grows becomes a developing embryo, becomes a fetus, and finally culminates with the conception as a new human being, it is called pregnancy. Although becoming pregnant is an amazing experience, there are dangers and uncertainty involved. It is crucial to protect the mother's wellness and health in addition to the developing fetus. Regular fetal health monitoring is essential to prenatal treatment in order to identify and quickly fix any possible problems. This is a complicated and transformational process. Monitoring the development of the fetus throughout pregnancy is one of the hardest and most complex treatments. Although the average duration of this incredible journey is forty weeks, individual experiences may vary greatly [1]. The growing child of a person around the final stages of pregnancy is called a fetus. It is a crucial phase that comes after the embryonic stage and before childbirth during the entire human gestational process. In the fetus, the life form develops significantly. Usually, the fetus is just a few millimeters long at the start of the fetal stage, which occurs during the ninth week of development [2]. The fetus may grow to a size of 19 to 21 inches or greater by the conclusion of the trimester. The following are the phases of fetal growth. Weeks 9–12 of the first trimester, the fetus experiences tremendous expansion and growth. Important organs and tissues develop, and the fetus starts to take on characteristics of a little human. Weeks 13–27 of the second trimester, the fetus's body is growing as well as becomes more proportional. The embryo starts to move more deliberately and has the ability to grab items and sucks its thumb. Weeks 28 to Birth of the third trimester, a noticeable increase in size characterizes the last trimester.

This tissues and structures of the fetus develop more in order to get prepared for living beyond the mother's body [3]. The mother can clearly observe the fetus's movements, and it is capable of reacting to outside stimuli. A fetus is vulnerable to various issues throughout the course of pregnancy. Obstetrics carelessness can have devastating consequences, such as during childbirth fetal mortality, deaths from stillbirth, including over time infant neurological abnormalities. More than 1.3 million fetal fatalities happen throughout childbirth every year [4]. Birth asphyxia represents one causing the main causes of fetal death. Birth asphyxia, also known as hypoxia, is the result of a disruption in the blood supply via the placenta, which results in low oxygen levels in the fetus's

brain. Hypoxia-induced fetal distress can result in a range of anomalies during birthing that can be classified as either life-threatening or non-life-threatening. A newborn's brain is very susceptible to the effects of oxygen; hence a shortage of oxygen can have fatal consequences for the developing brain. Therefore, in order to identify fetal acidic conditions early on, we require an effective method that can track the fetal condition in real time and notify obstetricians when something odd happens so they may act quickly to save the fetus from irreversible harm. Birth asphyxia caused hypoxia causes permanent mental and physical disabilities such as spinal cord injury, deafness and visual impairment, speech difficulties, and autism. One typical outcomes diagnosis linked to fetal/perinatal brain damage is cerebral palsy (CP).

Most people agree that cerebral palsy (CP) is a disorder for neurological growth that causes dyskinesias and spastic quadriplegia or diplegia, and hemiplegia. In full-term newborns, the rate of CP ranges from 2.5 to 4.0 in 1000 births. However, this number rises to 16–22 per 1000 live births for children delivered preterm or individuals that are tiny for their gestational age (growth limited). In industrialized nations, the Maternal Mortality Ratio (MMR) is significantly lower than in impoverished nations. High MMR frequently results in issues such as pre-eclampsia, insufficient tracking of both the maternal and unborn child's health, and pregnancy-related diabetes. With the right medical attention, MMR can be decreased and avoided. Monitoring of the baby is a routine practice carried out in the third trimester. Fetal tracking involves assessing the unborn child's health [2]. The well-being of the mother has a direct impact on fetal development. Cardiotocography is used to continuously measure the well-being and development progress of the fetus in order to prevent such issues. The goal of the cardiotocography is to assess the maternal uterine contractions while simultaneously monitoring the fetus' heartbeat. This procedure could be carried out in the last trimester, after the fetus's development has fully synchronized with its heart beat. Because this technique is simple and inexpensive, it should only be used by qualified medical professionals to diagnose fetal condition early and lower fetal mortality. The results of the CTG will show the mother's uterine contractions alongside the unborn child's heart rate, acceleration, deceleration, among other intricate measurements. Mother and fetal well-being are closely related. Managing the well-being of mother as well as baby depends on lowering the number of fetal deaths and keeping an eye on the circumstances of fetal health [5]. A prenatal test used to track the heartbeat of the fetus and uterine contractions throughout both gestation and delivery is called CTG, or Electronic Fetal Monitoring (EFM).

These variables are monitored by two sensors, and the initial value, allowable variations, decelerations, and accelerations are used to classify the fetal health state. Medical professionals regularly look at these amounts and classify the fetus's health. Any numbers that deviate from a healthy state should raise suspicions about one's health. Healthcare workers review the data and assign an identifier to each characteristic. The CTG technique, which uses an electromagnetic field (EMF) equipment to track heart rate and uterine reductions throughout pregnancy, is used to get these data. Healthcare professionals physically categorize collected information and match it within a category in which the criteria are fulfilled; whenever the values fall outside of this range, an anxious condition is indicated. Through health state prediction, machine learning techniques can help physicians determine the fetal medical condition [6]. Doctors often use cardiotocography (CTG) for their clinical duties to track and evaluate the fetal status throughout gestation and delivery. CTG entails constant recording of both uterine contraction (UC) and fetal heart rate (FHR) signals. However, as fetal physiological changes are intricate and controlled through neurological mechanisms, there is typically a great deal of intra-observer and inter-observer discrepancy when utilizing standard criteria over visual interpretation of FHR signals. Obstetricians reduce diagnostic errors during labour by doing several subjective judgments. The key issue with the previously described procedure, nevertheless, is that it cannot be empirically realised; instead, obstetricians rely their conclusions only their own observations. As a result, the frequency of needless cesarean sections (CSs) brought on by subjectively mistake is rising, and this has made the pursuit on an additional accurate examination of the FHR signal its primary motivation.

The principal technique used most commonly in hospital routine tests for fetal status identification is the cardiotocogram (CTG). Prenatal surveillance of CTG primarily uses two physiological signals: fetus heartbeat and uterine contractions. The distress of the fetus affects FHR, resulting in anomalous high or decreased FHR occurrences. Initial pathogenic condition identification is accomplished with the help using such data. CTG data may be used to categorize the fetus's pathogenic status in relation to regular, which indicates its healthy state. A hypoxic fetus is extremely susceptible and might be temporarily impaired or even die after birth. Over half of all the deaths that occur can be attributed to insufficient therapy and misinterpretation of FHR [7]. Fetal health diagnosis is a challenging procedure that depends on a number of input elements. The identification of fetal healthy state is made based on the levels or range of values associated with these symptoms. Determining the precise amounts for the periods among the provided signs that influence the diagnosis's outcome can be challenging with occasions. Physicians frequently divide the entire pain phase value into smaller segments, examine each segmented segment, and determine the person's overall health status based on their analysis. These periods frequently convey uncertainty and might vary from patient to patient. Additionally, distinct patients may respond to similar illnesses in varying ways. Women who are getting ready to become mothers have begun looking for prenatal guidance and knowledge about risks while illness symptoms through online resources. Despite approximately 3.7 billion application downloads in 2017, there were over 325,000 fitness, health, and medical applications accessible; pregnancy-related apps make up a significant portion of this category [8].

Apps for smartphones and tablet computers can help expectant mothers obtain information, track the growth of their fetus, comprehend alterations to their own bodies, and get comfort when they have worries. A gadget like a video

camera, wellness tracker, Kegel "exerciser," fetal heart rate "listener," or another kind of device allowing participants to monitor and communicate their personal data might be linked to maternity applications. On the other hand, nothing exists regarding the way smartphone app-based health treatments affect mother's behaviours or perinatal well-being [9]. However, there is a lack of research on the effectiveness of apps, their content, how mothers use them, or the best methods to include them into normal prenatal education and care. Midwives along with other professionals often speak to pregnant women that download and utilize applications. Classification systems for fetal health aid in the early detection of anomalies, problems, or departures from the typical developing processes [10]. Healthcare personnel have the ability to swiftly implement suitable treatments since earlier diagnosis. Rapidly healthcare treatments might be critical towards avoiding or minimizing problems, and early diagnosis of fetal health abnormalities facilitates these therapies. Based on the severity of the problem, this may involve measures including suggesting surgery, giving medicine, or altering mom's lifestyle. Pregnant women might feel less stressed and anxious when they realize their unborn child is well and under constant observation. Improved outcomes and fewer needless healthcare procedures might arise from personalized care. More precise fetal health categorization enables improved delivery process preparation. This helps in deciding if early labour inducers or cesarean section is required, as well as ensuring the right doctors remain on hand for the birth. In healthcare applications, selecting features is a critical process that is handled using the Bat Algorithm. The research shows how this method may be used to improve model accuracy and comprehension by identifying the most pertinent characteristics in the Cardiotocography (CTG) dataset.

The following are the main contributions to the suggested work:

- In an initial processing measure, it employs class weighting to prevent overfitting when training the model.
- Sequencing and temporal connections in data are captured by RNNs. RNNs may simulate how fetal heart rate and uterine contraction patterns change over time within the framework of fetal health monitoring. This is necessary in order to identify any abnormalities or anomalies.
- A hybrid design fuses the RNN and XGBoost models together. This combination enables the model to take use of RNNs' capacity for capturing temporal dynamics and XGBoost's expertise in feature engineering.
- The output of RNN is fed into XGBoost for classification. RNN-XGBoost model had hyperparameters tuned using the BAT algorithm.
- In the end, the optimization process of the Bat Algorithm yields a collection of characteristics regarded most significant for the goal of classifying fetal health.

This article's remaining sections are organized as follows: In Section II, an overview of relevant studies is provided. Section III presents the problem description for the current system. The approach and architecture of the suggested BARXG model for Fetal health classification are explained in Section IV of the paper. Section V presents the findings from the investigation and the subsequent discussion. Conclusion and future application of the suggested paradigm are covered in Section VI.

II. Related Works

The research in [11] proposed a fetal health classification using T2-FNN method. The fetal medical diagnosis can be a challenging procedure which requires a variety of inputs elements. An assessment of fetal medical condition has been carried out via the numbers or varying numbers associated with those given signs. Their will likely be discussion among specialized physicians when determining the precise ranges that constitute gaps while identifying illnesses. Since a consequence, illness diagnosis frequently takes place in unreliable circumstances and occasionally results in unfavourable mistakes. Precisely a result, choices may be questionable due towards the ambiguous aspect of illnesses or insufficient patient information. The 21 intake criteria define the fetal medical condition. The estimation of these numbers included testing and observations. Three outcome diagnoses for good stages for fetal growth have been defined using potential amounts for these variables. Average, Suspected, as well as Abnormal include these. It had been possible to establish overall type-2 fuzzy neural networks (T2-FNN) method's architecture utilizing the quantity combined inputs and outcomes symptoms. Utilizing fetal records, the developed T2-FNN is evaluated. The structure of the system makes use of a variety of criteria. The design turns out that while the number of criteria increases, so does the efficiency of the system. Utilizing fetal records, the developed T2-FNN is evaluated. The structure of the system makes use of a variety of criteria. The design turns out that while the number of criteria increases, so does the efficiency of the system. Although T2FNNs become more sophisticated than regular neural networks, they may be costly to compute and more difficult to carry out, particularly for applications that operate in real time.

The research in [12] proposed a fetal health classification using machine learning techniques. Cardiotocography (CTG) depicts the fetus's condition while in labour within the uterus. Yet, based on the obstetrician's experience, evaluating the results might be a very biased procedure. Infant monitoring digitally collect data (such as baby heart rate, movements and accelerating). Many investigators have concentrated their efforts on CTG information in order to evaluate fetal health utilizing different AI algorithms. Utilizing fetal heart rate data, certain investigators utilized neural networks to forecast fetal health. The suggested approach used the Fetal Health Assessment information set, which consists of CTG files, along with five ensembles participants: Random Forest, AdaBoost, XGBoost, CatBoost, and LGBM. The voting classifier, sometimes referred to by the term Meta classifier, classifies the CTG information using the results obtained from RF, XGBoost, AdaBoost, CatBoost, and LGBM. To categorize

CTG data, a soft voting technique is implemented using the mean result from every ensemble classifier. Regarding situations when many ensembles learner work identically, a soft voting classifier may be useful. The deficiencies of each individual ensemble's learners might be compensated by combining their work. In order to improve the efficiency of the entire model, the soft voting classifier ultimately removes the flaw of one particular classifier. Ensembles approaches, including the majority of machine learning algorithms, were dependent on noisy data; particularly the existence of disturbance in fetal health surveillance information may have an influence overall the model's efficiency.

The study in [13] suggested a strategy for fetal health classification. It is usual practice to utilize uterine contractions (UC) activities to gauge when labour and delivery will begin. In order to monitor UC and discriminate between effective and unproductive contractions, electro hysterograms (EHGs) have lately been adopted. From this investigation, the researchers utilized a convolutional neural network also known as CNN to detect UC in EHG signals. In order to create a CNN model, an open-access database has been utilized. Utilizing by five times cross-validation, a model based on CNN was created then learned with DB1. The CNN framework created with DB1 was utilized with DB2, a separate clinical database, to assess its generalizability for identifying UCs. Employing the multiple channels of communication system as well, the EHG signals in DB2 have been collected via 20 pregnant women, as well as 308 parts have been retrieved. The number of trials might be increased by combining both databases that might be preferable to teach the CNN model. The research has shown how CNN would effectively distinguish UCs with EHG signals. This technique makes it possible to consistently and correctly identify UCs, offering a unique tool for keeping track of the status of the labour and the health of the mother and fetus. Uneven classes might exist in EHG datasets, including UCs occurring less frequently than non-UCs. Unbalanced data may generate unbalanced models while having an impact on effectiveness in reality. It might be challenging and exhausting to integrate the CNN approach within present clinical processes and medical records systems.

[14] suggested a fetal health monitoring approach. To limit development negotiation, lower mortality, and avert premature birth, considerable health care services have been devoted toward tracking risky pregnancies. Another crucial sign for prenatal health was recently identified as fetal movement. Surveys showed that undesirable delivery rates occurred in 25% of pregnancy with reduced fetal movement during the 3rd trimester. They provide a better iteration of the automatic FetMov identification they already recommended. FetMov means Processes identified as FetMov by an ultrasonographer. Activities not identified from the ultrasonographer as FetMovs but with FetMov-like characteristics are called artefacts (Artf). They consist of parental body motions and sensor shifts. Information from accelerometers have been pre-processed using separate component analysis while wavelet decomposition over the initial time. The categorization set of characteristics has been increased by one attribute to 31 factors. Various models have been assessed employing a ten-fold cross-validation approach with the aim evaluate the performance of the suggested parameters. Thirty-one characteristics were taken using acceleration information in order to recognize fetal movements. Various predictors had been used for distinguishing fetal from non-fetal moves according to these characteristics. The models' reliability has been investigated across various artefact levels within the categorizing information. Bagging classifier method produced the most effective results. Automatic identification systems could result in false positives or false negatives, which could cause worry in expectant parents and result in pointless treatments or undetected problems in professional settings. Datasets that are unbalanced may result from uterine contractions being comparatively uncommon occurrences as compared to non-contraction times. This disparity problem might not be sufficiently addressed by bagging, which could lead to skewed predictions.

The research in [15] proposed a Fetal health monitoring using IoT method. Digital health apps utilizing the Internet of Things provide helpful instruments enabling efficient and dispersed automated systems for diagnosis. In order to track mother's and baby messages over pregnancy at high risk, this research suggests developing a combined approach utilizing Internet of Things (IoT) sensors, extracted features from data analysis, along with a predictive evaluation assist method built around a single-dimensional CNN classifier. In addition to recording the heart rate of the fetus, a number of clinical indications connected with the mother are also tracked, including blood pressure, temperature, heartbeat rate, uterine tonus action, and oxygen consumption. A substantial volume of data is produced at various speeds along with diverse formats by various sources. Utilizing a fog computing layer, a critical diagnosis system is suggested, considering the acquisition of various features along with the computation of both linear and nonlinear measurements, intelligent analytics for health system is suggested. Lastly, taking into account six potential outcomes, a method of classification is suggested as a system of forecasting for the categorization of maternal, fetal, and simultaneous health status. The crisis system receives information produced by IoT devices and employs it to evaluate and figure out whether it detects either severe fetal or maternal discomfort. The healthcare team is notified right away if a critical situation emerges. Following this analysis stage, every feature is computed and transmitted to the suggested estimation system using a single-dimensional CNN in the cloud-based approach. Lastly, the healthcare professional is supplied with a categorization that validates the diagnosis of illness. Severe legal requirements have to be met by IoT devices utilized in the healthcare industry. It might take money and effort to fulfill these criteria.

When it comes to predicting specific fetal health problems, like with a late- difficulties, which might arise following regular monitoring happened, the current categorization approach may not be very reliable. Several variables, consisting as mother health, genetics, and surroundings, might affect the health of the fetus. Such factors may lead to fetal reaction inconsistency and make categorization more difficult. The categorization scheme is predicated on data gathered from

typical prenatal visits, although might not necessarily offer an all-encompassing picture of fetal health. Reliable evaluation of several crucial factors is difficult, including fetal activity along with placenta functioning. T-2FNNs are more complex than their Type 1 counterparts due to the additional dimension of uncertainty they handle. This complexity can make the model challenging to understand and implement, especially for healthcare professionals who may not be familiar with fuzzy logic or neural networks. In contrast to simpler models, Random Forest models might be more difficult to read, which can make it difficult to comprehend the rationale behind certain categorization decisions—a critical skill in medical contexts. AdaBoost are very complicated, it may also overfit. Despite CatBoost's economical architecture, it could need an extended period to train than other algorithms, which could be a drawback for healthcare applications that need to respond quickly. LGBM may not perform as well with small datasets, as it is optimized for large-scale data.

III. Problem Statement

There are a number of issues with the current Optimum Fetal Health Classification during Pregnancy Monitoring which might affect how accurate and useful it is. Compared with other classification models, T2FNNs can be harder to comprehend, which makes it harder to justify certain categorization choices. Readability is essential in medical settings to win over healthcare professionals' confidence along with approval. Several machine learning models, particularly over fitting ones, exhibit weak results with unknown data yet good performance on training information. Overfit methods can't adjust effectively to novel patients or circumstances in healthcare settings, which might result in inaccurate diagnoses. The methods used today frequently depend on predictive models along with past information, and this may not be able to appropriately forecast difficulties in the future or account for each person pregnancy variances. Aspects such as fetal position, mother bodily habits, and electrode location might affect the quantity of EHGs. Errors in categorization might result from noisy or unreliable information [16]. The deployment of bagging classifiers along with other algorithms based on machine learning in healthcare facilities may be limited due to their computing demands, which necessitate substantial expenditures for both training and real-time usage.

IV. Proposed Bat Algorithm-Driven XGB-RNN for Optimal Fetal Health Classification in Pregnancy Monitoring

Compiling information on pregnancy monitoring is the initial stage. The information collected might contain the fetus's patterns of motion, heartbeat, and additional indicators of wellness throughout duration. Before being analysed, the gathered data must be cleansed. In order to handle values that are absent, normalize the data, and perhaps identify pertinent features for the classification task, all of this must be done. The framework and hyperparameters for a machine learning model are optimized using the Bat Algorithm. It can assist in choosing among the most important characteristics, determining the ideal model variables, and enhancing the efficiency of the framework as a whole. Along with the methods for categorization is XGBoost. Most commonly, it's employed to offer a preliminary data categorization. Sequential data, such as data on fetal health over time, are analyzed using the RNN. Utilizing a combined method like layering or mixing, merge the outcomes of the RNN and XGBoost model. Classification is done after hyperparameter tuning by BAT algorithm. Then fetal health is classified using BARXG model. Fig. 1 shows the overall diagram of proposed BARXG model for Fetal health classification.

A. Data Collection

Cardiotocograms (CTGs) are an easy-to-use, reasonably priced method of evaluating fetal health that enables medical practitioners to implement preventative measures against mother and infant death. The gadget essentially functions by delivering ultrasonic pulses and interpreting the reaction, thereby providing information on a variety of topics including uterine contractions, fetal movements, and fetal heart rate (FHR). The dataset is collected from fetal health classification from the website Kaggle [17]. 2126 sets with features taken from cardiotocogram tests are included in this collection of data. Three experienced obstetricians divided the characteristics among three categories: Normal, Suspect, and Pathology.

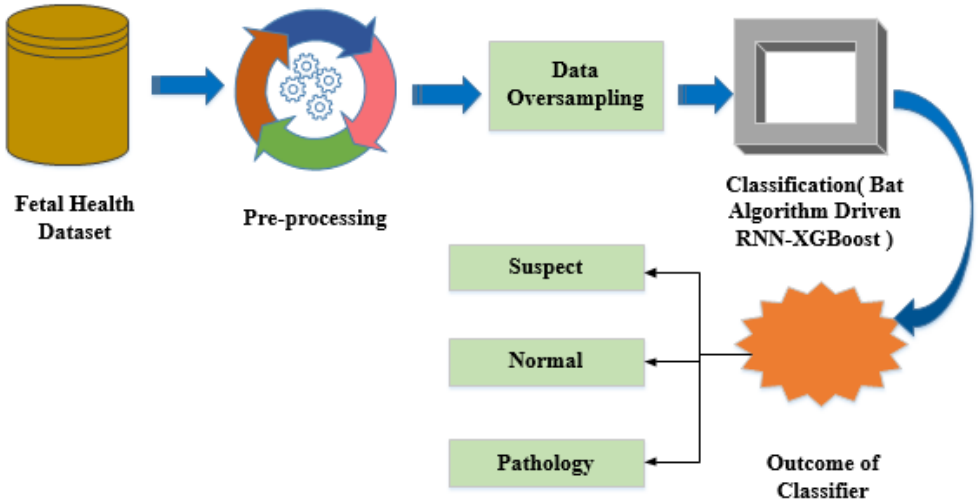

Fig. 1. Proposed BARXG model for fetal health classification.

B. Data Pre-processing

1) Data oversampling: To describe the relationship between variables during the model's development, the number of values provided in the dataset were standardized through a range from −1 to 1 during the preprocessing stage. The imbalanced dataset was handled using progressive class weighting following feature extraction. Adding some weight to every class to give the minority classes greater significance represents one among the easiest approaches to overcome this class imbalance and create a classifier which will learn similarly from all classes. It easily multiplies the entropy part of every class using the associated weight in a tree-based model, whereby the best split is defined using a certain metric, such lower entropy, to give the minority classes greater prominence.

In Eq. (1), a^1 represents a new value derived using the values, illustrates the normalizing and standardized procedure for feature extraction.

$$a^1 = \frac{a - min(a)}{max(a) - min(a)} \quad (1)$$

InEq. (2) provides the extended version that describes the polynomial expansion (PE) function utilized in feature extraction, where n denotes the degree of expansion and {b,c} are the independent variables within the dataset. Although the n degree in this study has been set at 2, the dataset in PE expands exponentially and horizontally with respect to n.

$$(b + c)^d = \sum\binom{d}{e} b^e c^{e-k} \quad (2)$$

However, computational expenses and horizontal expansion were kept to a minimal. Classes might be periodically evaluated by calculating their entropy function (f), as demonstrated by Eq. (3).

$$f = \sum_g q_g \log(q_g) \quad (3)$$

C. BAT Algorithm Driven RNN-XGBoost Model for Fetal Health Classification

This hybrid model combines the strength of XGBoost and Recurrent Neural Networks (RNN) with a feature selection method called Bat Algorithm (BA). The first step in the procedure is gathering data from fetal health monitoring. Numerous factors, such fetal heart rate and uterine contractions, are usually included in this data. The process of preparing data involves oversampling the dataset. The XGBoost and Recurrent Neural Network (RNN) models' hyperparameters are adjusted and refined by the BA. The goal of this optimization approach is to determine which hyperparameters will best fit the models and assist them capture intricate patterns in the fetal health data. Because RNNs are specifically designed to analyse sequential data, they are a good fit for time-series data sets such as fetal health monitoring. To increase prediction accuracy, XGBoost is used to the characteristics that were taken from the fetal health data. To arrive at a final forecast, the outputs of the RNN and XGBoost models are fused, or blended.

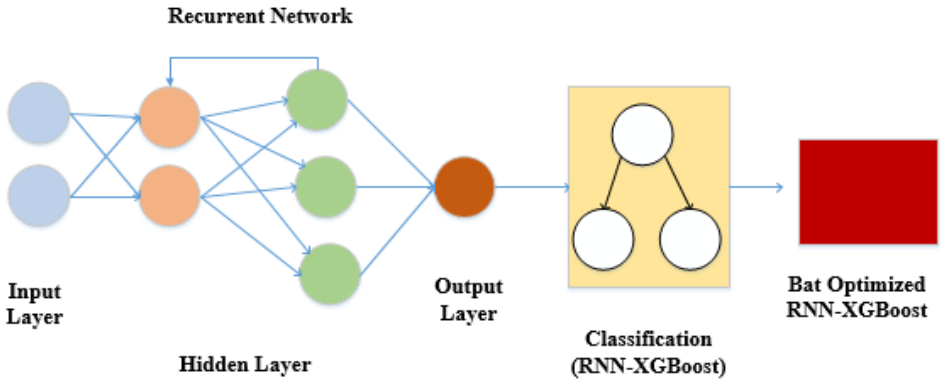

Fig. 2. Architecture diagram for proposed BARXG model.

The overall architecture diagram for Proposed BARXG Model is shown in Fig. 2. The Bat Algorithm-driven RNN-XGBoost model's overall design blends sequence modeling, combined learning, and bio-inspired optimization to produce a potent tool for classifying fetal health in prenatal monitoring. This novel strategy has the potential to greatly raise the standard of care provided to pregnant moms and their unborn kids.

1) RNN: An artificial neural network type called a recurrent neural network (RNN) is made to handle information in repetitions. These perform particularly well in tasks involving sequences, including speech, conversation, time series data, and numerous other tasks. For the purpose of to anticipate the layer's output, RNNs operate on the basis of reserving a certain layer's output then feeding it back into their input. One layer with recurrent neural networks is created by compressing the nodes within the various neural network layers. Both the present input data and previous inputs can be handled sequentially by an RNN. Because RNNs have memory within them, they are able to retain earlier inputs. Provide the RNN with a series of values as input at each time step. The Hidden state of an RNN, while retains certain details regarding a sequence, is its primary and crucial characteristic. Because the state retains recall of the prior input within the network, this state is known as well as Memory State. In order to create the output, it does a similar job on each of the inputs

and hidden layers using identical settings for each input. In contrast to other neural networks, that lowers the complexity associated with the features. During every time step, that exists a fixed activation function unit in the recurrent neural network. Every unit possesses an internal state known as its hidden state. During a particular time, each hidden state represents the prior information which the network presently possesses. This hidden state gets revised at each time step to reflect any modifications to the network's previous information. The recurrence relation listed below is used to modify the hidden state. The following is the formula to find the present state Eq. (4).

$$s_u = f(s_{u-1,} w_u) \tag{4}$$

where, s_u represents the present state; s_{u-1} represents the previous state; w_u represents the input state.

By using the following Eq. (5) the hidden state can be calculated.

$$H\_t = V(G^* w_u + U^* H\_(t-1) \ + n) \tag{5}$$

where, H_t represents the hidden state at time step; G represents the weight matrix that multiplies the current input w_u; w_u represents the input at time step; U is a weight matrix that is multiplied by H_(t-1) previous hidden state; H_(t-1) this refers to the hidden state that was a part of the present hidden state at a prior time step. H_(t-1): This refers to the hidden state that was a part of the present hidden state at a prior time step; n this represents expression for bias.

2) XGBoost algorithm: Gradient Boosting methods operate by learning ensembles on shallow decision trees. The framework fits the subsequent decision tree by using its remaining error in each iteration. A weighted total is used to get the final forecast after several trees have been constructed. In contrast, the trees in an Extreme Gradient Boost model are constructed parallel to one another rather than sequentially. In addition to improving speed, this shortens the period needed to fit data into a model. Within the scientific community, this framework is highly regarded for its ability to solve a wide range of issues. XGBoost is used for classification for fetal health.

For data preparation Let the value X represent the feature matrices, whereby the features are contained in a N x M matrix. Y, an N-dimensional vector containing the three fetal health labels (0 for Normal, 1 for Suspect, and 2 for Pathological), should be the desired vector. The total of the normalization and loss terms can be used to describe the objectives function in XGBoost. The total of the normalization and loss terms can be used to describe the objective function(o) in XGBoost is mentioned in Eq. (6).

$$o = L(x, \hat{x}) + \Omega(y) \tag{6}$$

where, the loss function quantifying the difference between the real names (x) and predicted names ($\hat{x}$) is represented by the expression $L(x, \hat{x})$.The regularization term, Ω(y) regulates the ensemble of trees' complexities. The anticipated designation for every specimen is acquired by adding the forecasts of many decision trees, every one of which is influenced using a coefficient α is mentioned in Eq. (7).

$$\hat{z}(y) = \sum \alpha^* k(y) \tag{7}$$

Where, α provides the weight of every decision tree k(y), and $\hat{z}(y)$ represents the expected labelling for a sample x. From an input feature vector x, every decision tree within the ensemble appears by the sum of its leaf scores (w) is mentioned in Eq. (8).

$$I(j) = \sum u \tag{8}$$

where, each decision tree's leaf scores are represented using the letter u. To regulate the level of complexity of the individual trees, the regularization term Ω(y) incorporates both L1 and L2 regularization over the leaf scores. XGBoost employs a gradient boosting technique to maximize the objective function(o) in order to determine the optimum combination among decision trees and associated variables, including α, u, and Ω(y).

3) BAT optimization for hyperparameter tuning: The bat algorithm, often known as the BA, was an algorithm which mimics the echolocation as an activity of bats to enable to carry out worldwide optimization. Considering its superior performance, the BA is frequently utilized across a variety of optimizations situations. The RNN and XGBoost models' hyperparameters may be optimized using the Bat Algorithm. Typically, bats utilize echolocation to locate food. Bats typically emit small pulses while removing it, but once they come upon food, they start sending off pulses more often along with higher rates. A frequencies-tuning result from a rise within frequency, which decreases overall echolocation period and improves the precision of location is men.

$$f_j(r+1) = f_j(r) + m_j(r+1) \tag{9}$$

$$c_l(r+1) = c_l(r) + \left(f_j(r) - w(r)\right).x_k \tag{10}$$

$$x_k = x_m + (x_a - x_m).\beta \tag{11}$$

When the quantity of repetitions rises, every k within the typical bat algorithm has a determined location f_j is mentioned in Eq. (9) and c_l velocity in the search space is mentioned in Eq. (10). One may compute the new coordinates x_k along with velocities in the following way Eq. (11). where β is a uniformly distributed randomized vector with a range of [0, 1]. The entire optimum solution at the moment is $w(r)$, where $x_m = 0$, $x_a = 1$ is mentioned in Eq. (11).

$$f_j(r+1) = \vec{e}(r) + \varepsilon \bar{B}(r) \tag{12}$$

where, ε is a random value between -1 and 1 is represented in Eq. (12). d signifies a random integer between -1 and 1 and l(d) is the population's average loudness. Furthermore, it accomplishes worldwide search via managing pulse rate $f_j(r+1)$ and loudness (Loudness (t +1) is mentioned in Eq. (13).

$$D_n(r+1) = \propto D_n(r) \tag{13}$$

$$w_i(r+1) = w_i(0)[1 - exp(-\gamma r)] \quad (14)$$

where, α >0, γ >0} when α and γ are constants. The starting ranges for pulse rate and loudness are denoted by (0)} and D_n (0)}, correspondingly is mentioned in Eq. (14).

The bat algorithm's processing phases are described in the following.

Step 1: Using Eq. (3), randomly create the frequency along with the location, velocity, and parameters for each bat.

Step 2: Use Eq. (1) as well as Eq. (2) to update each bat's location and velocity.

Step 3: Choose a random number (0<$r\ a\ n\ d$ 1<1) for every bat. If $rand1 < w_i(t)$ then update the temp location and compute the fitness level for the relevant bat using Eq. (4).

Step 4: Choose a random number (0<$r\ a\ n\ d$ 2<1) for every bat. If $r\ a\ n\ d$ 2<(t) and

$x\left(f_j(r)\right) < x(w(r))$, then update ($t$) and $r\ i\ (t$) using Eq. (5) along with Eq. (6), respectively.

Step 5: Sort each person according to fitness values, and then mark the top spot.

Step 6: When the condition is satisfied, the algorithm is complete; if not, proceed to Step 2.

The optimal configuration for both the RNN along with XGBoost models is represented by the optimum solution, or collection of hyperparameters, after the algorithm has finished running.

V. Results and Discussion

The results section provides a comprehensive overview of the outcomes and findings obtained from the experimental evaluation of the Bat Algorithm-Driven XGB-RNN For Optimal Fetal Health Classification in Pregnancy Monitoring. To ensure the quality of the dataset, preparation and data collection are the first steps in the procedure. XGBoost and RNN model modifying need independent optimization of hyperparameters, that's where the Bat Algorithm excels. The method of optimization includes the adjustment of hyperparameters such as RNN, tree depths, and learning rates. The Bat Algorithm runs repeatedly, assessing the accuracy of the models at each stage and modifying the hyperparameters according to ideas borrowed from echolocation. A measure of fitness that takes into account classification parameters such accuracy, F1-score, is used to gauge how well the framework performs. Whenever a termination criterion—such as a number of iterations or adequate model performance—is satisfied, the optimization loop keeps going. The hidden key to the model's performance is the resulting optimal selection of hyperparameters. The proposed framework is implemented in python. A device with an Intel(R) Core, 8GB of RAM, and windows 10 operating system is utilized.

A. Outcome of Fetal Health Classification by Proposed BARXG Model

Fig. 3 shows the categorization of fetal health dataset in percentage. As can be seen in the dataset, out of the 2126 samples, 1655 are normal, 295 are suspicious, and 176 are abnormal entries. Within the dataset, the fetal heart rate (FHR) patterns were classified as normal (0), suspicious (1), and abnormal (2).

The statistical summaries of the CTG data properties are displayed in Table I. This shows the outcome after the classification. The default Standard Scaler Python package is used to normalize the CTG data. By calculating the f-score along with bringing it into the same range, the Standard Scaler adjusts the data, facilitating computation and comparison.

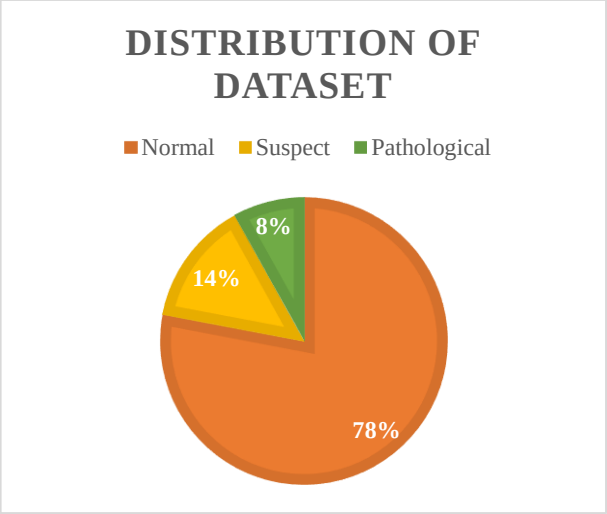

Fig. 3. Categorization of fetal health dataset.

TABLE I. Attributes from the Dataset

Attribute	Description and Unit	Mean	Std	Min	Max
Baseline value	Beats per minute	133.3039	9.840844	106	160
Accelerations	Accelerations per second	0.003178	0.003866	0	0.019
Fetal movement	Fetal movements per second	0.009481	0.046666	0	0.481
Uterine contractions	Uterine contractions per second	0.004366	0.002946	0	0.015
Fetal health	Fetal state class (0: normal (N); 1: suspect (S); 2: pathological (P))	-	-	0	2

TABLE II. RESULTS OF PROPOSED BARXG MODEL

Category	Accuracy (%)	Precision (%)	Recall (%)	F1 Score (%)
Normal	0.98	0.98	0.96	0.97
Suspect	0.93	0.88	0.84	0.85
Pathology	0.90	0.87	0.86	0.86

Table II summarizes the results of the proposed BARXG model for the categorization of fetal health. The total accuracy provided by the proposed BARXG model was 98.2%. Precision, recall, and F1-score outperformed for each of the three classes. The accuracy of the forecast for healthy fetal cases is 98%, that of suspected fetus cases is 93%, and that of pathological fetus cases is 90%.

B. Performance Evaluation

For comparison the SVM, Random Forest Classifier, LGBM, EHG methods performance is compared with the proposed BARXG model. Precision, recall, F1-score, and accuracy were utilized as segmentation of the driver drowsiness evaluation criteria for comparison. The model was evaluated using these parameters. They are shown below:

A frequently used indicator to assess the effectiveness of categorization tasks is accuracy. The accuracy is computed by dividing the total number of predicts by the number of right predictions. It is described using an Eq. (15).

$$Accuracy = \frac{RN+RP}{RP+AP+RN+AN} \quad (15)$$

where, 'RN' means true negative; 'RP' means true positive; 'AP' means false positive; 'RN' means true negative; 'AN' means false negative.

A classification model's positive predictions are evaluated using a measure called precision. When false positive mistakes are expensive or undesired, it is especially crucial. To compute precision, use the formula below Eq. (16).

$$Precision = \frac{RP}{TP+FP} \quad (16)$$

where, 'RP' represents true positive and 'FP' represents false positive.

Recall, sometimes referred to as sensitivities or real-positive rate, is a statistic used to evaluate a classification model's capacity to accurately identify every relevant occurrence of a given class. The following Eq. (17) is used to calculate recall.

$$Recall = \frac{RP}{RP+AN} \quad (17)$$

The F1 score is a statistic that combines accuracy and recall to give a fair evaluation of the effectiveness of a classification model. It is especially helpful when you're trying to balance reducing inaccurate results (precision) and avoiding false negatives (recall) while maintaining accuracy. Eq. (18), which calculates the F1 score, is as follows.

$$F1\ score = 2 * \frac{Precision*Recall}{Precision+Recall} \quad (18)$$

The suggested model's accuracy is displayed in Table III. It compares the suggested approach's accuracy (98.2%) with existing approaches' recall (96.7%), precision (97.7%) and F1-score (98%) values. The proposed methodology, BARXG outperforms the currently used methods, Random Forest classifier (93%), EHG (88%), SVM (84%), Voting classifier (95%) and LGBM (96%), in terms of accuracy (98.2%) and precision (97.7%).

Fig. 4 depicts the graphic depiction of the performance metrics of proposed with existing approaches. The proposed BARXG method demonstrates the highest accuracy across all five categories Random Forest Classifier, EHG, SVM, Voting Classifier, LGBM, with 98.2% high accuracy. On tiny or noisy datasets, Random Forests may overfit, which will lower their capacity for generalization effectiveness. EHG is an invasive technique for measuring fetal growth since it requires affixing sensors onto the uterine wall. Because of their computational complexity, SVMs could not scale well to very big datasets. The variety of a Voting Classifier's base models determines how effective it is. It might not result in appreciable gains if the basic models are comparable. For LGBM models, hyperparameter tuning can be complex and time-consuming.

Fig. 5 shows the training and testing accuracy of proposed BARXG model. During training, the BAT Algorithm-Driven RNN-XGBoost model for fetal health classification performed well, with a training accuracy of almost 99%.

Nonetheless, it retained strong extrapolation to novel data, with an approximate 98% testing accuracy. This suggests that the model is a viable method for assessing fetal health in real-world clinical situations as it is capable of learning effectively via the training data and produce precise predictions on previously encountered cases.

TABLE III. PERFORMANCE METRICS OF PROPOSED BARXG MODEL IS EVALUATED WITH EXISTING METHODS

Method	Accuracy (%)	Precision (%)	Recall (%)	F1 Score (%)
SVM [18]	84	86	88	85
EHG [13]	88	87	86	86
LGBM [19]	96	95	94	95
Voting Classifier [12]	95	94	93	94.8
Random Forest Classifier [20]	93	91	92	94
Proposed BARXG Model	98.2	97.7	96.7	98

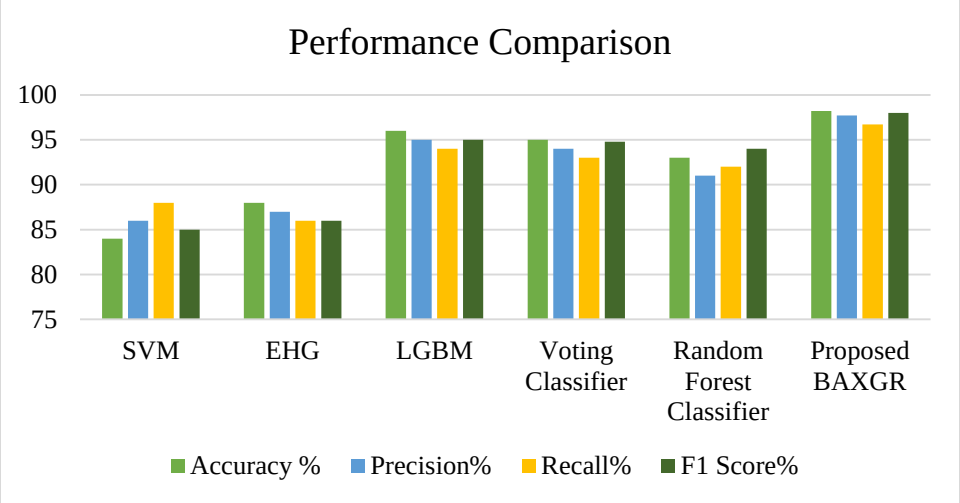

Fig. 4. Graphical depiction of the performance metrics of proposed BARXG with existing approaches.

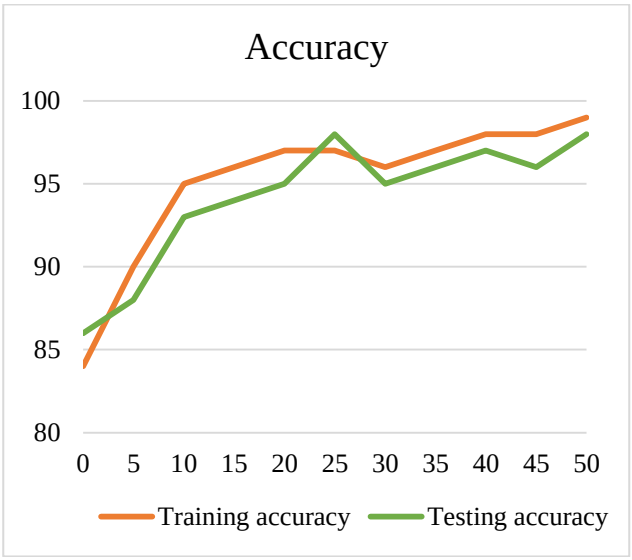

Fig. 5. Graphical depiction for training and testing accuracy of proposed BARXG model.

Fig. 6. Graphical depiction for training and testing loss of proposed BARXG model.

Fig. 6 shows the training and testing loss of the proposed model. The main goal of this model's training phase is to use the Bat Algorithm to fine-tune the RNN and XGBoost models' parameters. During the testing phase, the model's generalization skills are evaluated by analysing how well it performs on untested data. This step involves computing the testing loss.

The accuracy of the model and its ability to generalize to new, untested fetal health data are measured by the testing loss. The testing loss evaluates the model's capacity to produce accurate predictions on fresh, untested data, ultimately determining the efficacy of this novel approach in fetal health classification. The training loss is minimized by optimizing model parameters using the Bat Algorithm.

C. Discussion

Recurrent neural networks (RNNs) and XGBoost in combination with the Bat Algorithm (BA) show promise as a way to categorize fetal health in pregnancy monitoring. The accuracy of prediction of the XGB-RNN model is improved by the creative application of BA for parameter optimization. BA modifies model parameters by mimicking the echolocation behaviour of bats, which may enhance the precision of fetal health forecasts. The combination of XGBoost's gradient boosting and RNNs' sequence modelling allows for the effective processing of time-series data, such as fetal monitoring records. With the help of BA, this innovative method provides insights into complex data patterns, which could improve our comprehension of the dynamics of fetal health. Further research could improve scalability by addressing adaptability issues and convergence rates in a variety of data distributions, as well as handling bigger datasets and real-time processing. Larger datasets will be used in future research to assess BARXG's adaptability and continuous processing capabilities. The Bat Algorithm's continued adaptation to a variety of datasets and its implementation into healthcare systems are important future directions. A few of the research limitations are that enormous datasets may not scale well, validation of continuous processing is required, and the Bat Algorithm may not be as

flexible with various data distributions. In order to classify fetal health throughout pregnancy monitoring, BARXG's wider application will need to carefully validate and take these factors into consideration when investigating extension in various healthcare environments.

VI. Conclusion and Future Scope

In conclusion, a potential advancement in the field of maternal-fetal medicine is the investigation concerning the Bat Algorithm-Driven XGB-RNN for optimal fetal health categorization in pregnancy monitoring. Fetal health assessment becomes more potent and precise when the synergistic powers of XGBoost and RNNs are combined with the optimization inspired by nature of the Bat Algorithm. This method's benefits—such as enhanced precision, reliable analysis of time series, and clinical applicability highlight its potential to transform pregnancy monitoring and enhance outcomes for pregnant women and their unborn babies. It is obvious that the knowledge gathered by refining and validating this approach will have a significant influence upon clinical practice, ultimately resulting in healthier pregnancies and better care for the mother and fetus. Future improvements, thorough clinical validation, and continuous development will be necessary as this research develops in order to fully realize the potential of this novel strategy, which will ultimately help pregnant women and their kids as well as improve the present level of healthcare in the area of pregnancy monitoring. Maternal-fetal medicine may be profoundly impacted by more validation and clinical practice integration of this strategy. Working together with organizations and healthcare practitioners is essential to guaranteeing the method's efficacy in practical settings. It is crucial to investigate strategies for elucidating the model's predictions. Because they can comprehend and confirm the reasoning behind each categorization, healthcare professionals' trust may be increased through the development of interpretable models.

Abstract*—Early identification is essential for successful treatment of melanoma, a potentially fatal type of skin cancer. This work takes a fresh approach to addressing the urgent need for an accurate and economical melanoma categorization system. Inaccuracy, efficiency, and resource usage are common problems with current techniques. A model that incorporates a number of innovative methods to get beyond these restrictions was used in this study. To improve data quality, first applied the pre-processing with a Gaussian filter and augment our dataset with Generative Adversarial Networks (GAN). To extract and classify features, this suggested model makes use of Convolutional Long Short-Term Memory (LSTM) networks. The model performs better and is substantially more accurate when Firefly Optimization is used. It analyses the model's ability to lower healthcare costs by doing a cost-effective analysis, especially when detecting melanoma, including situations involving bleeding lesions. The proposed FFO Enhanced Conv-LSTM's cost-effective analysis makes it possible to compare it favourably to deep convolutional neural networks (DCNN), showcasing its promise for melanoma classification accuracy and healthcare resource allocation optimization. For this study, Python software was used as the implementation tool. The suggested model achieves a 99.1% accuracy rate, which is better than current techniques. A comparative study with well-known models such as Res Net 50, Mobile Net, and Dense Net 169 highlights the notable enhancement provided by the proposed Firefly Optimization-enhanced Conv-LSTM method. This model offers a promising advancement in the precise and economical classification of melanoma due to its high accuracy and cost-effectiveness. In comparison to existing approaches like Res Net 50, Mobile Net, and Dense Net 169, the suggested Firefly Optimization-enhanced Convolutional LSTM (FFO Enhanced Conv-LSTM) method shows an average gain of roughly 5.6% in accuracy.

Keywords*—Melanoma; cost effective analysis; long short-term memory; firefly optimization; generative adversarial network

I. INTRODUCTION

Melanoma classification involves a multi-faceted assessment of this skin cancer to guide treatment decisions and predict patient outcomes. Histological categorization is one step in this procedure, which divides melanomas into subtypes depending on how they appear under a microscope [1]. Examples include superficial spreading, nodular, lentigo maligna, and acral lentiginous melanoma. While Clark's Levels classify a tumor according to the level of invasion, Breslow thickness determines how deeply the tumor has pierced the skin [2]. Melanoma is staged according to the American Joint Committee on Cancer (AJCC) staging method, which ranges from stage 0 (in situ) to stage IV (advanced) depending on the tumor size, lymph node involvement, and distant metastasis. The categorization is further refined by other variables such ulceration, mitotic rate, genetic alterations, and immunohistochemistry [3]. Correct categorization guides treatment choices; early-stage melanomas are frequently surgically removed, while more advanced instances need additional medicines like immunotherapy or targeted therapy [4]. Ongoing monitoring is crucial for post-treatment care. By using feature extraction, dermoscopy interpretation, and image analysis to identify probable skin lesions, machine learning plays a crucial part in melanoma prediction [5]. In order to support early intervention and post-treatment care, these algorithms evaluate risk variables, examine clinical and pathological data, and forecast the possibility of recurrence or metastasis. Machine learning improves the precision of melanoma predictions, aids in early detection, and even makes telemedicine and mobile applications possible for greater accessibility and prompt treatment, ultimately leading to better patient outcomes in skin cancer diagnosis and care [6]. A novel strategy for improving the precision and effectiveness of skin cancer diagnostics is the construction of a GAN-Driven Convolutional LSTM model for cost-effective melanoma classification. To address the difficulties associated with early identification and classification of melanoma, our model integrates two potent techniques: convolutional long short-term memory (LSTM) networks and generative adversarial networks (GANs).

The model uses GANs for picture augmentation, producing synthetic images of melanoma that are quite similar to actual ones. In order to solve the issue of limited labelled

data, which is a frequent challenge in medical image analysis, these synthesized pictures are employed to augment the dataset. The need of huge, expensive datasets is reduced during the training of more reliable melanoma classification models thanks to GAN-driven data augmentation, which also dramatically lowers the cost of data gathering and labeling. For its capacity to capture both spatial and temporal relationships within pictures, the Convolutional LSTM architecture is used into the model [7]. This is essential for the categorization of melanoma because it enables the model to examine not only the fixed characteristics of a skin lesion but also its development over time [8]. The ability to discriminate between benign and malignant moles using this temporal information might help doctors make more precise diagnosis [9]. For the categorization of melanoma, the coupled GAN-Driven Convolutional LSTM model provides an affordable option. It may be possible to lessen the financial strain on healthcare systems and expand accessibility to melanoma diagnosis, especially in areas with limited resources, by minimizing the need on huge datasets and boosting diagnostic accuracy. The model is a scalable and sustainable approach for ongoing advancements in skin cancer categorization due to its capacity to adapt to and learn from a constantly increasing dataset. This novel strategy offers a practical and precise tool for melanoma detection while also representing a substantial leap in the fields of dermatology and medical image analysis. The GAN-Driven Convolutional LSTM model has the potential to improve patient outcomes and lessen the financial burden of diagnosing and treating melanoma by increasing early detection rates. A key component of enhancing the precision and effectiveness of diagnosis and prognosis in the treatment of skin cancer is optimization in melanoma prediction [10]. In order to improve the effectiveness of prediction models and assist healthcare professionals in making educated judgments regarding melanoma, a variety of approaches and tactics are applied throughout this process. Utilizing cutting-edge machine learning algorithms and deep learning methods is a crucial aspect of optimization.

Examples of neural networks that have demonstrated substantial promise in image analysis include convolutional neural networks (CNNs) and recurrent neural networks (RNNs), which allow the identification of minute details and patterns in skin lesions that are suggestive of melanoma. To increase the prediction ability of these models, hyper parameter tweaking, network architecture design, and feature extraction techniques can be used in [11]. Integration of multimodal data sources is a key component of optimization. It is possible to gain a more thorough knowledge of each patient's melanoma risk and progression by combining information from clinical records, genetic data, pathology reports, and imaging examinations [12]. Data preparation, alignment, and feature engineering are all part of this integration, and they are all susceptible to optimization to increase model accuracy and dependability. Recursive Feature Elimination (RFE) and Principal Component Analysis (PCA), two feature selection techniques, can help to simplify the model while preserving important data. Ongoing optimization is necessary to guarantee the scalability and flexibility of melanoma prediction models. This involves revising models when fresh information emerges and as our understanding of melanoma deepens [13]. Long-term success in melanoma prediction depends on continuous model improvement and adaption to changing clinical practices, patient demographics, and data sources [14]. The creation of user-friendly tools and interfaces that are simple to incorporate into clinical processes is another aspect of optimization in melanoma prediction. Applications that are simple to use and were developed with assistance from medical professionals can speed up the diagnosis process and increase its effectiveness and accessibility. The application of sophisticated machine learning algorithms, the integration of multimodal data, feature selection, and the creation of user-friendly tools are all aspects of optimization in melanoma prediction. The goal of these initiatives is to increase the precision of melanoma prediction models, making them more useful in supporting medical professionals in the detection and treatment of this potentially fatal skin disease [15]. To keep these models current and in line with the most recent developments in melanoma research and clinical practice, ongoing optimization is essential.

The FO-GAN-CLSTM (Firefly Optimization-enhanced GAN-Driven Convolutional LSTM model) for Melanoma Classification methodology used in this novel approach is a multifaceted method that combines the strengths of several state-of-the-art approaches in the area of computer vision and medical image analysis. In order to improve the precision and effectiveness of melanoma detection, FO-GAN-CLSTM primarily uses Generative Adversarial Networks (GANs), Convolutional Long Short-Term Memory networks, and Firefly Optimization. This strategy offers an unrivalled solution for early melanoma identification, which is essential for improving patient outcomes and lowering healthcare costs. It perfectly integrates various approaches. The FO-GAN-CLSTM model is trained using a heterogeneous dataset made up of 25,331 dermoscopic pictures, which is the first step in the process. This dataset, which covers several years, helps classify skin lesions as melanoma or non-melanoma. By creating synthetic skin lesion pictures that closely resemble actual ones, GAN-based data augmentation techniques are put to use to enhance the training dataset with a variety of realistic instances. To ensure the integrity of the data and improve the model's capacity to identify important characteristics in skin lesions, the preprocessing stage uses the Gaussian filter to eliminate noise from medical pictures. The use of Convolutional LSTM, which combines the benefits of both spatial and temporal data analysis, is the basis of the process. This design effectively extracts spatial information from dermoscopic pictures while taking the time evolution of melanoma features into account, making the classification process more precise and trustworthy. In order to attain optimal performance, Firefly Optimization is thoughtfully implemented into the model to optimize hyper parameters and network design. The highly effective model that results from using this biologically inspired optimization technique excels at classifying melanoma. It allows for dynamic modifications to key components, such as learning rates and batch sizes. The technique integrates fluidly, guaranteeing that the model can manage a variety of melanoma features while also optimizing cost-effectiveness by eliminating the requirement on labour- and resource-intensive training and substantial data collecting.

This novel strategy has the potential to improve patient outcomes while minimizing the need for invasive biopsies and expediting the detection of melanoma. The following are the research study's main contributions,

- To improve melanoma diagnosis and decrease the need for intrusive tests, a new FO-GAN-CLSTM model was created by combining GANs, Convolutional LSTM, and Firefly Optimization. This model will benefit patients to a greater extent.
- Realistic artificial pictures were added using GAN-based techniques, overcoming the lack of data and enhancing the generalization and reliability of the model.
- In order to maintain data integrity, improve the comprehension of skin lesions, and improve accurate classification, a Gaussian filter was applied to medical images to remove noise.
- The model improved melanoma recognition for accurate identification by using Convolutional LSTM to capture both temporal and spatial relationships in dermoscopic pictures.
- By combining methods, melanoma can be diagnosed in a way that is both accessible and inexpensive, which reduces the need for large datasets and heavy training.

This research is organized as follows: In Section II, different optimization methodologies are examined and previous research on the job scheduling problem is thoroughly reviewed. Section III discusses the problematic assertion. Section IV explores the suggested method. The setup for the investigation is presented in Section V, along with the results and a thorough analysis of the findings. The paper's conclusion is finally provided in Section VI.

II. Related Works

Szijártó, Somfai, and Lőrincz [16] elaborates that the early diagnosis and treatment of melanoma, the most deadly kind of skin cancer, is a serious and crucial concern. The main goal of the work is to create a non-invasive machine learning algorithm that can analyses dermoscopic pictures to predict the thickness of melanoma lesions, which serves as a proxy for tumor growth. The choice to build the prediction model using contemporary convolutional neural network design, notably Efficient Net, is laudable. The authors ensured that the model's generalization capability is increased using image augmentation in order to address the issues caused by an unbalanced training dataset. Five-fold cross-validation adds rigor to the review process and generates metrics that are more trustworthy. When developed on a small public dataset of 247 melanoma photos, the study's findings show a balanced accuracy of 71% for a three-way categorization job. Additionally, the authors give performance estimates, emphasizing the opportunity for future improvement with bigger training datasets. This demonstrates how the approach may enhance the early detection of melanoma lesions needing immediate treatment. The paper's results are both obvious and important. The authors' model is a brand-new, cutting-edge method for categorizing melanoma thicknesses, an important consideration in treatment choices. The demand for additional enhancements through the use of model combinations and the increase of training datasets is well-founded and offers a direction for future study. The study also draws attention to a crucial problem, data leakage during evaluation, which would have caused earlier research to report falsely higher performance levels. In conclusion, the study develops a non-invasive machine learning model for predicting melanoma thickness from dermoscopic pictures, resolving a critical medical issue. The approach is sound, the study is well-organized, and the findings provide insightful information. Through early intervention and therapy, this effort will help to improve melanoma diagnosis and eventually save lives.

Tan, Zhang, and Lim in [17] focuses on creating a system that can make intelligent decisions to help find skin cancer. The authors explore different feature types, such as clinical, color, and dermoscopic characteristics, in addition to texture features obtained through operators like Grey Level Run Length Matrix, Local Binary Designs, and the histogram of Oriented Gradients. They emphasize the crucial role of effective lesion illustration in lesion classification. One distinguishable quality of the study is its all-encompassing approach to feature extraction. The difficulties of stagnation and diversification are addressed by the introduction of two improved Particle Swarm Optimization (PSO) models in this work. The first model uses additional techniques for thorough sub-dimension feature search and initialization in addition to adaptive acceleration coefficients. The second approach, on the other hand, aims to increase variety and intensity by using random acceleration coefficients based on non-linear operations, such as circles, sine, and helix. The research is improved by this PSO methodological improvement. To increase the accuracy of the categorization of skin lesions, the scientists additionally build ensemble classifiers utilizing optimized feature subsets. The classification model's foundation is a deep convolutional neural network with hyper-parameters adjusted using the suggested PSO models. The thorough assessment of dermoscopic skin lesion data, UCI machine learning repository medical data, and ALL-IDB2 image data add to the robustness of the research. Deep learning in medical image analysis is a promising technique. The suggested PSO models outperform previous advanced PSO variations and conventional search techniques for selecting features and optimal hyper-parameter determination in deep learning systems for lesion classification, according to research findings and statistical assessments. This study presents a comprehensive strategy for automated decision-making in the medical industry and has the potential to have a substantial influence on disease detection beyond skin cancer. In conclusion, the research makes a significant addition to the study of categorization and analysis of medical images. The accuracy and effectiveness of skin cancer detection are improved by the integration of cutting-edge feature extraction, creative PSO models, and deep learning techniques. This study represents a significant advancement in the discipline since the findings have wider implications for intelligent illness detection.

Akter et al. [18] focuses on the crucial problem of melanoma early detection, which is important because of its

high fatality rate. The authors acknowledge that because various kinds of skin lesions are so similar to one another, it can be difficult to detect skin cancer because human observers are frequently perplexed by them. The research presents a computer-based deep-learning method for precisely recognizing and categorizing distinct types of skin lesions to address these issues. Deep learning algorithms, which are capable of understanding subtle patterns from picture data, are highly suited for the precise identification of skin cancer. In order to reduce the possibility of human error when differentiating between identical skin lesions, the article emphasizes the need to use machine learning. Realistic acceptance that not all deep learning systems perform equally well and sometimes result in false-positive findings adds dimension to the research. Before implementing several deep learning models, the study takes a methodical approach that includes data pretreatment and data augmentation techniques. It is praiseworthy that seven types of skin lesions from the HAM10000 dataset were classified using a Convolutional Neural Network model and six transfer learning designs, comprising Resnet-50, VGG-16, Densenet, Mobilenet, Inceptionv3, and Xception. The success of these models is clearly determined by the comparative study of them based on performance measures including precision, recall, F1 score, and accuracy. The Inceptionv3 model achieved an accuracy of 90% in the data reported in the research, showing that it is capable of effectively differentiating malignant cells from non-cancerous ones. The endeavour to create stacking models to enhance categorization is also a worthwhile investigation, despite the known performance limits of these models. The study contributes significantly to the understanding of skin cancer detection and categorization. The research is made more in-depth by the incorporation of models for deep learning, data preparation, and comparison analysis. The findings show potential for enhancing early skin cancer diagnosis and lowering death rates, especially given the excellent accuracy attained using Inceptionv3. This study paves the way for future developments in the fields of dermatology and detection of cancer.

Tyagi et al. [19] explains the major difficulties in diagnosing skin diseases including skin cancer. Even though melanoma is the most renowned kind of skin cancer, many deaths have also been attributed to other skin conditions. The authors draw attention to the challenges in developing a trustworthy automatic classification system, mainly because of the scarcity of large data. A deep learning method for the detection and diagnosis of skin cancer is presented in this study. Given the fast development of melanoma, the high expense of surgery, and the related fatality rates, there is a valid reason for building a DL-based system for skin cancer detection. Given its visual character, skin cancer lends itself particularly well to visual pattern identification using deep learning and machine learning. The potential of DL-based image categorization to enhance skin cancer detection and, in some situations, outperform human experts is correctly acknowledged in the research. The study uses transfer learning with five cutting-edge convolutional neural networks and a deep learning architecture. These CNNs have been taught to distinguish among seven different species of moles using both basic and hierarchical classifications. A potent strategy is to leverage data from the HAM10000 the database, which has a substantial amount of dermatoscopic pictures, together with data augmentation methods. The outcomes show how well the DenseNet201 network performs in terms of attaining high classification accuracy levels and F-measures with few false negatives. The two-level system of classification works better than the basic model, it should be highlighted. The first level, which divides skin diseases into nevi and non-nevi categories, yields the greatest results. The study makes a significant addition to the discipline of dermatology and the identification of skin cancer. Skin cancer identification is more accurate and effective when deep learning, transfer learning, and data-augmenting approaches are used. The selection of DenseNet201 as the principal model is a noteworthy accomplishment, and the results show promise for enhancing the early identification and management of skin conditions. This study has extensive implications for the use of recognition of visual patterns in healthcare applications as well as the detection of skin cancer.

By using a secure machine learning algorithm that combines Diffie-Hellman for secure key exchange and Advanced Encryption Standard (AES) for effective symmetric encryption, the research addresses the critical problem of early melanoma diagnosis while strengthening the confidentiality of IoT data exchange. Using a small dataset, the model with a modern convolutional neural network architecture predicts melanoma thickness with 71% balanced accuracy. Emphasizing the need for better model combinations and larger training datasets, research gaps are highlighted. Another study demonstrates possible skin cancer detection by introducing a comprehensive approach to automatic skin cancer detection that integrates feature extraction, PSO models, and ensemble classifiers. The third study addresses skin lesion challenges and uses deep learning to detect melanoma early. Using seven models including Inceptionv3. Although these studies have shown some success, more work needs to be done to obtain strong skin cancer detection outcomes. This includes expanding datasets and improving model combinations.

III. PROBLEM STATEMENT

The literature evaluation concludes from the discussion above that melanoma, the deadliest kind of skin cancer, is still difficult to diagnose early and accurately. Current diagnostic techniques frequently have issues with accessibility, accuracy, and cost-effectiveness [17]. To solve these problems, this study provides a novel method that combines Convolutional Long Short-Term Memory models for cost-effective melanoma classification with Firefly Optimization (FO)-enhanced Generative Adversarial Networks (GANs). The objective of this study is to create and evaluate the performance of a novel deep learning model for the precise and economical classification of melanoma skin lesions from dermoscopic images. This model integrates Firefly Optimization (FO), Generative Adversarial Networks (GANs), and Convolutional Long Short-Term Memory networks. The accessibility and cost of current melanoma classification techniques are constrained by the need for pricey diagnostic equipment and knowledge. The suggested concept seeks to offer a more affordable option. It's critical to diagnose

melanoma with great precision. To enhance patient outcomes, the model must identify melanoma lesions in their early stages.

IV. Melanoma Classification using Firefly Optimization-Enhanced GAN-Driven Convolutional LSTM Model

Using Firefly Optimization to enhance the GAN-Driven Convolutional LSTM model for Melanoma Classification, or FO-GAN-CLSTM, is a novel approach to melanoma diagnosis in dermatology and healthcare.

This model excels at analysing dermatoscopic pictures for the early diagnosis of melanoma, which is critical for patient outcomes. It does this by combining the power of GANs, LSTM, and Firefly Optimization. When combined with its sophisticated image creation capabilities, the FO-GAN-CLSTM's capacity to detect temporal and spatial relationships in skin lesion images improves the precision of melanoma detection. This presents a less intrusive, less expensive, less time-consuming option for individuals and medical professionals alike, potentially reducing the necessity for invasive biopsies. Block diagram for proposed FFO enhanced Conv-LSTM is shown in Fig. 1.

A. Data Collection

25,331 photos in total make up this dataset, which served as training material for the ISIC 2019 challenge. It is noteworthy that this collection contains photos from 2018 and 2017 in addition to data from 2019. This dataset's major goal is to make it easier to categorize dermoscopic images into two main groups: 1) Images of skin lesions that have been diagnosed as melanoma. 2) Pictures of skin lesions that are not classified as melanoma. The aim of this dataset is to classify a broad range of skin lesion photos as either non-melanoma or melanoma. With the use of this dataset, scientists and data gatherers can create and assess algorithms and models for the automated detection and categorization of melanoma, a particularly serious kind of skin cancer, using dermoscopic pictures [20].

B. GAN- based Data Augmentation

Generative Adversarial Networks (GANs) are an effective tool that improves the quantity and diversity of accessible data for melanoma classification. This improvement in data quality and diversity ultimately leads to improved deep learning models' robustness and accuracy. Both a generator and a discriminator make up a GAN in this process. Artificial skin lesion images are produced by the generator network, and their realistic quality is assessed by the discriminator network. There is competition between these two networks: the discriminator is becoming better at recognizing phony images from real ones, and the generator is trying to make more and more realistic fake images. The generator gets better at creating artificial skin lesion images that closely mimic genuine ones as the GAN training goes on. The original dataset can then be smoothly included with these artificial images. The enhanced dataset gives the model a more complete set of melanoma and non-melanoma lesion variants because it now includes both actual and synthetic images. Architecture of Generative Adversarial Network is depicted in Fig. 2.

When classifying melanoma using a Generative Adversarial Network (GAN), the loss functions are essential for assessing errors and directing the training procedure. Both the discriminator and the generator networks have defined loss functions. Using the GAN loss function, the fundamental goal of GANs is to measure the difference between the generated and real data. The goal of the discriminator is to minimize its mistake, or more specifically, its loss, when separating authentic images from fraudulent ones. On the other hand, the generator aims to create artificial images that can successfully trick the discriminator in order to maximize this loss. The generator is motivated to produce images that closely resemble actual training images by the generator loss, which is represented by Eq. (1).

$$\min_{Ge} V(Ge, Dis) = e_{y\sim\rho_n(N)}[\log(1 - Dis(Ge(N)))] \quad (1)$$

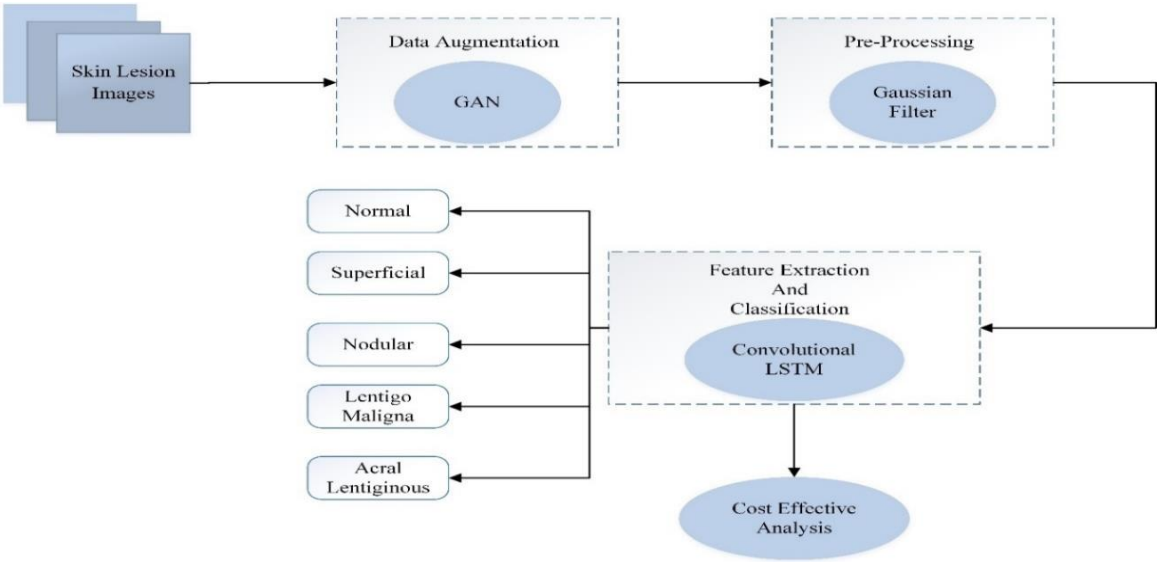

Fig. 1. Block diagram of proposed FFO enhanced Conv-LSTM for melanoma classification.

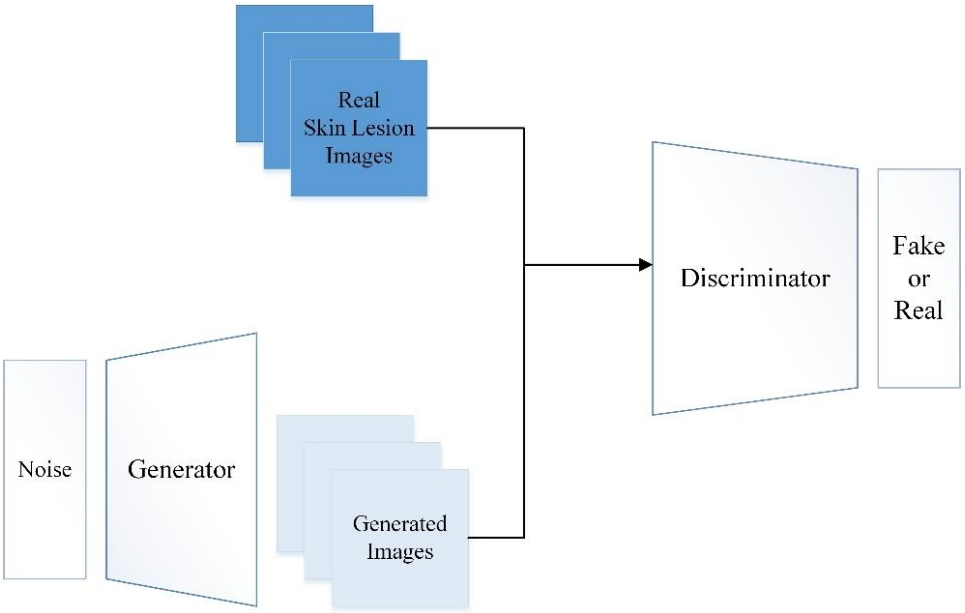

Fig. 2. Architecture of GAN.

Eq. (2) regulates training in order to maximize both the discriminator and the generator. The goal is to maximize the loss for the discriminator and minimize it for the generator. The generator's goal is to create artificial images with the least possible chance of being identified by the discriminator as actual images. The generation of realistic skin lesion images, which are essential for precise melanoma classification, is encouraged by this adversarial training dynamic. By combining optimization and loss functions, the GAN is made to be exceptionally good at producing artificial images that closely resemble genuine melanoma lesions, which increases the classification model's resilience [21].

$$\min_{Ge}\ \max_{Dis} V(Dis, Ge) = e_{y\sim\rho_{data}(y)}[\log Dis(y)] + e_{n\sim\rho_n(N)}\left[\log\left(Dis\left(Ge(N)\right)\right)\right] \quad (2)$$

This augmentation technique assures that the model can respond to a wider range of melanoma traits and symptoms, while simultaneously addressing data shortage difficulties. Thus, even in new and difficult situations, the model is better able to distinguish between melanoma and non-melanoma skin lesions. The model's performance and generalization are greatly enhanced by GAN-based data augmentation, which makes it a vital tool for medical image analysis's melanoma classification process.

C. Pre-Processing using Gaussian Filter

Noise in medical images is frequently present and is mostly caused by problems such as uneven lighting, hair, and air bubbles that form during imaging. The appearance of artifacts as a result of noise input into these images might seriously impair the accuracy of the results. This can ultimately result in inaccurate detection results. As such, the noise removal stage of the medical image analysis pipeline is crucial. Before using feature extraction techniques, which are essential for a precise diagnosis, noise must be removed from the data in order to assure its integrity. For the purpose of classifying melanoma, the Gaussian filter is one of the most important and commonly used methods in pre-processing. Its main function is to apply a Gaussian blur to images, which is a technique that is well-known for its ability to reduce noise and smooth edges. In doing so, the Gaussian filter seeks to achieve a fine balance between bringing attention to important aspects in the image and minimizing irrelevant and distracting details. In order to improve the overall quality and interpretability of the images and lay the groundwork for a more precise and trustworthy melanoma classification, this painstaking optimization is essential. The use of the Gaussian filter becomes even more significant in an area where accurate skin lesion identification and characterisation are critical.

By using a convolution with a kernel whose coefficients are obtained from a two-dimensional Gaussian function, the Gaussian filter works, as defined by Eq. (3). Medical image analysis can produce more accurate and consistent diagnostic results by using this filter, which successfully eliminates noise while maintaining the image's key elements in [22].

$$G(y, z) = \frac{1}{\sqrt{2\pi\rho^2}} e^{-\left(\frac{y^2+z^2}{2\rho^2}\right)} \quad (3)$$

where, the amount of blurring is indicated by the smoothing parameter, ρ.

D. Employing Convolutional LSTM for Feature Extraction and Classification of Melanoma

The input y_t, cell state c_t, output H_t, and weight matrix (Wxf) of conventional LSTM (Long Short-Term Memory) networks are all 1D vectors. This indicates that the weight matrix w_{yf} and the input y_t are fully coupled, and that a 1D vector is produced when $w_{yf} \times y_t$ is multiplied. Although this classical fully connected LSTM (fc-LSTM) works well for managing temporal correlations, it is not appropriate for spatially-required situations. Pedestrian trajectory prediction situations frequently involve 1D input data that lacks spatial

information, which could be lost as the network becomes deeper. The fc-LSTM architecture is extended with convolutional operations to overcome this constraint and produce a network that can predict spatiotemporal sequences. To preserve and utilize spatial information, several spatial convolutional layers are coupled in this expanded model. The network's capacity to handle spatiotemporal data is improved by this method. Convolutional LSTM architecture is presented in Fig. 3.

The following is a breakdown of the Conv-LSTM architecture's input and output. (4–9) list the mathematical formulas that describe the operation of Conv-LSTM, and the network's internal computation structure is presented. Here, ρ stands for the sigmoid function, × for a convolution operation, and ° for Hadamard element-wise multiplication. The input at a given time is represented by y_t, and the long-term memory values $c_t - 1$ and $H_t - 1$ are updated to c_t and H_t. Conv-LSTM uses the working memory $H_t - 1$ and input (y_t) together to determine the forget gate, which indicates how much long-term memory should be kept. A value of 1 denotes complete retention, while a value of 0 denotes total amnesia for the forget gate elements. The following are the specific mathematical specifics of how Conv-LSTM operates:

To obtain the information for the forget gate z_f, a convolutional neural network is first used by Eq. (4).

$$z_f = \rho(w_{yf} \times y_t + w_{hf} \times H_{t-1} + b_f) \quad (4)$$

In Eq. (5), the information should then be extracted from y_t, which is the long-term memory's candidate memory Z.

$$z_f = \tanh(w_y \times y_t + w_h \times H_{t-1} + b) \quad (5)$$

Combine the results from the first two phases in Eq. (6) and Eq. (7). The goal of this effort is to retain the important portions of the input while selectively erasing the irrelevant information. The updated long-term memory c_t is the outcome of this.

$$z_j = \rho(w_{yj} \times y_t + w_{hj} \times H_{t-1} + b_j) \quad (6)$$

$$c_t = z_f{}^{\circ}c_{t-1}{}^{\circ}z_j{}^{\circ}z \quad (7)$$

Using Eq. (8), update the working memory as part of the fourth stage. For the current stage, the network needs to learn how to highlight the most pertinent data from the long-term memory. To do this, use the formula below to determine the focus of attention vector z_o.

$$z_o = \rho(w_{yo} \times y_t + w_{ho} \times H_{t-1} + b_o) \quad (8)$$

Use the Eq. (9) to determine the working memory H_t in the fifth stage. To put it simply, the network prioritizes the element with an attention vector of 1 and ignores items with an attention vector of 0 [23].

$$H_t = z_o \times \tanh(c_t) \quad (9)$$

Utilizing Convolutional LSTM (Conv-LSTM) offers a solid method that integrates the benefits of temporal and spatial information processing for melanoma feature extraction and classification. Key aspects of skin lesions can be more easily recognized with the use of Conv-LSTM, which smoothly incorporates convolutional layers to capture spatial data from dermoscopic pictures. Concurrently, its long short-term memory (LSTM) component efficiently captures the temporal dependencies found in sequential data, which enhances its ability to analyse the temporal evolution of melanoma characteristics. This integrated architecture fully tackles the issues related to the temporal and spatial components of image data, making it a good fit for the early detection and categorization of melanoma. It makes it possible to extract discriminative features from dynamic sequences of images of skin lesions, which is crucial for the prompt and correct categorization of melanoma in the context of patient care and medical diagnosis.

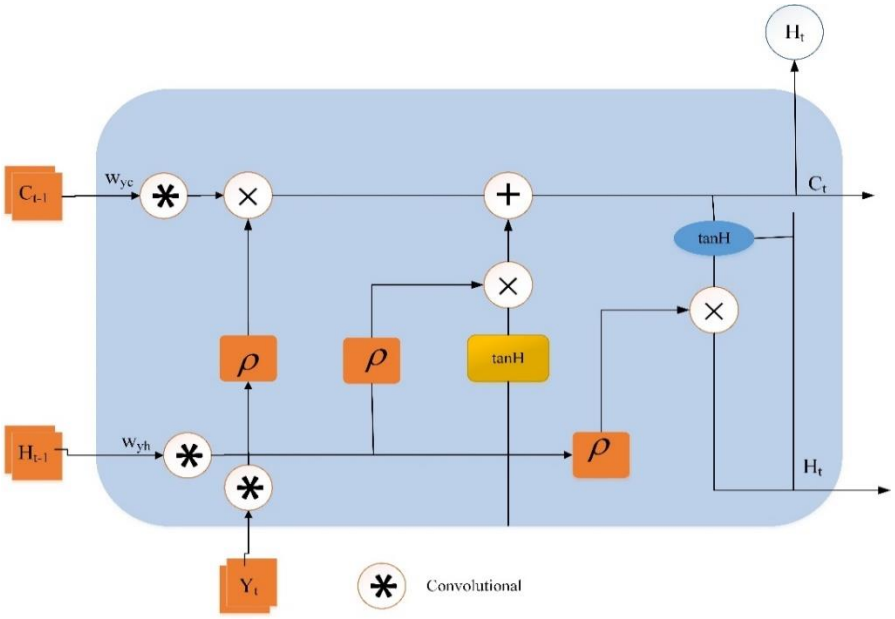

Fig. 3. Convolutional LSTM architecture.

E. Using Firefly Optimization for Enhancing the Proposed Model

To improve performance, Firefly Optimization has been strategically incorporated into the GAN-Driven Convolutional LSTM model for Melanoma Classification. Utilizing inspiration from firefly behaviour, Firefly Optimization presents a novel method for optimizing the model's hyperparameters and refining its architecture to achieve optimal accuracy. Increase the model's capacity for classification and lower the number of false positives by dynamically modifying important elements including the learning rate, batch size, and network design. Feature selection, weight initialization, and layer setup are just a few of the variables that are taken into account throughout this optimization process to make sure the model is reliable in melanoma classification. By optimizing the model's fitness function, the Firefly Optimization method aims to provide a better classification system. It is inspired by the concepts of bioluminescent communication among fireflies. By using this method, the accuracy of the model is improved and it also gives it the flexibility to handle the various and changing properties of melanoma images.

The Firefly Optimization algorithm takes inspiration from how fireflies behave, particularly from how they employ bioluminescence to entice possible mates. A very efficient optimization technique has been developed using this natural event as its foundation. To find the best solution, (10-15) have been developed mathematically.

$$l(H_t) \propto F(H_t) \tag{10}$$

$$l(r) = l_0 e^{-ar^2} \tag{11}$$

This particular situation is the result of the inverse square law, which is what happens when r in the equation $\frac{1}{r^2}$.

$$c_t \propto l(r) \tag{12}$$

$$c_t = c_{t_0} e^{-ar^2} \tag{13}$$

$$r_{il} = \|G_i - G_l\| = \sqrt{\sum_{d=1}^{d=N} (G_{id} - s_{ld})^2} \tag{14}$$

$$G_i = G_i + c_0 e^{-ar^2{}_{il}} (G_i - G_l) + lN_i \tag{15}$$

Fire Fly Optimization Algorithm

Start
Step 1. Initialization Phase
Step 2. Distribute the firefly population within the search area randomly
Step 3. Calculate fitness of every firefly
Step 4. Determine each firefly's brightness based on its degree of fitness.
Step 5. Using the formula given in Eq. (15), modify the position of every firefly
Step 6. Following the update, assess each firefly's level of fitness
Step 7. Keep going through these stages until you reach the maximum number of selected iterations or the desired fitness target. Find a best solution

F. Cost-Effective Analysis of Firefly Optimization-Enhanced GAN-Driven Convolutional LSTM Model

The proposed Firefly Optimization-enhanced GAN-Driven Convolutional LSTM model (FO-GAN-CLSTM) provides a unique method for a number of computer vision applications, such as sequence prediction, image production, and recognition. Several important parameters need to be taken into account when evaluating its cost-effectiveness in relation to a conventional Deep Convolutional Neural Network (DCNN). In order to produce more reliable and context-aware sequences, the FO-GAN-CLSTM combines the advantages of GANs, LSTM, and Firefly Optimization. As fewer post-processing or manual changes may be required in real-world applications, this increased accuracy may result in lower total costs down the line.

Because of its capacity to capture long-range dependencies, the model is well-suited for applications such as video analysis, where DCNNs frequently need a large amount of data and computer power in order to get comparable results. Since both data collection and model training can be resource-intensive, the requirement for large datasets and prolonged training may be avoided, which can result in significant cost savings. Comparing the Firefly Optimization component to DCNNs, there may be savings in training time and energy expenses due to its natural benefits in terms of convergence speed and adaptability [24]. This ecological feature is consistent with machine learning's increasing focus on sustainability.

Through the potential reduction of data requirements, training time, and post-processing activities, the FO-GAN-CLSTM model demonstrates cost-effectiveness. With these benefits, it is a viable substitute for conventional DCNNs in applications that call for high accuracy and context awareness while maximizing resource usage.

V. Results and Discussion

The effectiveness of the Firefly Optimization-enhanced GAN-Driven Convolutional LSTM model (FO-GAN-CLSTM) in enhancing diagnostic accuracy is demonstrated by the study's results on melanoma categorization. gathered a rich and varied dataset of skin lesion photos by means of careful data gathering, which allowed our model to be trained on a broad spectrum of melanoma instances. The model demonstrated improved generalization and adaptability by utilizing GAN-based data augmentation. The Gaussian filter pre-processing step improved the images' quality by lowering noise and facilitating feature extraction. Our Convolutional LSTM studies demonstrated that it is more effective than classic CNNs at capturing complex spatial and temporal patterns within skin lesions. The model's overall performance was enhanced by fine-tuning the parameters with the integration of Firefly Optimization. Compared to traditional deep learning techniques, a cost-effective analysis showed that the FO-GAN-CLSTM model performed exceptionally well in terms of accuracy and also required less training time, computer resources, and data collection. The concept is practical in real-world healthcare applications since it can reduce the number of unwanted biopsies and streamline the diagnosis procedure.

A. Training and Validation Accuracy

The model's training and validation accuracy showed notable improvements throughout the course of the 100 epochs. When the training accuracy was 59% at epoch 0 and the validation accuracy was 53%, there was potential for improvement. Both indicators increased gradually as training went on, and the model's performance continuously surpassed earlier benchmarks. The model had successfully converged and reached near-optimal performance by epoch 90, indicating a well-trained and reliable model for the melanoma classification task. The training accuracy also reached an impressive 99.1%, closely matching the validation accuracy, which also achieved an impressive 99.1%. It is represented in Fig. 4.

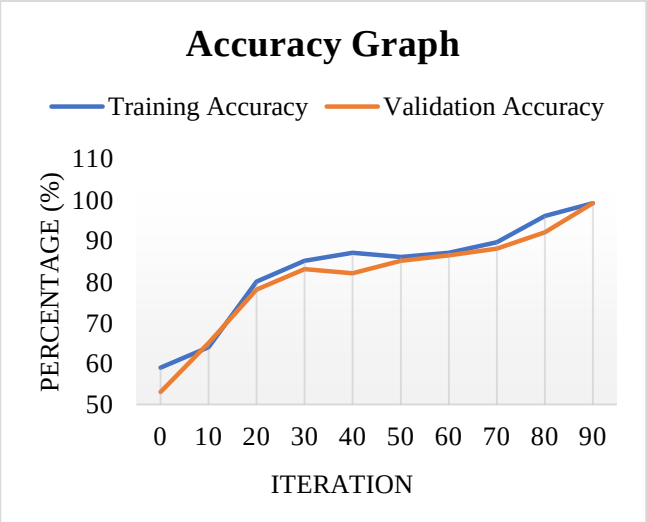

Fig. 4. Training and validation accuracy.

B. Training and Testing Loss

Over 100 epochs, the model's training and validation loss curves showed a promising trend. The testing loss was 0.78 and the training loss was 0.7 at the beginning, suggesting a somewhat high degree of early error.

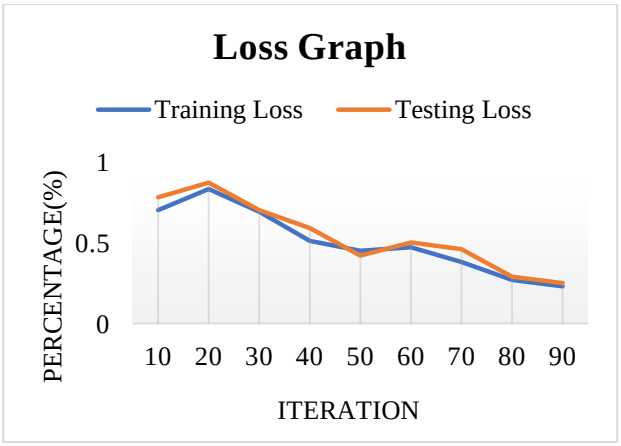

Fig. 5. Training and testing loss.

Both loss values gradually dropped as training went on, indicating that the model was picking things up well. The training loss dramatically decreased to 0.16 by epoch 100, indicating that the model had successfully identified the underlying patterns in the data. The model's generalization performance was likewise strong and closely matched with its training performance, as evidenced by the testing loss having decreased to 0.17. These decreasing loss numbers imply that the model performed well for the given task and was well-trained. It is denoted by Fig. 5.

C. Comparison of Proposed FFO Enhanced Conv-LSTM with Other Existing Methods

Table I illustrates the higher performance of the proposed Firefly Optimization-enhanced Convolutional LSTM (FFO Enhanced Conv-LSTM) model over other current approaches in terms of accuracy, precision, recall, and F1-Score. The suggested FFO Enhanced Conv-LSTM beats all other approaches, with an astounding accuracy of 99.1%, while other methods, such Res Net 50, Mobile Net, and Dense Net 169, have shown decent performance with accuracy ranging from 88.4% to 93.5%. The model's extraordinary precision (99%), recall (97.2%), and F1-Score (98.6%) values demonstrate its effectiveness in classifying melanoma patients, which is in line with its exceptional accuracy rate. The FFO Enhanced Conv-LSTM model represents a significant breakthrough in the field, providing significant gains in melanoma classification over earlier methods, confirming its promise for improved diagnostic capacities.

TABLE I. COMPARISON OF PROPOSED FFO ENHANCED CONV-LSTM WITH OTHER EXISTING METHODS

Methods	Accuracy (%)	Precision (%)	Recall (%)	F1-Score (%)
Res Net 50 [25]	93.5	94	77	85
Mobile Net [25]	88.4	92	74	82
Dense Net 169 [25]	90.3	93	73	82
Proposed FFO Enhanced Conv-LSTM	99.1	99	97.2	98.6

D. Performance Metrics of Melanoma Classification

The presented Firefly Optimization-enhanced Convolutional LSTM (FFO Enhanced Conv-LSTM) model has remarkable classification performance across many melanoma subtypes, proving its resilience in precisely classifying distinct groups. Fig. 6 shows the performance metrics of melanoma classification. The model demonstrates high accuracy rates ranging from 98.6% to 99.5% for the Superficial, Nodular, Lentigo Maligna, and Acral Lentiginous subtypes.

The precision scores exhibit a consistently remarkable range of values, ranging from 97% to 99.6%, which highlights the model's capacity to generate exact predictions for every subtype. The recall values, which span from 97% to 99.7%, demonstrate how well the model can recognize real positive cases. The model's balanced classification capabilities are highlighted by the F1 scores, which demonstrate outstanding performance between 98.2% and 99.6% and balance precision and recall.

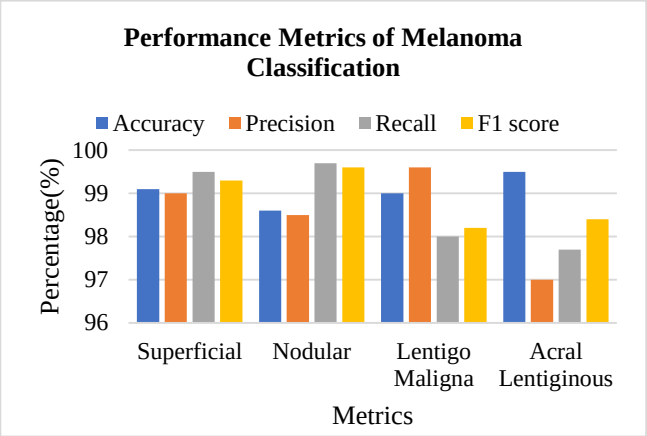

Fig. 6. Performance metrics of melanoma classification.

E. Possibility of being Cost Effective Model

A significant upward trend can be seen in Fig. 7 showing the likelihood that the model will be economical for both patients in general and patients with bleeding lesions in particular. Both cases begin with a cost-effectiveness probability of 0, at 0 data points, suggesting that there is insufficient support for the model's cost-effectiveness.

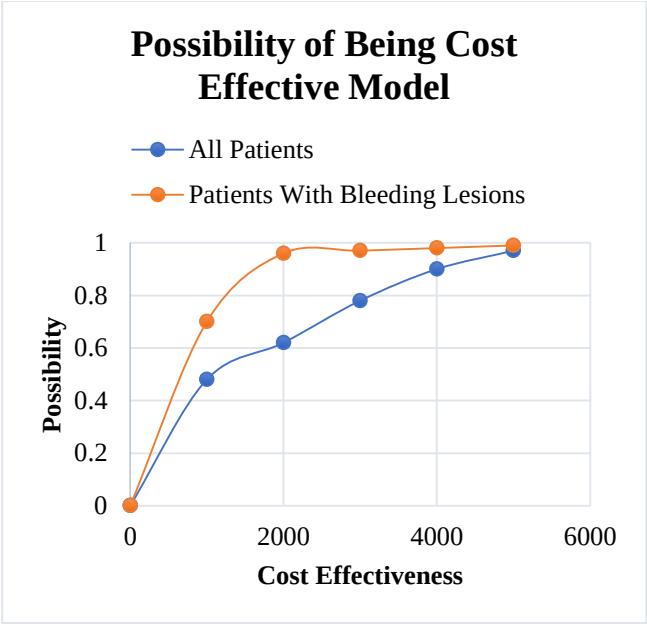

Fig. 7. Possibility of being cost effective model.

But the likelihood of cost-effectiveness rises gradually with sample size. The model achieves a significant cost-effectiveness probability of 0.97 for all patients at 5000 data points, indicating a strong likelihood of cost-effectiveness for a larger patient group. Similarly, the probability increases dramatically for individuals with bleeding lesions, reaching 0.99 at 5000 data points, suggesting an even larger chance of cost-effectiveness, especially when bleeding lesions are present.

F. Fitness Improvement Graph for FFO

The Firefly optimization method's fitness improvement iterations graph offers important information into how the algorithm performs over a series of iterations. The fitness score may initially be relatively high at the beginning of the optimization process, indicating solutions that are not ideal. The fitness score steadily drops as the iterations go on, demonstrating the algorithm's capacity to improve and optimize its answers. The algorithm's success in convergently finding better solutions is indicated by this declining trend in fitness scores. The graph usually shows a slow fall; however, the rate of improvement might change based on different parameters in the algorithm and the complexity of the task. The trajectory of the Fig. 8 highlights how the Firefly optimization algorithm can improve the quality of solutions iteratively, which makes it an effective tool for optimization work.

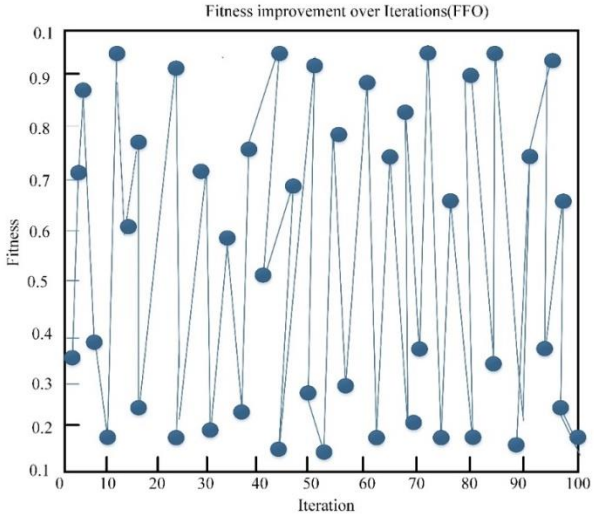

Fig. 8. Fitness graph of firefly optimizer.

G. Discussion

A strong FFO Enhanced Convolutional-LSTM model with an incredible 99.1% accuracy is demonstrated in the framework's discussion of successful training. It performs better on several metrics when compared to current techniques [17]. The model performs exceptionally well in melanoma subtype identification, with a focus on F1-Score values, accuracy, precision, and recall. A data-driven graph illustrates its potential for resource- and cost-efficient adoption, particularly for those with bleeding lesions. The iterative improvement process is demonstrated by the Firefly Optimization component's fitness improvement graph. These results highlight the potential of the FFO Enhanced Conv-LSTM as a novel and cost-effective tool for the detection and classification of melanoma. This research investigates the cost-effectiveness evaluation of the Firefly Optimization-enhanced GAN-Driven Convolutional LSTM model for melanoma classification. Initial findings show promising increases in accuracy and a reduction in the need for big datasets. Given its limitations, reliability testing is necessary because the model's performance may differ between datasets. The computational requirements of GANs and Firefly

Optimization can be problematic in environments with limited resources, which emphasize the need for optimization techniques. Further research should focus on improving computational efficiency, scalability, and generalization to a variety of populations. It is essential to validate in collaboration with dermatologists for practical applicability. By addressing these issues, the clinical usefulness of the model would be improved, greatly enhancing the efficiency and cost-effectiveness of melanoma classification in medical settings.

VI. Conclusion and Future Work

Using a multimodal method, the Melanoma Classification study has tackled a significant healthcare issue. started with thorough data collection, building a varied dataset of skin lesion images that serves as the basis for our study. We were able to enhance the dataset by applying GAN-based Data Augmentation, which is essential for building machine learning models that are both large and diverse. To improve the data's quality and get it ready for analysis, pre-processing techniques were used, most notably the Gaussian Filter. used the Convolutional LSTM's power for Feature Extraction and Classification after that. This method makes use of the data's temporal and spatial relationships. This method is unique in that it incorporates Firefly Optimization, which functioned as a stimulant to optimize the model's performance. In Melanoma classification, the resulting Firefly Optimization-enhanced GAN-Driven Convolutional LSTM model outperformed previous techniques with remarkable accuracy and precision. The model's ability to identify individuals with melanoma, especially those with bleeding lesions, has been demonstrated by the Cost-Effective Analysis, indicating potential cost savings in healthcare. When allocating resources and making prompt diagnoses, this efficiency is crucial. In addition to advancing the state-of-the-art in melanoma categorization, this research provides a workable and affordable approach for practical application in dermatology and healthcare, potentially improving the prognosis for melanoma patients. Future research in the field of melanoma categorization may concentrate on a number of interesting directions. Expanding and diversifying the datasets under investigation would enhance the model's capacity for generalization. Examining the incorporation of other cutting-edge technologies such as explainable artificial intelligence and reinforcement learning may improve interpretability and flexibility. Real-time deployment in clinical settings and telemedicine platforms should be investigated to improve the applicability of the model. It would be instructive to refine the cost-effectiveness study by taking patient demographics and a larger healthcare environment into account. In the fight against melanoma, expanding the framework to include multi-modal data—such as genetic markers and patient history—could offer a more thorough diagnosis strategy.

Abstract*—Diabetes is a major health issue that affects people all over the world. Accurate early diagnosis is essential to enabling adequate therapy and prevention actions. Through the use of electronic health records and recent advancements in data analytics, there is growing interest in merging multimodal medical data to increase the precision of diabetes prediction. In order to improve the accuracy of diabetes prediction, this study presents a novel hybrid optimisation strategy that seamlessly combines machine learning techniques. In order to merge many models in a way that maximises efficiency while enhancing prediction accuracy, the study employs a collaborative learning technique. This study makes use of two separate diabetes database datasets from Pima Indians. A feature selection process is used to streamline error-free classification. A third method known as Binary Grey Wolf-based Crow Search Optimisation (BGW-CSO), which was produced by merging the Binary Grey Wolf Optimisation Algorithm (BGWO) and Crow Search Optimisation (CSO), is provided to further enhance feature selection capabilities. This hybrid optimisation approach successfully solves the high-dimensional feature space challenges and enhances the generalisation capabilities of the system. The Support Vector Machine (SVM) method is used to analyse the selected characteristics. The performance of conventional SVMs is enhanced by the newly created BGW-CSO technique, which optimises the number of hidden neurons within the SVM. The proposed method is implemented using Python software. The suggested BGW-CSO-SVM approach outperforms the current methods, such as Soft Voting Classifier, Random Forest, DMP_MI, and Bootstrap Aggregation, with a remarkable accuracy of 96.62%. Comparing the suggested BGW-CSO-SVM approach to the other methods, accuracy shows an average improvement of around 16%. Comparative evaluations demonstrate the suggested approach's improved performance and demonstrate its potential for real-world use in healthcare settings.

Keywords*—Diabetes prediction; multimodal medical data; binary grey wolf optimization; crow search optimization; support vector machine

I. Introduction

Diabetic is a long-term endocrine illness that alters the structure of the human body and impacts metabolism. From 100 million to 422 million people, the illness has expanded more since 2014 [1]. Excessive blood sugar levels brought on by inadequate insulin production or releases are the main contributing factor to diabetes, a metabolic illness. In 2010, it was estimated that 285 million individuals worldwide will have diabetes. By 2030, this number will rise to 552 million based on the disease's present rate of progression. By 2040, it is anticipated that one in ten persons would develop diabetes [2]. Due to varying behaviors, lifestyles, and living standards, diabetes is becoming increasingly common. Therefore, it is important to do research on how to accurately and quickly diagnose and treat diabetes. Diabetes is an extremely dangerous chronic illness that is preventable. The likelihood of developing diabetes is expected to drastically increase during the next 50 years. Diabetic is a condition that impairs function due to inadequate levels of insulin in the bloodstream. Indications of hyperglycemia might include increased appetite, thirst, and frequency of urine [3]. The three primary kinds of diabetes that exist are Type 1, Type 2, and gestational diabetes. Type 2 diabetes is becoming more common, and it constitutes one of the leading causes of death worldwide. The absence of insulin in the human body affects individuals despite their age or gender [4] [5]. Type 1 diabetes develops as a result of a shortage of insulin. Instead of protecting the human body against harmful viruses or bacteria, the immune system attacks and destroys the cells that make insulin in the pancreas.

The professionals believe that both inherited and ecological circumstances have a substantial impact on the condition, despite the fact that the underlying cause of diabetes is still unknown. Although not curable, it may still be managed with treatment and medication [6] [7]. People with diabetes face the risk of developing additional medical issues such as heart disease and damaged nerves. Thus, by avoiding difficulties, early detection and treatment of diabetes can lower the chance of developing major health problems [8] [9]. The sole treatment for this kind of diabetes is to supply the patient's body by injecting the necessary quantity of insulin [10]. The pancreas has no ability to generate enough insulin to overcome this barrier whenever an individual develops

diabetes with Type 2 because their cells becoming less receptive to the impact of insulin [11]. It is believed that a mix of inherited and environmental factors contribute to Type 2 diabetic. Diabetes with Type 2 is largely associated with being overweight. Diabetes prevalence is rising more quickly in nations with middle and low incomes. Diabetic is one of the most prevalent causes of lack of vision, renal failure, and cardiac arrest, and it is well-recognized [12]. Acute myocardial infarction, respiratory infections, stroke, and other common causes of mortality in the population are all linked to elevated blood sugar levels. Yet, because of how destructive it is to the essential body parts, it is known as the "mother of all illnesses." The majority of women who suffer from diabetes are unaware of their condition, reported to the World Health Organisation (WHO). The condition can spread to kids, particularly among pregnant women. In addition to additional chronic and fatal illnesses, diabetic women are in danger of premature delivery, renal failure, heart attacks, lack of vision, and other conditions. Determining diabetic in pregnant women as quickly as feasible is therefore crucial [13]. In India, 32 million persons had diabetes overall in the year 2000. The Diabetes Epidemic in India is explored in Fig. 1. The number rose to 41 million people in 2007, then to 62 million in 2011, and finally to 73 million in 2017. By the decade 2045, 134 million more individuals are anticipated to be living in this situation.

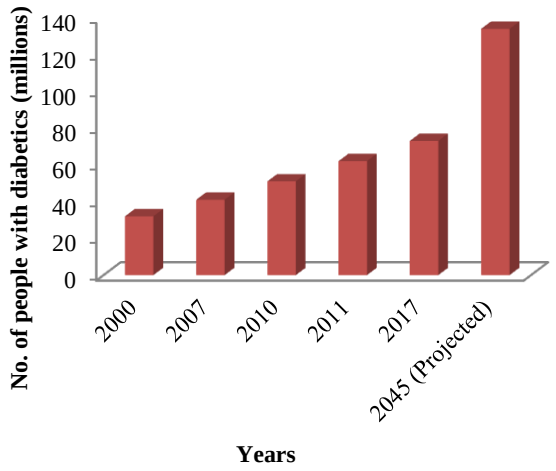

Fig. 1. Diabetes Epidemic in India during the year of 2000 to 2045 [14].

For more precise and timely prediction, an advanced medical framework for suggestions is becoming ever more important daily. In order to lower the likelihood that these diseases will strike individuals, research call for a system that is effective at spotting and effectively treating life-threatening ailments like diabetes. Forecasting accurately an individual's risks for the disease may facilitate personalized medical treatment and wellness management strategies as well as give healthcare system decision-makers an overview of upcoming illness risk variations in the community, allowing them to develop plans for the provision of associated healthcare services and lowering the burden of illness on society as a whole. Machine learning methods are employed in many sectors, and they have a successful association with the medical field. It is utilized to reduce the price of diagnostics as well as to increase diagnostic accuracy. According to the process of learning, it is difficult to identify a condition from a medical text since the information is unstructured [15]. In order to investigate the predictive modelling of various illness risks for patients, this research uses SVM systems.

The following are the study's main contributions.

- The combination of an extensive range of multimodal medical data, including data analytics and electronic health records, makes a substantial contribution to the study. By adding this, improve the accuracy of diabetes prediction and offer a more thorough knowledge of the variables affecting the condition.
- This work presents a novel hybrid optimization method that integrates the Binary Grey Wolf Optimization Algorithm (BGWO) with the Crow Search Optimization (CSO). This revolutionary approach aims to improve diabetes projections' accuracy and reliability, thereby making a significant contribution to the field of medical condition prediction modelling.
- The use of ensemble learning techniques in the research advances diabetes prediction tools. The goal of the research is to optimize diabetes prediction accuracy by utilizing the advantages of several different models. In the context of intricate medical data, this method offers a useful viewpoint for enhancing the accuracy of predictive models.
- The study makes an important contribution by effectively employing the Support Vector Machine (SVM) mechanism to the analysis of medical time-series data. This application improves the prediction abilities of the model, especially when handling complex temporal patterns found in medical data. Predictive modelling and medical data analysis could benefit from the methodological improvement represented by the use of SVM.

Following is the structure for the remaining portion of the paper: In Section II relevant work based on different approaches for diabetes prediction is discussed, and in Section III and Section IV, the procedure of feature selection and classification for the suggested method is described. Section V addresses the results and debates, and Section VI accomplishes by outlining the future's potential use.

II. Related Works

C. Zhu, Idemudia, and Feng [16] demonstrates that Utilising the PID database, the data mining-based technique looks toward early diabetic diagnosis and prediction. Despite the fact that K-means is simple and appropriate for a wide range of data kinds, it is highly dependent on the original positions of clustering centres that characterize the ultimate clustering result, that either yields a sufficient and effective organised data set for the method of logistic regression or offers a lesser quantity of data as a result of incorrect accumulating of the first set of information, limiting the efficacy of the logistics regression. The major objective was to identify methods for enhancing the reliability of the k-means

cluster and logistical regression results. This framework uses the logistic regression technique, k-means, and PCA. In comparison to the outcomes of other previously reported research, the experimental findings demonstrates that PCA improved the performance of the logistic regression and k-means clustering method classification system, with a k-means outcome that included 25 more properly categorized information and a logistic regression reliability of 1.98% greater. As a result, it is demonstrated that the framework may be effective for autonomously forecasting diabetes utilizing information from patient electronic health records. Due to clustering's complexities and incapacity of recovering from database damage, this approach is ineffective.

D. Wang et al. [17] examines how having diabetes raises your chance for renal failure and significant consequences which includes heart disease. If this condition is detected and treated right away, individuals can live better and have a higher quality of life. Many supervised machine-learning techniques that have been created and trained on relevant datasets can assist in the early detection of this disease. The objective of this research is to create efficient machine-learning-based classification approaches for diagnosing diabetes in individuals using medical data. In this study, the following machine-learning techniques will be taught using various datasets. The investigation has employed label-encoding and normalization as two efficient techniques for pre-processing to boost system dependability. Investigations have also identified and ranked other categories of risk factors using a range of selection of features approaches. The model's effectiveness has been examined through a number of experiments using two different datasets. The results show that, depending on the information's sources and the ML technique utilized, the recommended methodology can deliver higher accuracy with values ranging from 2.71% to 13.13% when the recommended structure is compared to other recent research. The research implements this framework into a web application using the Python Flask web development environment. The findings of this work imply that suitable pre-processing pipelines on medical information and the use of ML-based categorization may correctly and effectively predict diabetic. Due to a small quantity of data set, this strategy is ineffective [18].

Cappon et al. [19] presents the research paper titled "Individualized Models for Glucose Prediction in Type 1 Diabetes: comparing black-box approaches to a physiological white-box one" addresses the critical need for accurate blood glucose prediction in Type 1 diabetes management. The study compares black-box models commonly used for glucose prediction. By individualizing the physiological model through a Bayesian approach, the paper explores the efficacy of different prediction techniques, including non-parametric models, deep learning methods (LSTM, GRU, TCN), and a recursive autoregressive model with exogenous input (rARX). Results demonstrate that black-box strategies, particularly non-parametric models, outperform the personalized white-box model across various prediction horizons. Despite the physiological model's individualized parameters, the study highlights the continued preference for black-box approaches in glucose prediction. These findings contribute valuable insights for the development of next-generation tools in T1D management and decision support systems, emphasizing the importance of optimizing predictive accuracy for patient care and treatment planning.

Xie and Wang [20] offers the research paper titled "Benchmarking Machine Learning Algorithms on Blood Glucose Prediction for Type I Diabetes in Comparison with Classical Time-Series Models" intends to evaluate the effectiveness of several artificial intelligence models to anticipate blood glucose concentrations in Type 1 diabetes individuals using time-series data versus a traditional Auto regression using an Exogenous input model. The study analyses various input characteristics, regression model ordering, and prediction techniques to assess ML-based regression models, particularly deep learning models like LSTM and TCN. The performance measures for determining the likelihood of false alarms on hypo/hyper glycemia occurrences include RMSE, chronological gain, and normalised efficiency of second-order differentiation. The outcomes show that for both prediction approaches, the ARX model gets the lowest absolute RMSE, while ML models do not exhibit a significant advantage over the classic ARX model, except for TCN's robustness in handling BG trajectories with spurious oscillations. The study offers insightful information that will help researchers and medical professionals choose the best algorithms for BG predictions in T1D. However, it suggests that ML models do not outperform the ARX model, highlighting the importance of considering the context and characteristics of the data when choosing prediction models for diabetes management.

M. Alirezaei et al. [21] explores that data analysts look at diabetes mellitus for a variety of causes, including the serious health issues that might arise for those who have it, the financial burden it places on healthcare systems, and so on. Investigators examine the patient's lifestyle, genetic data, etc. to determine the primary causes of this illness. Finding patterns that facilitate quick identification of the illness and appropriate therapy is the aim of data mining in this situation. The supply of the proposed treatment technique quickly became nearly impossible because of the large number of information associated with therapeutic settings and illness diagnostics. This supports the application of pre-processing methods and information reduction strategies in these situations. Clusters and meta-heuristic techniques continue to play crucial roles in this area. In this study, outliers are initially recognized and eliminated using a technique depending on the k-means clustering technique. The selection of the least significant traits with the greatest categorization efficacy is then made using four bi-objective meta-heuristic procedures. This is accomplished using SVM, a form of ML technique. Utilizing the tenfold cross-validation method, the constructed model is also verified. This method is ineffective because it works inadequately with large data sets and when the data set contains extra noise.

Diabetes can result from either one of two causes, including insufficient insulin synthesis or insufficient cell sensitivity to the effects of insulin. The purpose of this inquiry is to locate diabetes mellitus using data mining approaches. Numerous techniques can be used to diagnosis diabetic. Data

mining techniques are one method. Health information has benefited from the usage of methods for data mining, leading to some important, effective advancement that can help clinicians make the best decisions. This study suggests a combined method for identifying diabetes using the Sequential Minimal Optimisation (SMO) classifier technique and the FF clustering approaches. The FF clustering technique is used to separate the data into a number of groups. Computation time was greatly reduced as a result of the dataset's reduced dimensionality. The clustered result is sent into the SVM-based classifier. It accurately divides individuals into diabetes and non-diabetic groups, or confirmed negatives and positives. 768 diabetes patient specimens from the Pima Indians Dataset are included in the information set utilized in the identification of diabetics. The trial's results showed that a hybrid data mining strategy could help doctors make better clinical decisions concerning diabetic diagnosis for patients. This approach is ineffective since it is inappropriate for usage with huge datasets [22].

The literature reviews address several approaches to diabetes prediction and diagnosis, each with unique difficulties. A method based on data mining that employs PCA, k-means, and logistic regression. The effectiveness of logistic regression may be impacted by k-means' reliance on initial grouping positions, which might result in errors. greater accuracy but limited by small dataset when using supervised machine learning for diabetes detection. Black-box models for Type 1 diabetes glucose prediction, demonstrate the superiority of non-parametric models over customized white-box models. Machine learning techniques for the prediction of blood glucose, showing that ML models does not perform appreciably better than conventional time-series models and highlighting the significance of taking data features into account. When dealing with enormous datasets and noise, data mining and meta-heuristic approaches are ineffective for diagnosing diabetes. Although FF clustering and the SMO classifier work well together, large datasets are not well served by this combination approach while data volume, model dependence, and contextual factors present difficulties, this research offer valuable insights into the diagnosis and prognosis of diabetes overall.

III. Problem Statement

From the aforementioned debate, the literature review tackles the urgent need for more precise and timely diabetes prediction, a worldwide health issue. Although electronic health records and multimodal medical data are readily available, it's possible that current approaches aren't completely using this rich data source for accurate diabetes diagnosis. The main problem is to increase the model's generalisation capabilities and get over the constraints put on us by high-dimensional feature spaces. In order to increase the precision of diabetes prediction, this work intends to create a novel hybrid optimisation model that smoothly combines machine learning methods, notably Support Vector Machine. Support Vector Machines have a reputation for handling high-dimensional data well and for being able to locate the best hyperplanes to divide various classes in large datasets. This is especially helpful for predicting diabetes because medical data frequently contains a wide range of factors. SVM is a good option due to its resilience in handling such data and its ability to clearly distinguish between instances that are diabetic and those that are not [23].

IV. Proposed BGW-CSO-SVM Approach

For precise and reliable diabetes prediction, this study suggests a unique hybrid optimization approach that incorporates Machine learning. Using a hybrid optimization model and multimodal medical data, the analysis techniques for enhancing diabetes prediction form an all-encompassing strategy. Z-score normalization is used to standardize features across various modalities and fill in missing values in the data as part of the first pre-processing processes. After that, the BGW-CSO algorithm—a hybrid optimization model that includes Crow Search Optimization, Binary Grey Wolf Optimizer—is used for feature selection. To improve model efficiency, this stage seeks to determine which attributes are most pertinent. After that, the features that were chosen are used in the classification stage, when the Support Vector Machine (SVM) method is applied. Utilizing the advantages of feature selection, pre-processing, and classification, the overall strategy combines these techniques to produce a strong framework for diabetes prediction, maximizing the hybrid model's performance on multimodal medical data. Fig. 2 shows how the suggested technique is presented.

A. Data Collection

Databases 1 and 2 were the two databases utilized to test the forecast of Type 2 diabetes. Although the more recent information was gathered through the Mendeley Data website, the earlier data was obtained via the Kaggle website. Database 1, which was first compiled by the National Institute of Diabetes and Digestive and Kidney Diseases in 2004, contains all female patients with diabetes who are at least twenty-one years old and of Pima Indian descent. Following the value that was missing is removed; the database has 392 entries and eight variables, comprising their ages, pregnancy, blood pressure, skin elasticity, the sugar glucose, and insulin levels. The second data set was obtained from the labs of Medical City Hospital and the Specializes Centre for Endocrinology and Diabetes-Al-Kindy Teaching Hospital and is originating from the Iraqi society. Age, urea, Hemoglobin A1c (HBA1C), creatinine ratio, high-density lipoprotein (HDL), cholesterol, very-low-density lipoprotein (VLDL), triglycerides, body mass index (BMI) and low-density lipoprotein (LDL) are the 10 parameters included in this set of information that make up the data characteristic utilized in this investigation. Only information from the diabetic and non-diabetic classes was used to make predictions for Type 2 diabetes. For this investigation, 392 records from this dataset—which is identical to Dataset 1—were chosen at randomness [24].

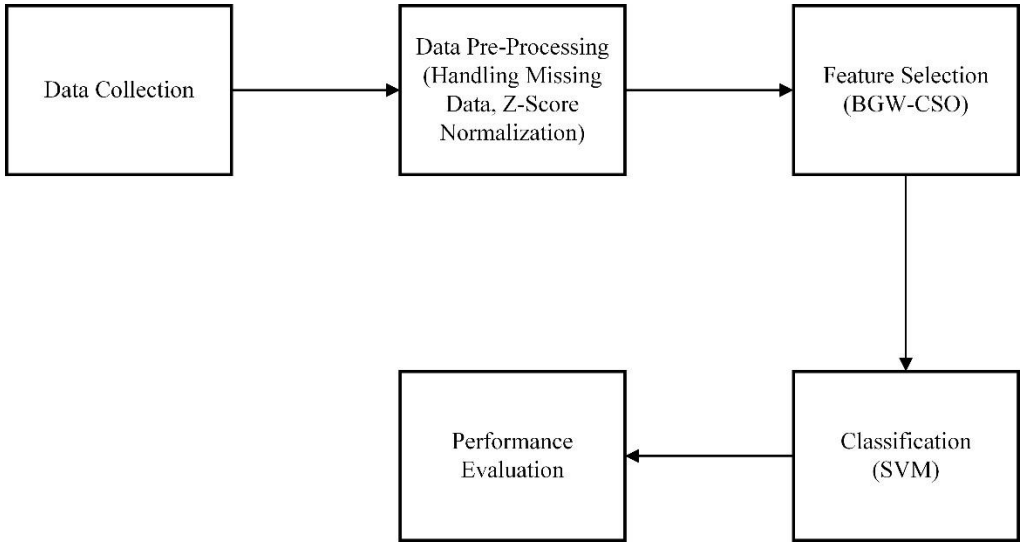

Fig. 2. Proposed methodology.

B. Pre-processing using Handling Missing Data and Z-Score Normalization

The pre-processing phase in the proposed architecture comprises the removal of outliers (S), filling in for missing data (M), and standardisation (R), which are simply defined as follows: The outlier is a data point that differs noticeably from other occurrences. Considering the classifiers are particularly dependent on the data range and the distribution of the characteristics, they need to be excluded from the distribution of the data. This literature's outlier rejection quantitative formulation may be expressed as in Eq. (1).

$$S(y) = \begin{cases} y, \ if M_1 - 1.5 \times IMR \leq x \leq M_3 + 1.5 \times IMR \\ reject, \ Otherwise \end{cases} \quad (1)$$

In this case, y represents the specific occurrences of the feature vectors that lie in n-dimensional space, where y $\in R_n$. The first, third, and interquartile ranges of the characteristics are designated as M1, M3, and IMR, correspondingly, where M1, M3, and IMR $\in R_n$.

After the outliers were eliminated, the attributes were processed to fill in any missing as well as null values because they may cause any classifier to make an incorrect prediction. Instead of dropping, the suggested framework substituted the deficient or null values with the average values of the characteristics, which may be expressed as in Eq. (2). The use of the mean for imputation is advantageous since it attributes continuous information without adding outliers.

$$M(y) = \begin{cases} mean(y), if \ y = \frac{Null\ value}{Missed\ value} \\ y, otherwise \end{cases} \quad (2)$$

Where y represents for the feature vector occurrences in n-dimensional space, which are represented by the expression y belongs to Rn. The process of rescaling the characteristics to create a conventional distribution that is normal with a zero mean and a unit variance is known as standardisation, sometimes known as Z-score normalisation. The data distribution's skewness is likewise lessened by standardisation (R), as seen in Eq. (3).

$$R(y) = \frac{y - \bar{y}}{\sigma} \quad (3)$$

where, y is the n-dimensional instances of the feature vector, y $\in R_n$. $\bar{y} \in R_n$ and $\sigma \in R_n$ are the mean and standard deviation of the attributes.

C. Feature Selection using BGW-CSO

Utilize the BGW-CSO algorithm for feature selection processes. In order to improve the efficacy and efficiency of the ensuing classification model, this entails picking the most pertinent features from the multimodal medical data. In diabetes forecasting, the selection of features is the method of selecting a subset of important traits from the initial information to build an effective predicting model. One can find the most useful and discriminating traits that have a big impact on predicting whether diabetes will exist or not. In diabetic forecasting, selecting features aims at enhancing modelling precision, reducing the dimension, enhancing interpretability, streamlining calculation, and promoting generalization to novel information. Selecting the most relevant factors helps to construct accurate and efficient models for prediction for the assessment, evaluation of risk, and scheduling of diabetes medication. BGW-CSO chooses the features in this case.

1) Binary Grey Wolf Optimization: GWO seems to be a reliable optimization technique. It imitates the harmonious, well-defined interactions at work present in grey wolf eating behavior. Grey wolves frequently live in packs of five to twelve individuals that are rigidly structured under the strong command of the wolf. The predation method used by the GW squad consists of three steps: hunting, encircling, and killing. The leader of the pack was usually the most notable wolf, also known as α wolf. β Wolf and δ wolf, respectively, are the GWO terms for the second and third tiers of leading wolves. These auxiliary wolves, which are second and third in rank, assist the lead wolf in making hunting decisions. The other wolves there are all recognized as ω wolves, and they use these powerful wolves to chase and kill the prey.

In hunts, the encircling of victim's tactic is used. The following Eq. (4) and Eq. (5) for repetition *x* shows how this technique makes sense,

$$\vec{F} = \left|\vec{Z} \times \overrightarrow{A_b}(x) - \vec{P}(x)\right| \quad (4)$$

$$\vec{A}(x+1) = \overrightarrow{A_b}(x) - \vec{F}.\vec{H} \quad (5)$$

In this case, $\vec{F}$ and $\vec{Z}$ are effective factors, which is denoted by the formula $\vec{F} = 2\vec{e}.\overrightarrow{v_1} - \vec{e}$ and $\overrightarrow{Z} = 2.\overrightarrow{v_2}$. Where the randomized vectors $\overrightarrow{v_1}, \overrightarrow{v_2}\ \varepsilon\ (0,1)$ and $\overrightarrow{e} = e_1(1 - {}^{x}/_{maxx})$, gradually decline from e_1 to zero; the value of e_1 was set as 2 in the real GWO. *maxx* also means as many repeats as is feasible. The GWO's top three hunting alternatives have been $\propto$ wolves, β wolves, and γ wolves. The three best possibilities' positions have therefore been kept in the group, and the remaining ω wolves have changed their locations to reflect them. Eq. (6) illustrates the simulation theorem for this location update approach.

$$\vec{A}(x+1) = {\left(\overrightarrow{A_1} + \overrightarrow{A_2} + \overrightarrow{A_3}\right)}/{3} \quad (6)$$

Where, $\overrightarrow{A_1}, \overrightarrow{A_2}, and\ \overrightarrow{A_3}$ is evaluated by Eq. (7),

$$\begin{aligned} \overrightarrow{A_1} &= \overrightarrow{A_\propto}(x) - \overrightarrow{F_1}.\overrightarrow{H_\propto} \\ \overrightarrow{A_2} &= \overrightarrow{A_\beta}(x) - \overrightarrow{F_1}.\overrightarrow{H_\beta} \\ \overrightarrow{A_3} &= \overrightarrow{A_\gamma}(x) - \overrightarrow{F_1}.\overrightarrow{H_\gamma} \end{aligned} \quad (7)$$

Here, $\overrightarrow{H_\propto}$, $\overrightarrow{H_\beta}$, and $\overrightarrow{H_\gamma}$ are evaluated by Eq. (8),

$$\begin{aligned} \overrightarrow{H_\propto} &= \left|\overrightarrow{Z_1} \times \overrightarrow{A_\propto}(x) - \vec{A}\right| \\ \overrightarrow{H_\beta} &= \left|\overrightarrow{Z_2} \times \overrightarrow{A_\beta}(x) - \vec{A}\right| \\ \overrightarrow{H_\gamma} &= \left|\overrightarrow{Z_3} \times \overrightarrow{A_\gamma}x) - \vec{A}\right| \end{aligned} \quad (8)$$

In simple terms, feature selection is a binary issue since the bounds of the feature selection space for searching are zero and one. In the basic GWO method, the process of searching space is ongoing. Consequently, using native GWO to solve the feature selection challenge is not an option. It is necessary to create a modified (binary) variant of the method. To modify the positions of the agents searching for the method known as GWO in the binary searching space, the subsequent sigmoid function was added in Eq. (9):

$$A_{binary}(t+1) = g(a) = \begin{cases} 1, & sigmoid\ \left(\frac{A_1+A_2+A_3}{3}\right) \\ & \geq x \\ 0, & otherwise \end{cases} \quad (9)$$

From the uniform distribution ∈ [0, 1], a random variable *x* is obtained. Here, the binary updating mechanism is $A_{binary}(t+1)$. The sigmoid function *S(a)* is given in Eq. (10).

$$\text{S(a)} = \frac{1}{1 + e^{(-10*(a-0.5))}} \quad (10)$$

2) Crow search algorithm: Askazadeh proposed the Crow search algorithm (CSA), a method with natural form cues [25]. The method is used in based on population evolutionary computation models crow birds' behavior and social relationships. Undoubtedly intelligent creatures with larger-than-average neurons, crows are clever. They dwell in groups called flocks and hide their food in places that may still be found and retrieved a few months later. Additionally, they experience self-consciousness when carrying out the mirror test. They are able to recall appears, and if a poor one is noticed, they can converse with one another incomprehensibly to alert the other crows. Similar to other social animals, crows occasionally steal by carefully determining where other crows store their meals and then taking them. Whenever a crow suspects that someone is tracking it in an effort to deceive a thief, it is going to a new position that is distant from where the food is.

There are N solutions in the population, and the task's parameters are (overall of crow). The vector $l_j^t = \left[l_{j1}^t, l_{j2}^t, \ldots\ldots\ldots, l_{je}^t\right]$b or j=1, 2, 3... N labels the locations of each crow *j* at cycle t, where l_j^t is the potential possible placement options for crow *j* in dimensions e.

If a crow *j* proclaims that it is interested in robbing another crow *i*, one of two things may happen:

According to Eq. (11), Crow *j* will locate Crow *i*'s food store and update Crow *i*'s location rather than really following Crow *i*.

$$l_j^{(t+1)} = l_j^{(t)} + r_j * ck_i^{(t)} * (n_i^{(t)} - l_j^{(t)}) \quad (11)$$

Where the journey distance, *ck* is shown. r_i was randomly selected from the range [0, 1].

i pursue the crow to see where its food is concealed after realizing it is an endangered species. The crow *i* in the scenario does irregular dancing to trick the crow *j*.

In reality, the two parts may be mixed numerically as seen below in Eq. (12);

$$l_j^{(t+1)} = \begin{cases} l_j^{(t)} + r_j * ck_i^{(t)} * \left(n_i^{(t)} - l_j^{(t)}\right), r_i \geq BP_j^t \\ Select\ a\ random\ position, \quad Otherwise \end{cases} \quad (12)$$

where, *j* and *i* are random integers between 0 and 1, BP_j^t is the probability that Crow *i* at Iteration *t* will be aware, and r_j and r_i are random numbers. The ability of the crow to seek is affected by the values of *ck*. Low values of *ck* will aid in local optimal while high values will aid in global search.

Every crow is assessed as the technique is running using a well-defined fitness function. The crows then relocate themselves according to where they are most comfortable. The viability of every new role is evaluated. Using Eq. (13), the crows' memory is enhanced.

$$n_j^{(t+1)} = \begin{cases} l_j^{(t+1)} jg\ c\left(l_j^{(t+1)}\right) & is\ better\ than\ c\left(l_j^{(t)}\right) \\ n_j^{(t)}, & Otherwise \end{cases} \quad (13)$$

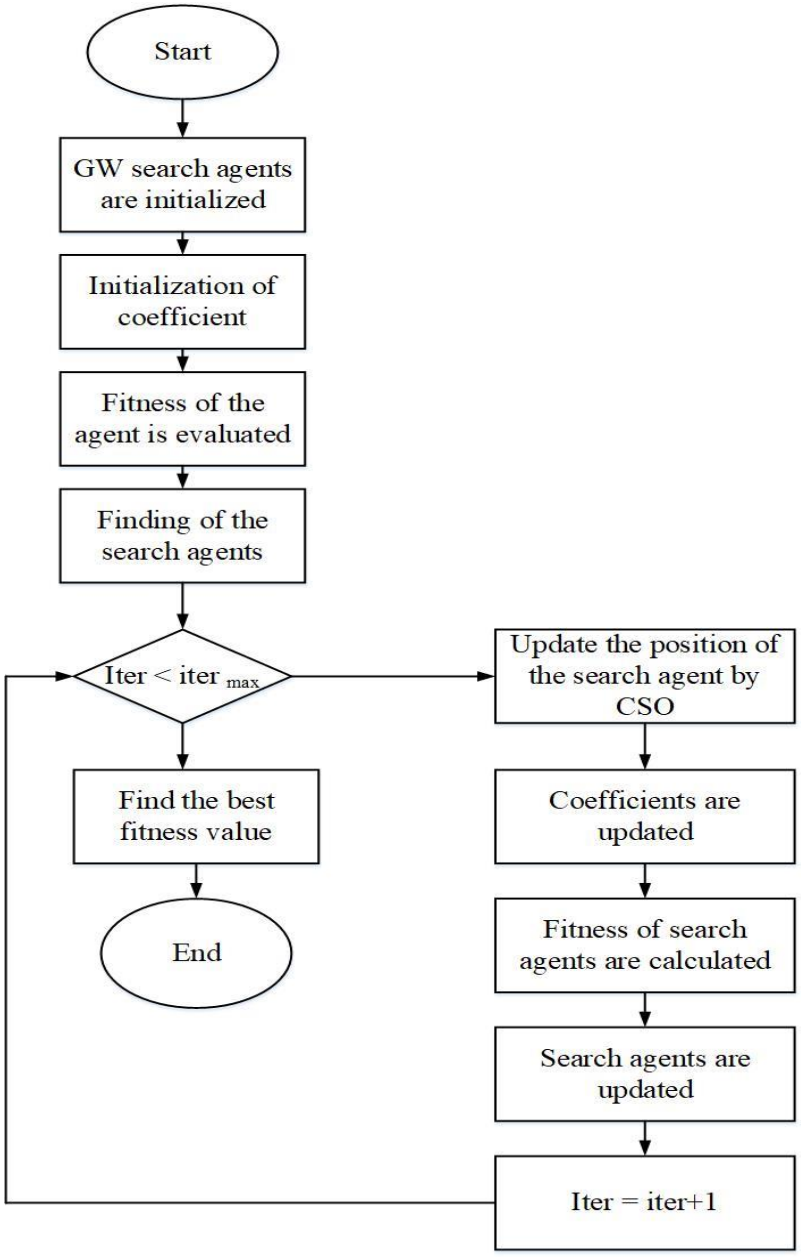

Fig. 3. Flow method of BGW-CS.

3) BGW-CS algorithm: To address the problem of immature integration, an improved research phase for BGWO is suggested in the current work. Through this method, BGWO and CSO algorithms are hybridized. In order to increase response accuracy, the created hybrid algorithm (BGW-CS) has a stronger propensity to pass over local optimal solutions. The flow methodology of BGW-CS is represented in Fig. 3. The equation of the hybrid BGW-CS is in Eq. (14),

$$A_{binary}(t+1) = \begin{cases} l_j^{(t+1)} jg\ c\left(l_j^{(t+1)}\right) & is\ better\ than\ c\left(l_j^{(t)}\right) \\ n_j^{(t)}, & Otherwise \end{cases} \quad (14)$$

D. Classification using Support Vector Machine

Apply the classification algorithm known as Support Vector Machine. Utilizing the multimodal medical data, train the SVM model with the pre-processed and chosen features to forecast diabetes outcomes because SVM can distinguish intricate correlations between features and is efficient in managing high-dimensional data, it is a popular choice. The SVM is used to group and stratify diverse classes of heterogeneous medical data, allowing for more precise predictions and individualised healthcare interventions. SVM uses its ability to construct hyperplanes that maximise the segregation of points of information in a multidimensional space of features to help categorise records of patients, outcomes of tests, and other important medical data. This categorization strategy is a crucial component of our model,

enhancing its accuracy and effectiveness in diabetes forecasting and providing healthcare practitioners with crucial information for better patient care and management approaches. The structural risk reduction idea is applied in SVM. Here, the learning machine's error rate is thought to be constrained by the interaction between the training error rate and the Vapnik Chervonenkis (VC) 1 dimension term. The hyper-plane that optimally distinguishes the data points for N training sets (X_i , Y_i) with labels, where $X_i \in$ Rn and $Y_i \in$ {–1, 1}, is illustrated in Eq. (15):

$$f(X_q) = \sum_{i=1}^{N} Y_i \propto_i K(X_q, X_i) + b \quad (15)$$

The sign of f (X_q) is used to calculate X_q in cases where the kernel functions are represented as K (.) and indicates the membership of the query sample. Making an ideal hyperplane is comparable to figuring out all nonzero _i, which stands for the bias b and the support vectors. The least amount of loss is anticipated while making a decision.

Using BGW-CSO to optimize the feature set and SVM to accurately forecast diabetes are the three main components of the comprehensive analysis methodology. Utilizing the advantages of each technique, this hybrid strategy seeks to improve the predictive model's overall performance.

V. Result and Discussion

The offered information from a research article describes a study that suggests a unique hybrid optimisation approach for enhancing the reliability and accuracy of diabetes prediction. To use multimodal medical data from the Pima Indian and Mendeley diabetes datasets, the model combines a Machine learning mechanism and an ensemble learning technique. To minimise the dimensions of the features, a hybrid technique known as Binary Grey Wolf-based Crow Search Optimisation (BGW-CSO) is utilized for selecting features. The selected features are then passed to a BGW-CSO-based Support Vector Machine (SVM) with enhanced hidden neurons. Utilising multiple performance criteria, the suggested model, BGW-CSO-SVM, is assessed and contrasted with existing methodologies. The findings show that the suggested methodology improves diabetes prediction accuracy, enabling early detection of at-risk patients and facilitating individualised patient management. According to the study, the hybrid optimisation model has the potential to significantly advance the science of diabetes prediction and help medical professionals make wise choices.

A. Evaluation of Performance Metrics

Accuracy, F1-score, precision, and recall were the four assessment measures used in the experiment to evaluate the models. These particular definitions of these parameters are given in Eq. (16) to Eq. (19):

$$\text{Accuracy} = \frac{\text{TP+TN}}{\text{TP+TN+FP+FN}} \quad (16)$$

$$\text{Recall} = \frac{\text{TP}}{\text{TP+FN}} \quad (17)$$

$$\text{Precision} = \frac{\text{TP}}{\text{TP+FP}} \quad (18)$$

$$\text{F1score} = \frac{2*\text{Recall}*\text{Precision}}{\text{Recall+precision}} \quad (19)$$

The total amount of data which were correctly classified as positive out of all the positive data is referred to as the TP. The number of data which were incorrectly classified as negative out from one of is referred to as the TN. FN, Is it common for the model to mistakenly classify positive data as negative when, in fact, they were positive in the dataset. FP, Is it common for the model to mistakenly classify data as positive when, in reality, they were negative in the dataset. Recall is the ratio of the strategy's correctly classified positive pieces of information to those correctly classified positive pieces of information in the data set. In terms of the total quantity of variables that were classified as positive, precision is the proportion of data that the algorithm correctly recognised as positive. The F1 score is the harmonic average of recall and accuracy. Table I compares the performance of various classification methods or models. The methods evaluated include Soft Voting Classifier, Random Forest, DMP_MI, Bootstrap Aggregation, and a Proposed BGW-CSO-SVM.

Among the efficacy metrics that are assessed are F1-score, recall, accuracy, and precision. Accuracy is a measure of how well the strategy projections as a whole were predicted. Precision is the proportion of accurately predicted positive occurrences among all positive forecasts, whereas recall measures the ability to recognise positive examples. A single statistic called the F1-score integrates accuracy and recall. The Presented BGW-CSO-SVM approach obtained the greatest accuracy, precision, recall, and F1-score, showing greater efficiency when compared with the other techniques, as can be shown in Table I.

In Fig. 4, the Proposed BGW-CSO-SVM demonstrates the highest accuracy with a score of 96.62%. Following closely behind is the Random Forest method with an accuracy of 94.1%. The Bootstrap Aggregation technique achieves an accuracy of 94.62%, while the DMP_MI method achieves 87.1% accuracy. The Soft Voting Classifier has the lowest accuracy among the methods, with a score of 79.08%.

TABLE I. Comparison of Performance Metrics with Proposed Model

Methods	Accuracy (%)	Precision (%)	Recall (%)	F1-score (%)
Soft Voting Classifier [26]	79.08	73.13	70	71.56
Random Forest [27]	94.1	97.6	94.3	95.9
DMP_MI[28]	87.1	80.6	85.4	83.0
Bootstrap Aggregation [29]	94.62	94.7	94.6	94.6
Proposed BGW-CSO-SVM	96.62	98.54	96.3	97.8

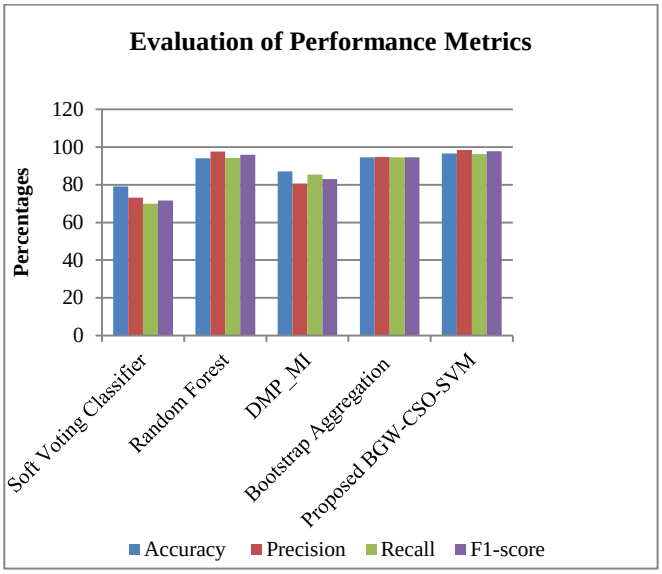

Fig. 4. Comparison graph of evaluation parameters.

In Table II, the proposed BGW-CSO-SVM model achieves the highest ROC value of 0.98, indicating strong discrimination capability between positive and negative instances in diabetes prediction. The Soft Voting method also demonstrates a high ROC value of 0.96, followed by LightGBM with a value of 0.95. XGBoost and Random Forest have ROC values of 0.93 and 0.94, respectively. AdaBoost shows a slightly lower ROC value of 0.92. Fig. 5 depicts the performance assessment of ROC curve. These results suggest that the proposed BGW-CSO-SVM model outperformed the other methods in terms of ROC value, indicating its potential for accurate prediction and effective management of diabetes.

The effectiveness of a classifier is often assessed using the ROC values in binary categorization tasks. Greater numbers denote greater performance. It shows a model's capacity to discriminate among both positive and negative examples.

A. Dataset Comparison

In Table III, the efficacy of the suggested BGW-CSO-SVM model in comparison to the approach presented by Taz, Islam, and Mahmud [30] is evaluated using two datasets: the Mendeley Diabetes Dataset and the PID Dataset. Fig. 6 depicts the proposed system dataset compared with existing approach. The evaluation metrics used are accuracy, precision, recall, and F1-score. The proposed BGW-CSO-SVM model consistently achieves higher accuracy, precision, recall, and F1-score on both the Mendeley Diabetes Dataset and the PID Dataset compared to the approach.

Table IV and Fig. 7 presents the results of a diabetes prediction study using different methods and their respective Root Mean Square Error (RMSE) values. The methods evaluated are Vanila-LSTM, BI-LSTM, and the Proposed Model.

TABLE II. COMPARISON OF PROPOSED SYSTEM ROC VALUE WITH EXISTING APPROACH

Methods	ROC value
Light GBM [30]	0.95
XGBoost [30]	0.93
AdaBoost [30]	0.92
Random Forest [30]	0.94
Soft Voting [30]	0.96
Proposed BGW-CSO-SVM	0.98

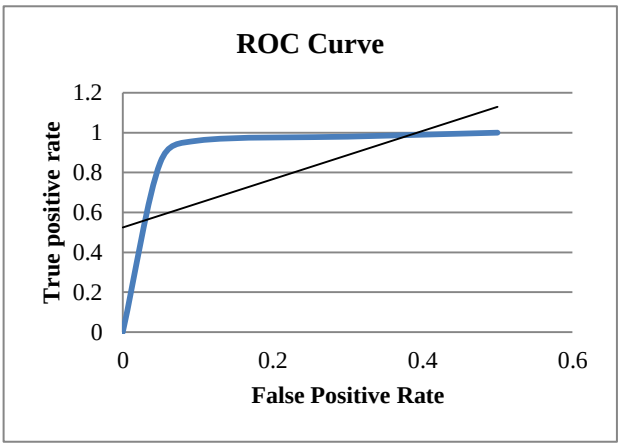

Fig. 5. ROC curve for the proposed model.

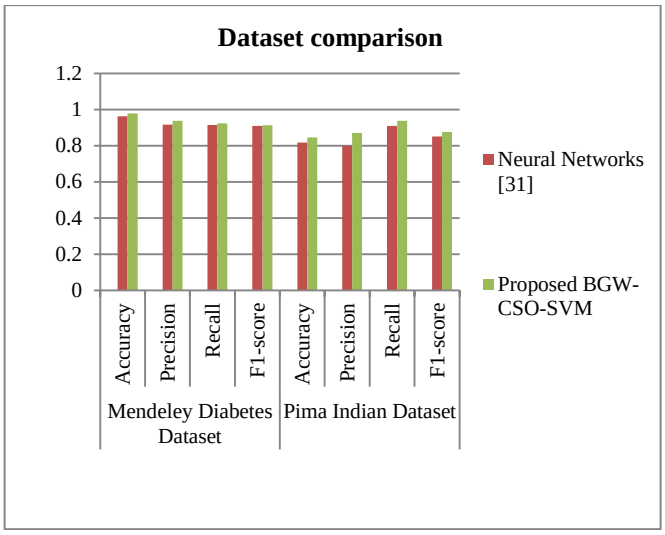

Fig. 6. Dataset comparison.

TABLE III. DATASET COMPARISON MDD AND PID

Methods	Mendeley Diabetes Dataset				Pima Indian Dataset			
	Accuracy	Precision	Recall	F1-score	Accuracy	Precision	Recall	F1-score
Neural Networks [30]	96.24%	91.65%	91.46%	90.96%	81.82%	80.00%	90.91%	85.11%
Proposed BGW-CSO-SVM	97.9%	93.8%	92.36%	91.4%	84.63%	87.1%	93.8%	87.6%

TABLE IV. ERROR RATE COMPARISON

Method	RMSE
Vanila-LSTM [31]	15.43
BI-LSTM [31]	15.22
Proposed SVM	14.58

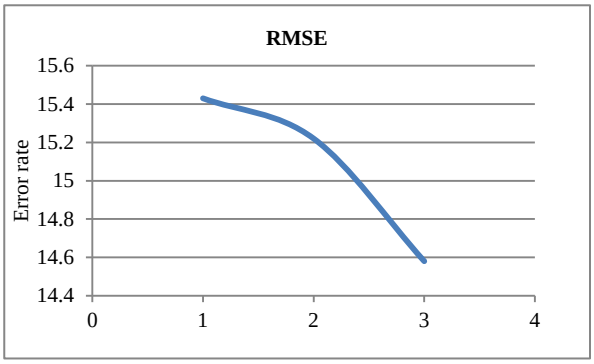

Fig. 7. Error rate graph.

B. Discussion

The study employs a feature selection technique, minimizes feature size, and ensures error-free classifications to effectively solve the difficulty of high-dimensional feature space in diabetes prediction. The research provides a novel methodology for feature selection, improving the model's capacity for generalization. It does this by introducing the revolutionary Binary Grey Wolf-based Crow Search Optimization (BGW-CSO) method, which combines Binary Grey Wolf Optimization (BGWO) with Crow Search Optimization (CSO). By optimizing the number of hidden neurons in the Support Vector Machine (SVM) through the use of BGW-CSO, the study improves diabetes prediction models overall and enhances the effectiveness of conventional SVMs. The suggested BGW-CSO-SVM model consistently outperforms other existing techniques, demonstrating superior accuracy, precision, recall, and F1-score through rigorous assessments on the Mendeley Diabetes Dataset and Pima Indian Dataset. The study's objective of creating a reliable diabetes prediction model that can be adjusted to fit a variety of datasets is perfectly aligned with this performance. Most importantly, the hybrid optimization model BGW-CSO-SVM greatly improves diabetes prediction accuracy, allowing for early at-risk individual identification, timely interventions, and individualized patient management. The results of the study highlight how well the objective of increasing the accuracy and consistency of diabetes prediction was met, and they may have ramifications for better patient outcomes in medical settings.

VI. CONCLUSION AND FUTURE WORK

The study addresses the pressing global health challenge of accurate and timely diabetes diagnosis. It introduces a novel hybrid optimization strategy that seamlessly integrates machine learning techniques to enhance the precision of diabetes prediction. This advancement is achieved by harnessing the potential of multimodal medical data, electronic health records, and advancements in data analytics. To ensure precise classification, two distinct datasets from the Pima Indian diabetes databases are used, alongside a rigorous feature selection method. The introduction of the BGW-CSO approach, a fusion of BGWO and CSO, bolsters feature selection capabilities. This innovation not only addresses the challenges posed by high-dimensional feature spaces but also significantly improves the system's ability to generalize. The performance of conventional Support Vector Machines (SVMs) benefits greatly from optimizing SVM techniques using the newly devised BGW-CSO approach. This proposed strategy, referred to as BGW-CSO-SVM, demonstrates substantial enhancements in diabetes prediction accuracy, as evidenced by a comprehensive examination using various performance metrics and comparisons with existing methodologies. This breakthrough enables the rapid identification of individuals at risk, paving the way for personalized and effective treatment interventions. In order to ensure the applicability of our methodology across a wide range of healthcare contexts, future research endeavours should prioritize testing its usefulness across varied datasets and demographics. It is important to prioritize creating solutions that are easy to use, accessible, and readily embraced by medical professionals. By facilitating a smooth transition into clinical settings, this strategy hopes to improve patient care and diabetes diagnosis on a larger scale. The research can demonstrate the robustness and generalizability of the suggested technique, increasing the likelihood of its widespread adoption and beneficial effects on healthcare practices. This can be achieved by expanding the validation to include a broad variety of datasets and demographic differences.

A Hybrid Movies Recommendation System Based on Demographics and Facial Expression Analysis using Machine Learning

Mohammed Balfaqih
Department of Computer and Network Engineering, College of Computer Science and Engineering
University of Jeddah, Jeddah, 23890, Saudi Arabia

***Abstract*—Cinemas and digital platforms offer an extensive array of content requiring tailored filtering to cater to individual preferences. While recommender systems prove invaluable for this purpose, conventional movie recommendations tend to emphasize specific attributes, leading to a reduction in overall accuracy and reliability. Notably, the extraction process of facial temporal attributes exhibits a suboptimal level of accuracy, thereby influencing the classification of attributes and the overall accuracy of the recommendation system. This article introduces a hybrid recommender system that seamlessly integrates collaborative filtering and content-based methodologies. The system takes into account crucial factors such as age, gender, emotion, and genre attributes. Films undergo an initial categorization based on genre, with a subsequent selection of the most representative genres to ascertain group preferences. Ratings for these selected movies are then predicted and organized in descending order. Employing Convolutional Neural Network (CNN) and Long Short-Term Memory (LSTM) models, the system achieves real-time extraction of facial attributes, particularly enhancing the accuracy of emotion attribute extraction through sequential processing. The CNN model demonstrates a commendable 55.3% accuracy score, the LSTM model excels with a 59.1% score, while the combined CNN and LSTM models showcase an impressive 60.2% accuracy. The performance of the recommendation system is rigorously evaluated using standard metrics, including precision, recall, and F1-measure. Results underscore the superior performance of the proposed system across various testing scenarios compared to the established benchmark. Nevertheless, it is noteworthy that the precision of the benchmark marginally surpasses the proposed system in the age groups of 8-14 and 15-24.**

***Keywords*—Recommender system; movies recommendation; emotion prediction; k-means clustering; deep learning**

I. Introduction

Recommender systems play a pivotal role in facilitating user exploration and item selection within the expansive choices available on web or electronic platforms. These systems employ advanced strategies, including content-based, collaborative, and hybrid approaches [1-4], to systematically filter and prioritize information, delivering clients tailored and pertinent data. Content-based filtering, a component of these systems, tailors recommendations based on individual preferences, effectively addressing the challenging cold start problem. Concurrently, collaborative filtering relies on user similarities or machine learning algorithms to recommend items. Hybrid recommender systems integrate both content-based and collaborative approaches, synergistically optimizing performance and honing the precision of recommendations. The amalgamation of these techniques empowers recommender systems to furnish users with suggestions that are not only personalized but also highly accurate [5-8].

A consumer's emotional state influences their decision-making process. Emotion is an unconscious mental state that arises spontaneously, accompanied by physiological and psychological changes in human organs and tissues, such as heart rate, facial expression, and the brain [9]. However, the recommendation process typically neglects the viewer's emotional state due to the intricate interplay of physiological signals with emotions, making subtle emotional expressions easily misunderstood. Prior research has predominantly focused on understanding user emotions through various means, such as ratings, comments, and helpfulness votes, among others [10, 11].

The Affective Video Recommender System (AVRS) has emerged as a prominent research area within recommender systems, diverging from traditional text, image, and speech emotion recognition. Focused on analyzing emotional states within videos and discerning emotions in distinct scenes [12], AVRS strategically recommends video content to viewers based on identified emotional states. An insightful study revealed gender-based disparities in movie preferences, with men exhibiting variations between mood and movie choices, while women tend to demonstrate a more congruent pattern [13]. To provide personalized recommendations in theaters or movie platforms devoid of recorded user data, the incorporation of face recognition becomes imperative. This facilitates the identification of attributes such as age, gender, and emotion estimation.

Within the domain of pattern recognition and computer vision, face recognition involves the identification of individuals by assessing distances between key facial points or the angles formed by facial components [14]. The creation of an efficient face recognition system necessitates considerations for speed, accuracy, scalability for system updates, and improvements in subject recognition. Fundamental face recognition approaches include holistic matching, feature-based (structural) methods that analyze local features, and hybrid techniques combining both holistic and feature

This work was funded by the University of Jeddah, Jeddah, Saudi Arabia, under grant No. (UJ-21-DR-47). The author, therefore, acknowledges with thanks the University of Jedah technical and financial support.

extraction methodologies [15]. The culmination of these efforts results in the development of a functional and practical face recognition system.

An exhaustive review of literature on movie recommendation systems has identified two pivotal research challenges. Firstly, existing solutions for tracking and extracting facial temporal attributes exhibit substantial computational complexity and diminished accuracy, impacting attribute classification and diminishing the precision of recommendation systems. Secondly, prevalent movie recommendation systems concentrate on specific attributes, leading to a decline in overall accuracy and reliability [16-23]. As an extension of our previous work in [24], this study seeks to elevate the accuracy and efficacy of movie recommendations by crafting a precise face recognition system capable of discerning age, gender, and emotion from video data. Additionally, it discerns the most accurate deep learning models by incorporating multiple attributes, including user emotion and gender.

- A hybrid movies recommendation system based on demographics and facial expression analysis using machine learning. The system effectively captures user age, gender, and emotion in real-time through CNN and LSTM models to solve information overload and data sparsity problems.
- The system ensures the suitability for both new and existing users, providing effective movie recommendations, regardless of the presence of historical records or ratings. Movies are initially grouped by genre, selecting the most representative of preferred genres as the group's choice. Ratings for these movies are then predicted and listed in descending order.
- The study conducts experiments using real-world facial expressions data to demonstrate the excellent performance of the proposed methodology in the existing recommendation approach. It also identifies facial expressions as a crucial factor in movie recommendations.

The paper's structure is organized as follows: Section II addresses the research background, encompassing recommendation systems and face attribute recognition techniques, along with an exploration of related works and distinctions from existing systems. Section III provides a comprehensive overview of the proposed hybrid movie recommendation system, detailing the components of face attribute extraction, movie clustering, and recommendations. Section IV delves into the implementation setup and dataset usage, while Section V extensively discusses the findings derived from the proposed system. Finally, the paper concludes, summarizing the key insights and contributions.

II. Research Background

In this section, we explore the primary techniques employed by the proposed system, encompassing recommendation systems and facial attribute recognition. We also delve into recent research in these areas. In the final sub-section, we examine existing systems focused on integrating facial attributes recognition with movie recommendations, highlighting their limitations, and identifying research gaps.

A. Recommendation Systems

Recommendation systems, designed to address the information overload issue, filter pertinent information based on a user's interests, preferences, or observed behavior for a specific item [25, 26]. This problem arises as data volume increases, hindering effective decision-making [27]. The recommendation systems aim to provide meaningful user-specific recommendations for various items or products [28].

In the domain of movie recommendations, a multitude of recommendation systems has been explored in academic literature. Reddy S. et al. [16] proposed a framework akin to collaborative filtering techniques, integrating genre similarity and content-based filtering to enhance personalized recommendations. User feedback on films and genres significantly influences categorization, contributing to the customization of recommendations. Katarya Rahul [17] developed a hybrid recommender system utilizing the MovieLens dataset, incorporating the k-means clustering algorithm with bio-inspired artificial bee colony optimization.

Taking a distinct approach, [18] introduced an object-based collaborative filtering method, delving into the user's item rating matrix to establish connections among items for personalized recommendations. The author in [19] devised an efficient Graph Convolutional Network (GCN) algorithm, merging random walks and graph convolutions to generate embeddings. The author in [20] presented a comprehensive hybrid recommender system that integrates collaborative filtering via the Singular Value Decomposition (SVD) algorithm, a content-based system, and a fuzzy expert system. This expert system evaluates movie significance based on factors such as average rating and the number of ratings.

In contrast, [21] proposed a dynamic weighted hybrid recommender system, adapting the blend of collaborative filtering (CF) and content-based filtering (CBF) dynamically, deviating from fixed weights. Film-Conseil employs a machine learning algorithm to assess consumer advisory capability, replacing explicit movie scores [22]. Additionally, a movie recommendation system utilizes inductive learning, a machine learning method that effectively reduces sparsity and enhances scalability through experiments [23]. Nevertheless, current recommendation solutions exhibit limitations, lacking consideration for user emotions and demographics. Consequently, there is an imperative need to accurately and efficiently capture real-time user facial expressions.

B. Face Attributes Recognition Techniques

Feature detection and image matching are crucial tasks in machine vision, with varying computational efficiency and accuracy depending on the chosen feature detector and descriptor extraction algorithm. It is essential to select an appropriate algorithm for specific feature matching tasks [29].

In recent research, a significant focus has been placed on real-time analysis of age, gender, and emotional states. A pivotal study [30] employed a Convolutional Neural Network (CNN) to achieve a remarkable 95 percent accuracy in age and

gender identification using the IMDB-WIKI dataset. Simultaneously, the CNN demonstrated a 66 percent accuracy in emotion detection, leveraging the FER dataset. An alternative approach [31] utilized an artificial neural network, achieving a commendable 70.5 percent accuracy in age and gender recognition.

Imane et al. [32] introduced an innovative paradigm integrating the HAAR cascade and CNN for facial recognition, incorporating the FER2013 dataset for normalization and emotion detection. The integration of K-Nearest Neighbors (KNN) and Support Vector Machine (SVM) algorithms resulted in a 70% accuracy rate. Rajesh et al. [33] contributed to the field with a real-time emotion detection system based on a nine-layer CNN, demonstrating an approximate 90 percent accuracy in categorizing seven distinct emotions.

Additionally, a method proposed by [34] deployed the Local Binary Pattern (LBP) classifier, achieving impressive results with a score of 94.39 percent using the CK+ dataset and 92.22 percent with the JAFFE dataset. Lastly, the method introduced by [34] implemented Exploratory Data Analysis (EDA), SVM, and demographic classification strategies, achieving an outstanding 99 percent accuracy and efficiency.

C. Related Works

Several systems focused on integrating facial attributes detection with items recommendations have been proposed in the literature. The authors in [36] introduced a video recommendation system centered on emotion detection, with the potential to address various conditions through a focus on human emotions and cognition. This system suggests YouTube videos based on captured emotions in images, videos, or webcam feeds, considering emotion intensity. For instance, individuals expressing happiness receive recommendations for funny videos, while those displaying sadness are guided to motivational content. The system has achieved an average emotion detection accuracy of 56%. For the same purpose, a dataset was created in [37] with five classes and then compared with an alternative dataset, showcasing state-of-the-art performance. The results revealed that, apart from CNN and DenseNet201, VGG16, InceptionV3, and MobileNetV2 exhibited superior accuracy compared to the collected dataset, affirming the excellence of our dataset over the alternative one. The primary limitations of these works involve accuracy concerns and a lack of consideration for user age and gender, which may not fully align with users' preferences.

Haar cascade and Local Binary Patterns Histogram (LBPH) algorithms were utilized in [38] for face detection, feature extraction, and emotion detection. Emotion detection relies on the FER 2013 dataset, while age and gender detection use the Adience dataset. For web application development, they implemented the Django framework. The video recommendation system adopts a content-based approach, customizing recommendations based on detected emotions, age, and gender. These personalized suggestions are sourced from the internet, prioritizing videos aligned with the target emotion, popularity, or user interactions. Video categories encompass music videos, motivational speeches, quotes, movies, cartoons, humor, action, and lifestyle.

To automate the process of identifying users and deducing their preferences from their content feedback of TV applications, a solution based on face detection and recognition services was proposed in [39]. Demographic characteristics (age and gender) classified the user, addressing the cold start problem. Smiles and emotions detected served as automatic feedback during content consumption. Accurate results were achieved with a frontal view of the face, while deviations from this angle and suboptimal lighting conditions could hinder face detection and recognition, particularly if parts like the eyes or mouth were not clearly visible. In [40], an innovative approach was introduced to address the lack of affective data for newly added videos on platforms like YouTube. It used reinforcement learning and deep bidirectional recurrent neural networks to process videos, gather affective annotations, and integrate emotion and affective intensity aspects, refining as user feedback was collected. Both implicit and explicit interactions, including facial expressions in real-time video streams, were tracked to train personalized reinforcement learning models for short-term affective behavior learning. This approach also highlighted the value of sequencing videos in different contexts to understand long-term affective trends using context-aware features. Its effectiveness was tested in experiments on two diverse video datasets.

An advertising video recommendation process was introduced in [41], leveraging computer vision and deep learning to gauge users' emotional responses to ads in real time by analyzing their facial expressions. This involved a CNN-based predictive model for rating predictions and a real-time SIFT algorithm-based similarity model to identify users with similar preferences. Instead of relying on users' historical records, the approach continuously updated a dynamic user profile based on real-time facial expression changes. Experimental tests using food advertising videos showcased the superiority of this method compared to conventional approaches like random recommendations, average ratings, and traditional collaborative filtering, offering improved recommendations for both existing and new users in the realm of advertising video recommendations.

Table I summarizes the existing movies/video recommendation systems based on face feature extraction. While there have been previous studies on the integration of videos/movies recommendation systems with face attributes extraction techniques, there are still gaps in the literature that call for further research. It can be concluded that the primary limitations to be addressed in this study pertain to the suboptimal accuracy of recommendation systems due to inadequate data, and the complexity of data analysis, which results in elevated computational costs.

III. PROPOSED HYBRID MOVIES RECOMMENDATION SYSTEM

In this section, an overall description of the proposed hybrid movies recommendation system. The outline of the proposed system framework is illustrated in Fig. 1. The proposed system will be implemented on a mobile/web platform for use in movie theaters or personal digital devices with embedded cameras. The system is composed of three individual modules, i.e., Face attributes extraction module, Movies clustering model based on movies attributes, and recommendation system. The first module is used to extract the demographic and emotion attributes of the users, while the second module clusters the movies into 19 different genres based on their attributes. The outputs from these modules are utilized by the recommendation system module to provide movie cluster recommendations tailored to specific user groups, considering age, gender, and emotion. Furthermore, the list of movies is organized based on the predicted ratings for all movies within the users' groups. The next subsections describe each module in detail.

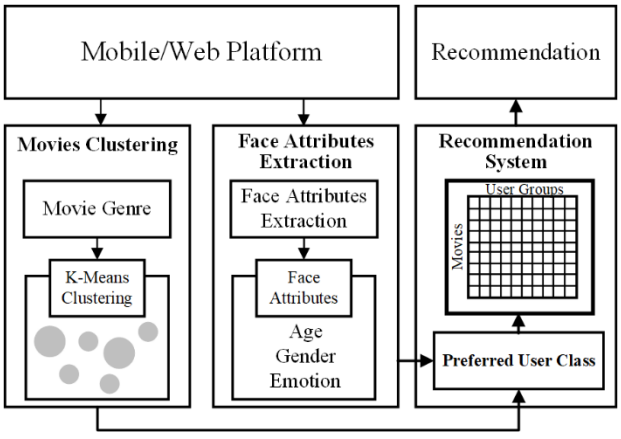

Fig. 1. A block diagram of the proposed system.

A. Face Attributes Extraction

The facial attribute extraction module is delineated into two discrete constituents: the CNN-based attributes extraction model and the LSTM-based attributes extraction model, as depicted in Fig. 2. This system facilitates real-time extraction of facial attributes, encompassing age, gender, and emotion. Positioned as a video-based application, its efficacy in capturing emotion attributes is heightened within a temporal sequence [42].

The CNN-based attributes extraction model concentrates predominantly on non-temporal features, with its output assuming a pivotal role in the ultimate synthesis. Notably, the Inception Net [43] and DenseNet [44] architectures are harnessed for their exceptional performance within this model. In contrast, the LSTM-based attribute extraction model is deployed for extracting vital expressive features, utilizing the VGG architecture to scrutinize emotional nuances within the temporal sequence. The symbiotic alignment of LSTM with the challenge's objectives manifests in competitive outcomes. The prognostications of facial attributes from the employed models are amalgamated by assigning weights to each method based on their performance metrics on the Acted Facial Expression in Wild (AFEW) validation set. The datasets utilized in this proposed system will be expounded upon in Section IV. The emotions considered for classification encompass Angry, Disgust, Fear, Happy, Neutral, Sad, and Surprise.

In both models, the initial step involves resizing the image to different scales, creating an image pyramid, which serves as input for the subsequent three-stage cascaded framework outlined in [45]. For face detection, candidate facial windows and their associated bounding box regression vectors are acquired using a fully convolutional network referred to as the proposal network (P-Net). Calibration of the candidates is performed based on the estimated bounding box regression vectors, followed by the application of non-maximum suppression (NMS) to consolidate highly overlapping candidates. Moving to the second stage, all candidates are directed through another CNN known as the refine network (R-Net), which serves to further eliminate a significant number of erroneous candidates, refine bounding boxes through regression, and perform NMS for accuracy. The final stage mirrors the second stage, with a focus on face regions that receive more supervision, leading to the network outputting the positions of facial landmarks.

1) CNN-based attributes extraction model: As shown in Fig. 2, the diagram of the model is divided into three main sections: Frames feature extraction, Frame-level feature aggregation, and classification. In frames feature extraction,

four networks are fine-tuned for the prediction of individual static images, specifically Inception V3, DenseNet121, DenseNet161, and DenseNet201. These networks were employed due to their efficient feature extraction and high image recognition accuracy. Inception-V3 is a popular CNN model known for its deep architecture and unique inception modules, enabling efficient feature extraction across multiple scales. It is optimized for CPU and GPU usage and has achieved accuracy rates exceeding 78.1% on ImageNet. On the other hand, DenseNet models are characterized by dense interconnections between layers. They vary in the number of layers, with DenseNet201 being the deepest. DenseNet models excel in image classification and feature extraction, delivering state-of-the-art results.

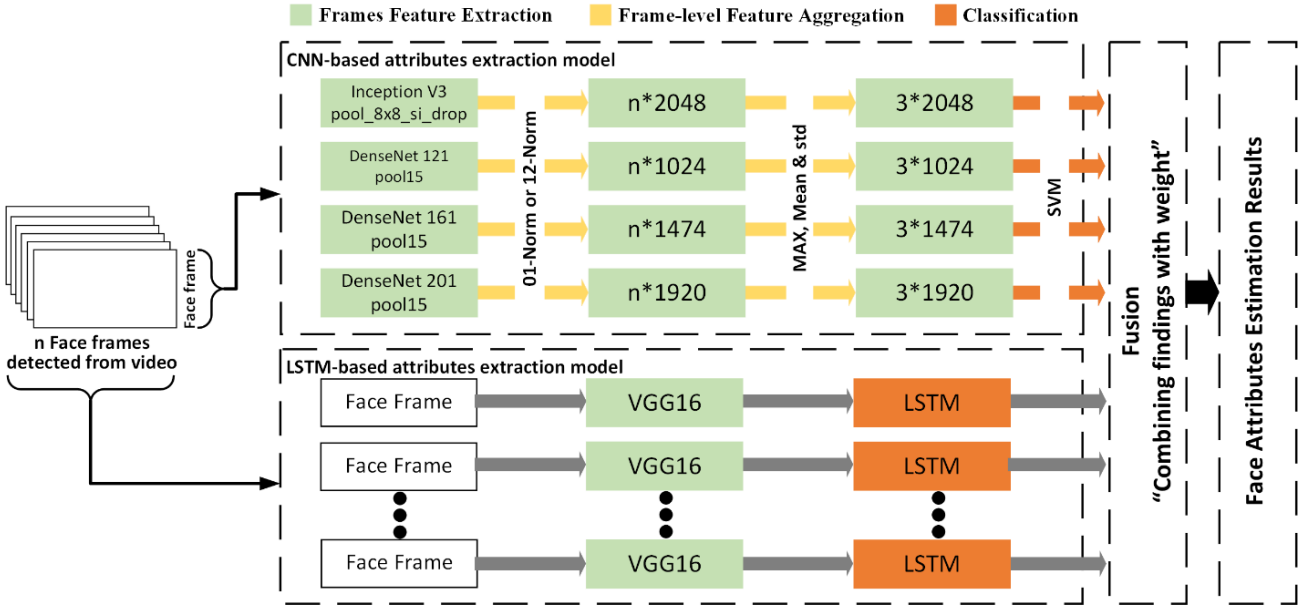

Fig. 2. Face attributes extraction module.

On the Real-world Affective Faces (RAF) validation test, these networks achieved accuracy scores of 82.74%, 83.84%, 83.25%, and 79.73%, with corresponding feature dimensions of 2048*3, 1024*3, 1474*3, and 1920*3, respectively. Subsequently, fine-tuned models extract features from the final layers of aligned faces, using them as the foundational representation. The Number of Features section shows the number of features extracted by each CNN layer. However, since the feature dimension in each video is directly linked to the number of detected faces and the layer dimension, normalization is used to standardize feature dimensions. The Video Features section shows the video features extracted by the CNN layers.

For frame-level feature aggregation, two normalization methods are applied separately to the features extracted by various CNN models from each aligned face in video frames using mean, max, and standard deviation. The video feature tripled compared to the initial CNN extraction. Following that, the RootSIFT and a normalization method ranging from [0,1] are applied to process the original feature [46]. Here's the calculation process:

$$F_i^{l2} = \frac{|F_i^v|}{\sum_j^n (F_j^v)^2} \quad (1)$$

$$F_i^{01} = \frac{F_i^v - \min(F^v)}{max(F^v) - min(F^v)} \quad (2)$$

Where F^v is the original feature extracted from a video, F_i^v is the index of feature in the feature vector. $max(F^v)$ and $min(F^v)$ stand for the maximum and minimum values in the video feature vector. F_i^{l2} and F_i^{01} are the features we normalized by l2-norm and 01-norm.

The classification step shows the output of the SVM. Linear SVMs were trained with various extracted features by the two normalization methods and four networks. Parameters were evaluated using 5-fold cross-validation. The results on the AFEW validation set for different features, based on SVM models, are notably lower than those in the RAF static image set. This difference can be attributed to the richer information in video clips regarding the expression process.

2) LSTM-based attributes extraction model: For face detection, the model is trained using VGG facial features on the AFEW training dataset. Maintaining stable face tracking is essential for optimal model performance in the analysis of the time sequence. Given that most video frames contain at least one face, the face detection threshold is set to a lower value to capture more faces while minimizing errors. A comprehensive set of face landmarks is leveraged to precisely locate the primary character's face, typically the one with the largest facial area. Additionally, a larger window is employed to capture finer details from regions like the forehead and chin.

For frame feature extraction, VGG-16 architecture is employed due to its exceptional quality of the FER2013 dataset in grayscale and its ample collection of meticulously selected faces. VGG-16 stands out for its depth, comprising 16 weight layers, uniform architecture with small 3x3 convolutional

filters, robustness, and high accuracy in image classification. The pre-trained VGG-Face Model is used on the FER2013 emotion dataset to fine tune the network and enhance its performance [14]. The images are resized to 224x224 in grayscale. Through the application of data augmentation techniques, 70.96% accuracy on the validation dataset is achieved which considered high level of performance.

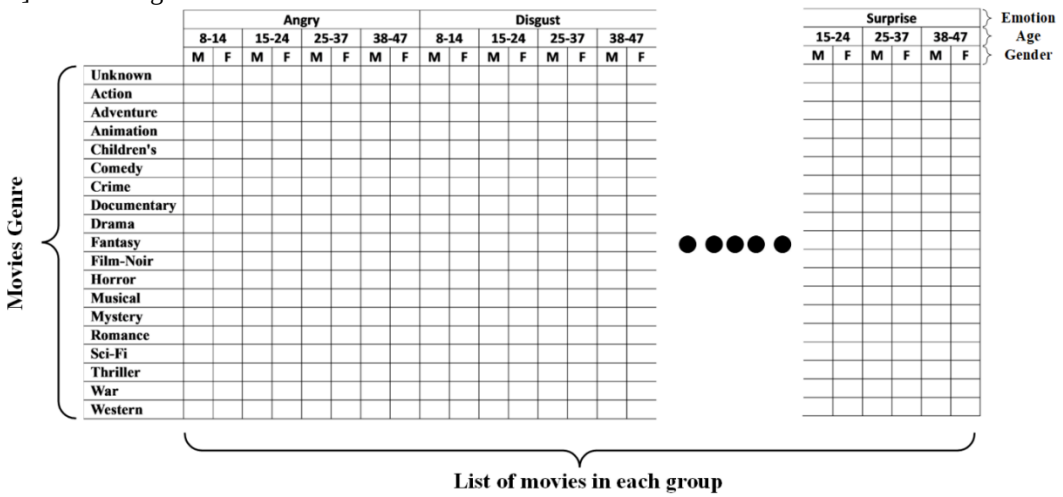

Fig. 3. Preferred movies based group clusters.

Finally, the classification is done using classic LSTM architecture, incorporating memory cell, input gate, output gate, and forget gate, was chosen. The implementation strategy aligns with [16]. LSTMs excel at handling long-term dependencies in sequential data, making them suitable for tasks like time series forecasting. Training videos have been segmented into 16-frame clips. An essential data augmentation step is the overlapping of clips by 8 frames, a well-established and effective technique for both training and testing. Additionally, mirror and multi-scale methods are employed. Temporal features from continuous video frames of facial expressions are extracted by the LSTM layer, utilizing a single LSTM layer with 128 embedding outputs. Notably, the final emotion prediction accuracy on the AFEW validation dataset achieves 46.21%. In contrast, utilizing an LSTM-256 layer instead of 128 leads to a slightly reduced accuracy of 43.07% in the validation dataset.

B. Movies Clustering based on Movie Attributes

Film characteristics will be derived from the Movielens dataset [47] to undergo system testing. Each film is delineated by its unique movie ID, title, release date, IMDb URL, and is classified across 19 genres, encompassing unknown, Action, Adventure, Animation, Children's, Comedy, Crime, Documentary, Drama, Fantasy, Film-Noir, Horror, Musical, Mystery, Romance, Sci-Fi, Thriller, War, and Western. To systematically categorize these films into distinct groups, the k-means algorithm will be employed—an unsupervised machine learning method.

This algorithm extracts insights from datasets through vectors, operating independently of labeled outcomes. It establishes a predetermined number (k) of cluster centroids within the dataset, computing the distances between each object and these centroids. Objects are subsequently assigned to the nearest cluster based on these distances, and the averages of all clusters are recalculated iteratively until the criterion function is satisfied. Attribute similarity is assessed using the Euclidean similarity approach, wherein objects with analogous attributes exhibit smaller dissimilarity distances, while those with disparate attributes display larger dissimilarity distances.

For a matrix X with i quantitative variables, the Euclidean distance d between two features, x_1 and x_2, can be computed as

$$d(x_1, x_2) = \sqrt{\sum_{i=1}^{n}(x_{1n}, x_{2n})^2} \quad (3)$$

The determination of the optimal K value in K-Means involves executing the algorithm with different k values and assessing variance. The selected K value corresponds to the point where variance is minimized. Variance, in this context, is computed as the cumulative sum of distances between each centroid and the items within its assigned cluster. The process includes plotting the variance against various K clusters, enabling the identification of the elbow point. The elbow point signifies the threshold at which the reduction in variance becomes notably stagnant. This allows for a systematic evaluation of K values based on variance metrics, providing a quantitative basis for determining the most suitable number of clusters in the K-Means clustering algorithm.

C. Movies Recommendation

Individuals are stratified based on attributes such as age group, gender, and emotional states to furnish tailored movie recommendations, as delineated in Fig. 3. The designated age cohorts encompass 8-14, 15-24, 25-37, and 38-47 years. Subsequently, the movies selected by each user are allocated to corresponding clusters. The cluster exhibiting the utmost representation of favored movie genres is identified as the group's preference. This determination relies on the cluster with the highest prevalence among all movie clusters, exemplified in a group with movie clusters [1, 1, 1, 2, 3, 3, 4, 1, 1], where cluster 1 is acknowledged as the favored group cluster.

Following this, the algorithm illustrated in Fig. 4 is employed to prognosticate movie ratings within each cluster. The system employs the Singular Value Decomposition (SVD) technique [47], a renowned Collaborative Filtering method. SVD, a matrix factorization method grounded in linear algebra, dissects a real matrix *X* into three matrices: *U*, *S*, and *V*. The SVD outcome encompasses matrix *U*, signifying user vectors, and matrix V^T, signifying movie vectors, with the singular values of *X* on the diagonal of matrix *S*, as depicted in the equation.

Algorithm: Ratings_prediction_of_movies

g: users' group (i.e., specific age, gender, and emotion)
m_g: a movie selected by a user group
m_c: a cluster of movies created by clustering module
C: representative movies cluster to specific user's group
m_i: a movie in the representative movies cluster
$\hat{X}$: rating of recommended movies
U: user vectors matrix
V^T: movies vectors matrix
S: diagonal matrix containing the singular values
m_p: movies preference for each *C*
Begin
for each users group *g* **do**
    selected movies $m_g \in m_c$ are listed
    identify *C* for each *g* by calculating maximum select movies cluster m_c
end for
for each movie $m_i \in C$ **do**
    rate the movies using $\hat{X} \approx U.S.V^T$
    list the movies preference m_p
end for
return m_p
End

Fig. 4. Algorithm of ratings prediction of the movies in each cluster.

$$X = U \times S \times V^T \tag{4}$$

SVD is selectively applied solely to movies in the favored group cluster, crafting a matrix where rows symbolize users in the same gender, age, and emotion category as active users, and columns signify chosen movies in a descending order. Matrix values denote the frequency of a specific movie being chosen. Ultimately, recommended movies with the highest ratings are ascertained through the dot product of *U*, *S*, and V^T, as elucidated in the equation.

$$\hat{X} \approx U.S.V^T \tag{5}$$

IV. Implementation Setup and Datasets

The computational framework is developed in Python and executed using Jupyter Notebook. Experimental procedures are conducted on a MacBook Pro featuring an Intel Core i7 processor and 8GB of RAM. Convolutional Neural Network (CNN) models, employed for facial attributes extraction, undergo pre-training utilizing the RAF and FER2013 datasets. The FER2013 dataset encompasses 28,709 training images, 3,589 validation images, and 3,589 testing images. Similarly, the RAF dataset comprises 12,271 training samples and 3,068 testing samples. Additionally, the AFEW dataset is applied for video clips emotion recognition, serving as a dynamic temporal facial expressions data repository derived from cinematic contexts. This dataset incorporates 957 samples, spanning six expression classes, and features neutral, natural head pose movements, occlusions, and a diverse array of subjects representing varied races, genders, ages, and other demographic characteristics. The Movielens 100k dataset is employed to facilitate the training and evaluation of the proposed system. Comprising 100,000 ratings across a 1 to 5 scale, the dataset involves 943 users rating 1682 movies, with each user contributing assessments for a minimum of 20 movies. The performance evaluation of the system involves the execution of 150 experimental observations.

V. Results and Discussion

This section first presents the outcomes of implementing a face attributes extraction model, followed by a movie recommendation model. The results of implementing face attributes extraction using CNN and LSTM based models individually and collaboratively are presented. Variations in sample sizes across classes highlight differences in category significance. To address this, class weights are employed, scaling scores by the square root of sample numbers, improving model performance in easily distinguishable categories. Model weights were determined through experiments on the validation set. The CNN-based model achieved a 55.3% score, while the LSTM-based model reached 59.1%. The combination of CNN and LSTM models achieved an impressive 60.07% accuracy which represents the overall accuracy of predicting the characteristics of the user correctly. However, the prediction accuracy of age, gender, and emotion are 86.3%, 87%, and 85%, respectively. Table II summarizes the accuracy findings of the proposed face attributes extraction model. Gender estimation errors mostly occurred among younger individuals aged 8-14. This may be due to the inherent difficulty in accurately predicting gender in children. On the other hand, age estimation exhibited a relatively high number of prediction errors in individuals aged [19-20]. This can be explained by the distinctiveness of aging patterns among individuals, which also varies based on gender.

Fig. 5. Preferred movies based group clusters.

In Fig. 5, an illustrative overview of movie recommendations incorporating estimated age, gender, and emotion is showcased. The assessment of movie recommendations' performance is undertaken, drawing comparisons with the methodology introduced in a prior study [32]. Assessment metrics include precision, recall, and F1-score. Precision, indicating the accuracy of movie predictions, is calculated as the ratio of true positive predictions to all positive predictions [49]. Recall, representing the model's

ability to predict occurrences, is computed as true positive predictions divided by actual positive predictions [49]. The F1-score, a harmonic mean of precision and recall, is determined using the specified formula [49].

The outcomes of these performance metrics are succinctly presented in Table II, underscoring the superior efficacy of the proposed system across various scenarios. While the benchmark system exhibits slightly higher precision in the 8-14 age group, the proposed system outperforms in recall and F1-score. Notably, the precision in the 15-24 age group reaches around 0.903, surpassing the proposed system's precision of approximately 0.862. Furthermore, in the 25-37 age group, the system achieves an average precision, recall, and F1-score of 0.873, 0.894, and 0.88, respectively.

TABLE III. THE ACCURACY OF THE PROPOSED FACE ATTRIBUTES EXTRACTION MODEL

		Emotion							Average (%)
Gender	**Age**	**Angry**	**Disgust**	**Fear**	**Happy**	**Neutral**	**Sad**	**Surprise**	
Male	**8-14**	55.42	53.12	56.45	56.34	53.22	56.65	57.37	55.51
	15-24	58.34	56.23	57.40	62.35	61.44	56.32	58.43	58.64
	25-37	63.21	60.75	61.21	64.23	64.23	64.15	63.75	63.07
	38-47	62.56	60.34	60.13	64.56	64.25	65.43	64.35	63.08
Female	**8-14**	55.40	54.02	56.34	55.64	52.95	56.67	56.77	55.39
	15-24	58.02	55.97	57.82	62.15	61.64	55.81	58.82	58.60
	25-37	64.51	59.63	62.19	62.43	63.73	64.03	63.82	62.90
	38-47	62.77	62.43	59.94	64.02	65.02	64.86	64.85	63.41
Average (%)		60.02	57.81	58.93	61.46	60.81	60.49	61.02	60.07

While the proposed system demonstrates relatively high accuracy, it may not be suitable for users who cover their faces (e.g., wearing Hijab), as facial features cannot be extracted under such circumstances. To address this limitation, the system could enhance its capabilities by integrating demographic feature extraction through voice analysis. Furthermore, the computational efficiency and complexity of the face attribute extraction module could be enhanced by leveraging the advantages of the You Only Look Once (YOLO) algorithm due to its superior efficiency and suitability for real-time applications [50].

VI. CONCLUSION

Film venues and digital platforms provide an extensive array of cinematic options, often overwhelming consumers faced with a multitude of choices. To address this issue and enhance the efficiency of the decision-making process for clients, sophisticated recommendation systems have been devised. Existing movie recommendation systems, characterized by intricate computational processes, exhibit a notable deficiency in accurately tracking and extracting temporal facial attributes. This limitation compromises the precision of attribute classification, consequently diminishing the overall accuracy of the recommendation system. Furthermore, prevalent systems tend to overlook various attributes, contributing to a reduction in overall accuracy and dependability. This study introduces a novel hybrid recommender system that seamlessly integrates collaborative filtering and content-based methodologies. The system takes into account diverse attributes such as age, gender, emotion, and genre to optimize movie recommendations. Initially, movies undergo categorization based on genre, with a preference determined by selecting the most representative genres. Ratings for these films are subsequently predicted and presented in descending order. Employing Convolutional Neural Network (CNN) and Long Short-Term Memory (LSTM) models, the system conducts real-time extraction of facial attributes, enhancing accuracy in emotion attribute extraction by ensuring sequential extraction of attributes. Results from the system's implementation reveal its superior performance compared to the benchmark system across various test scenarios. However, the benchmark system exhibits marginally higher precision in the age groups of 8-14 and 15-24. Despite the proposed system's commendable accuracy, it faces limitations when users conceal their faces, necessitating improvements through the integration of demographic feature extraction via voice analysis and optimization of the computational efficiency of the face attribute extraction module utilizing the YOLO algorithm.

***Abstract*—Ransomware is a significant threat to Android systems. Traditional methods of detection and prediction have been used, but with the advancement of technology and artificial intelligence, new and innovative techniques have been developed. Machine learning (ML) algorithms are a branch of artificial intelligence that have several important advantages, including phishing detection, malware detection, and spam filtering. ML algorithms can also be used to detect ransomware by learning the patterns and behaviors associated with ransomware attacks. ML algorithms can be used to develop detection systems that are more effective than traditional signature-based methods. The selection of the dataset is a crucial step in developing an ML-based ransomware detection system. The dataset should be large, diverse, and representative of the real-world threats that the system will face. It should also include a variety of features that are informative for ransomware detection. This research presents a survey of ML algorithms for ransomware detection and prediction. The authors discuss the advantages of ML-based ransomware detection systems over traditional signature-based methods. They also discuss the importance of selecting a large, diverse, and representative dataset for training ML algorithms. Two datasets are applied during the conducted experiments, which are SEL and ransomware datasets. The experiments are repeated with different splitting ratios to identify the overall performance of each ML algorithm. The results of the paper are also compared to recent methods of ransomware detection and showed high performance of the proposed model.**

Keywords*—Ransomware; machine learning; malware detection; phishing detection; spam filtering

I. Introduction

During today's rapidly evolving technological landscape, the menace of malware remains a formidable challenge, with ransomware at its forefront. Cybercriminals consistently innovate to breach computer systems, propelling the need for more advanced detection and prediction methods. Particularly, ransomware is a dire threat to Android systems, prompting the exploration of innovative strategies driven by the surge of artificial intelligence and machine learning (ML).

Ransomware is a pernicious form of malware that encrypts valuable data, demanding a ransom for decryption [1]. This cybersecurity threat spans servers, computers, and smartphones, jeopardizing critical personal data and daily operations [2]. Android systems, in particular, are a prime target due to their open-source nature, enabling attackers to encrypt and hold data hostage, thereby escalating the impact of ransomware attacks. The advent of cryptocurrencies like Bitcoin has further complicated tracking both the attackers and their extorted funds [3].

The integration of artificial intelligence particularly ML, has emerged as a potent tool in the fight against ransomware. ML algorithms, distinguished by their effectiveness in various domains, excel in detecting phishing attempts, identifying malware, and filtering spam [3]. These algorithms can be trained on extensive datasets containing benign and malicious software to discern the unique behavioral patterns that set ransomware apart. Once trained, they can recognize new ransomware variants, by analyzing these distinctive behavioral patterns. The advantages of using ML for ransomware detection over traditional methods are profound. ML algorithms can identify new, previously unknown ransomware variants, adapt to evolving threat patterns, and minimize false positives. This is achieved by focusing on behavior patterns rather than static signatures or predefined rules [4].

Ransomware behavior is evolving rapidly and it targets many important assets, including critical systems such as Android. Therefore, it poses a challenge to detect and prevent it, and automated learning methods are effective ways to detect malicious ransomware behavior.

This paper presents an analysis of the malicious behavior of ransomware targeting the Android system using several machine learning algorithms such as Naive bayes, Support vector machine, Decision tree, k-nearest neighbors, Random forest, and Logistic Regression. This was conducted on various data sets containing many of the most common types of ransomware, and the data was divided into different proportions to ensure the effectiveness of the ML models.

II. Related Work

As presented in study [1], ransomware is malicious software that seizes a victim's data, encrypts data, and extorts money from the victim in exchange for their data. It evolves rapidly, making its detection challenging requiring continuously evolving detection tools. The authors of [2] categorized Ransomware into three main methods: Computer locker, I/O centric Locker, and Crypto miner. It follows a five-step process, including infection delivery, environment verification, hiding to avoid detection, target selection, and displaying a blackmail message to the victim.

As presented in study [4], the authors proposed an automated education-based approach for detecting

ransomware through three key stages: data collection related to ransomware, extraction of shared ransomware behaviors, and precise identification of harmful ransomware behaviors. The authors also emphasized the effectiveness of automated education in evaluating and verifying information. Ransomware targets a wide range of categories, including individuals, due to the personal value of their data, business databases, and commercial companies. It also targets local servers to damage multiple systems potentially. Additionally, there are general guidelines for ransomware protection, such as encrypting backups, utilizing updated firewalls, using the latest antivirus software, and implementing a strategy of reduced user privileges [5].

As presented in study [6], ransomware has increased in recent years, primarily due to its profitability, and it has targeted various sectors, including healthcare, industry, and education. As explained in study [7], ransomware can be categorized into encryption-focused and screen-locking variants. The increase in ransomware attacks is attributed to its availability as a service, with some attackers offering ransomware creation tools and taking a 20% cut of the ransom. Victims facing such attacks have four options: pay the ransom, restore data from backups, and attempt to guess the decryption key through brute force, or lose the data.

As presented in [8], the methods for addressing ransomware are categorized into two key aspects: prevention, including measures like backups, and detection, further divided into four categories. These categories are behavior analysis of data to identify suspicious changes and trigger alarms and to compare current operations to past ransomware behaviors. Finally, event-based detection includes traffic and API monitoring and detection through automated learning algorithms. As shown in study [9], conventional intrusion detection systems fall short in countering advanced attacks, thus necessitating more sophisticated detection programs. It highlighted one advanced approach, the honey pot, which is a system purposefully crafted to emulate a genuine system luring in potential attackers. As presented in study [10], numerous mechanisms exist to safeguard against ransomware infections. These include maintaining up-to-date system updates, which address vulnerabilities with each release. Additionally, employing the latest ransomware detection tools is crucial.

As explained in study [11], several reasons contributed to the intensive increase of ransomware: Encryption algorithms are a double-edged sword used for privacy and attacks, and Electronic currencies that allow the attacker to be anonymous. With the rapid development of ransomware, it has become easy and available to obtain. As presented in study [12], a detection-assisting proposal called PEAD is based on the API of detecting the attack before encryption.

As presented in study [13], many victims find themselves compelled to pay the ransom. Email fraud is the primary method of victim targeting, accounting for 59%, followed by websites at 24%. Furthermore, it introduced a ransomware detection tool utilizing machine learning. This tool monitors CPU usage, detecting deviations from normal performance as indicators of potential ransomware activity. Additionally, it scrutinizes file extensions executed on the device, issuing warnings for suspicious programs. Notably, it successfully alerts users during an attack, displaying 0 for benign behavior and 1 for harmful behavior when detected. As presented in [14], ransomware poses a significant cybersecurity threat and is a prevalent form of malware in cybercrime. Numerous variants characterize ransomware and represent a criminal innovation primarily driven by monetary gains, often utilizing cryptocurrencies such as Bitcoin.

As presented in study [15], a strategy that relies on dynamic analysis of prevalent ransomware families, such as WannaCry, was devised. This strategy involves monitoring the real-time impact on a system, including adding or deleting files. Furthermore, it involves observing packet behavior in Wireshark; a change in the Multiplex ID indicates a potential infection.

As proposed in study [16], the researchers introduced a static analysis technique for identifying ransomware. It gathered executable code samples from various ransomware families, categorized them based on their characteristics and employed automated machine learning for classification. Ransomware detection can be approached through various primary methods. The first method is signature-based detection, which involves comparing malicious signatures with known ones. The second method is inferential disclosure, which relies on comparing malicious code [17]. The conducted experiments in virtual environments are used to assess ransomware detection techniques. It observed that these techniques exhibited improved performance after a 24-hour period. Dynamic analysis emerged as a more accurate method, while signature detection and inferential detection were found to be less effective in identifying new and mysterious malicious families.

As presented in study [18], ransomware typically leaves victims with limited recourse for addressing the attack, often necessitating a ransom payment. The study detailed an examination of various ransomware variants and established a virtual environment for scrutinizing DNS activity during such attacks. The researchers employed a trace capture tool both before and following the execution of the attack. As authors of [19, 20], the ransomware follows a specific lifecycle. It initiates by constructing a malicious program, followed by propagation, reaching the target device, identifying the data to encrypt, performing encryption or locking, and ultimately resorting to blackmail.

Ransomware employs various methods to infiltrate victims and compromise their critical data. One of the primary tactics involves encrypting the victim's data to seize control and another method employs a lock screen approach. It's essential to recognize that cybercriminals pursue their malicious objectives, such as extortion, sabotage, and financial gain. Understanding the consequences of ransomware and being knowledgeable about defenses against this threat can enhance user and asset security. Therefore, in this section we will conduct a comparative analysis of the studies, focusing on four main aspects: the ransomware methods employed in each paper, the objectives behind ransomware infection and its impact, and the countermeasures utilized.

TABLE I. COMPARATIVE ANALYSIS OF RANSOMWARE AND THEIR COUNTERMEASURES

Ref	Ransomware Method	Objective	Ransomware Effect	Security Countermeasure
[1]	Ransomware in general	Profitability –Disruptive – blackmail.	Encryption of victims data	A model that analyzes the level of risk using inferential detection.
[2]	Crypto-Ransomware infection	Profitability –Disruptive – blackmail.	Encryption of victims data	Inferential Behavior & API Linking.
[4]	Crypto Ransomware	Profitability –Disruptive – blackmail.	Encryption of victims data	Automated learning algorithm for ransomware prevention.
[5]	Lock screen or encryption	Profitability –Disruptive – blackmail.	Data damage either by encryption or lock screen	A proposal that prevents the attack, slows the encryption and reduces the impact.
[6]	Cryptographic Ransomware	Profitability –Disruptive – blackmail.	Encryption of victims data	Survey of ransomware detection techniques.
[7]	Ransomware in general	Profitability –Disruptive – blackmail.	Data damage either by encryption or lock screen	Diagram with instructions for dealing with ransomware.
[8]	Crypto Ransomware Attack	.Profitability –Disruptive – blackmail	Encryption of victims data	Proposal for early detection.
[9]	Ransomware in general	.Profitability –Disruptive – blackmail	Data damage either by encryption or lock screen.	A three-layer proposal based on a honey pot.
[10]	Lock screen or encryption	.Profitability –Disruptive – blackmail	Data damage either by encryption or lock screen.	A proposal based on three-tiered security.
[11]	Ransomware in general	.Profitability –Disruptive – blackmail	Data damage either by encryption or lock screen	A proposal that uses machine learning algorithms.
[12]	Crypto-Ransomware	Profitability –Disruptive – blackmail.	Encryption of victims data	PEDA pre-encryption algorithm.
[13]	Ransomware in general	Profitability –Disruptive – blackmail.	Data damage either by encryption or lock screen	A proposal to identify benign or harmful behavior with an API-based proposal.
[14]	Bitcoin and the Financial Impact of Ransomware	Profitability –Disruptive – blackmail.	Financial impact awareness and vision that contributes to solutions against attack	NA
[15]	WannaCry Ransomware	.Profitability –Disruptive – blackmail	Encryption of victims data	Dynamic analysis to collect malware indicators
[16]	Lock screen or encryption	Profitability –Disruptive – blackmail.	Data damage either by encryption or lock screen	Static analysis based proposal.
[17]	Lock screen or encryption	Profitability –Disruptive – blackmail.	Data damage either by encryption or lock screen	Dynamic analysis and code comparison.
[18]	WannaCry Ransomware	Profitability –Disruptive – blackmail.	Encryption of victims data	Conducting an analysis only contributes to the manufacture of mechanism.
[19]	Lock screen or encryption	Profitability –Disruptive – blackmail.	Data damage either by encryption or lock screen	Analysis of detection mechanisms such as honey pot and dynamic analysis based on API programming.
[20]	Ransomware in general	Profitability –Disruptive – blackmail.	Data damage either by encryption or lock screen	A proposal based on machine learning that compares the neural network.

In Table I, it proposes a comparative analysis of different ransomware methods by explaining the main objective of each method, its main effect and the proposed security countermeasure for preventing the threat.

III. MACHINE LEARNING METHODS FOR RANSOMWARE APPLICATIONS

Machine learning (ML) is a powerful tool that can be used to detect ransomware applications. ML algorithms can be trained on large datasets of both benign and malicious software to learn the behavioral characteristics that distinguish ransomware from legitimate software. Once trained, these algorithms can be used to identify new and previously unseen variants of ransomware, including zero-day attacks, based on their behavioral patterns. ML-based ransomware detection has several advantages over traditional signature-based and heuristic-based detection methods. First, ML algorithms can detect new or unknown ransomware variants that do not match existing signatures or patterns. Second, ML algorithms can adapt to changing ransomware behavior patterns over time. Third, ML algorithms are less prone to false positives than signature-based and heuristic-based detection, as they rely on detecting actual behavior patterns rather than static code signatures or predefined rules [21].

Ransomware threatens the Android system significantly, as we have seen its impact in the previous part of this research. Many traditional methods have been applied to

detect and predict this malicious attack. However, with the recent development of technology and artificial intelligence, modern and innovative methods have been developed to detect ransomware attacks. The application of machine learning algorithms is one of the branches of artificial intelligence that has several important advantages, including phishing detection, malware detection, and spams filtering and contributes to commercial tasks.

It can be classified into different categories. One such method is supervised machine learning, which uses algorithms that require outside supervision in order to provide a data set for testing and training. As a result, the model uses decision trees and support vector machines to enable categorization and prediction. The other form of algorithm is unsupervised education, where the algorithms produce data based on their models K-Means. Combining the first two forms, semi-supervised machine learning is the third type. The final type is reinforcement machine learning, in which the algorithm responds to good or bad signals by repeating the task performance [22].

There are numerous techniques to implement ML-based ransomware detection. Utilizing ML algorithms to search for suspicious activities in network traffic is a typical strategy. The usage of ML algorithms, for instance, can be utilized to spot ransomware attacks by spotting surges in encryption activity. Utilizing ML algorithms to examine the behavior of active processes is an alternative strategy. For instance, ML algorithms can be used to spot processes that attempt to connect to known ransomware servers or that encrypt a huge number of files. ML-based ransomware detection is a rapidly evolving field, and new techniques are being developed all the time. As ransomware attacks become more sophisticated, ML will continue to play an increasingly important role in ransomware detection and prevention [23].

IV. Proposed Methodology

In this paper, ML algorithms can be used to detect ransomware by learning the patterns and behaviors associated with ransomware attacks. ML algorithms can be used to develop detection systems that are more effective than traditional signature-based methods. As illustrated in Fig. 1, the ransomware dataset is split into training and testing where the training dataset is preprocessed and then different ML algorithms are applied to measure accuracy. The testing dataset is then applied to identify the best accuracy for each splitting ratio.

The objective of using machine learning (ML) in ransomware detection is to develop systems that are more effective and efficient at detecting ransomware attacks than traditional signature-based methods. Ransomware attacks are becoming increasingly sophisticated and difficult to detect using traditional signature-based methods. ML algorithms can learn to identify the patterns and behaviors associated with ransomware attacks, and they can be used to develop detection systems that are able to detect new and emerging ransomware variants. ML-based ransomware detection systems can also be more efficient than traditional signature-based methods. Traditional signature-based methods require security vendors to maintain and update databases of signatures for known ransomware variants [24]. The overall methodology for managing ransomware attacks is presented in the following steps:

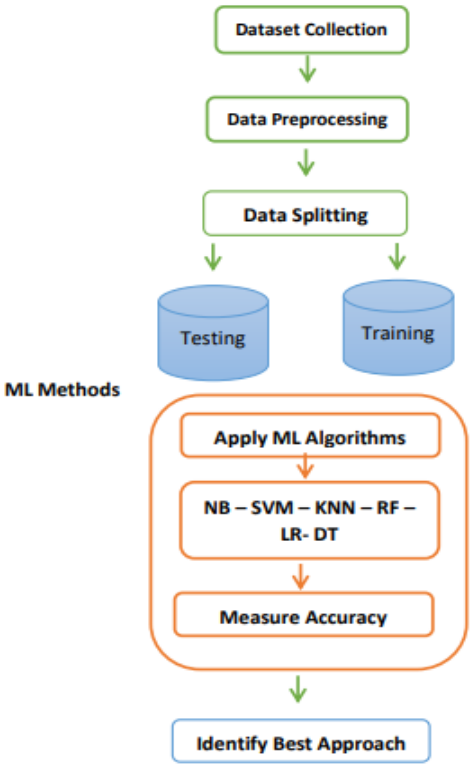

Fig. 1. Proposed ransomware methodology.

A. Dataset Collection

The selection of the dataset is a crucial step in developing a machine learning (ML)-based ransomware detection system. The dataset should be large, diverse, and representative of the real-world threats that the system will face. It should also include a variety of features that are informative for ransomware detection.

1) Security Engineering Lab (SEL) dataset: Ransomware threatens the Android system significantly, Many traditional methods have been applied to detect and predict this malicious attack. However, with the recent development of technology and artificial intelligence, modern and innovative methods have been developed to detect ransomware attacks. Applying machine-learning algorithms is a major advantage for phishing, malware, and spam detection. The Security Engineering Lab (SEL) dataset built in [25] based on 10153 samples of Android apps was used to be one of the latest data sets related to Android ransomware and benign software. As presented in Table I, the dataset contains 500 ransomware applications from several sources, such as the Ransom Proper Project, a timeline that classifies ransomware based on 15 families. It also contains 9653 benign applications collected from several reliable sources, such as the official Android store Google Play , that are distributed as presented in Table II.

TABLE II. DISTRIBUTION OF SEL DATASET

Type	Benign Programs	Ransomware Programs	Total
Number of Programs	9653	500	10153

2) Android ransomware dataset: In this dataset, 10 types of the latest ransomware for Android Taken from Kaggle [26], such as Pletor, Sim blocker, Wanna Locker, Jisut, SV peng, Porn Droid, Koler, Ransom BO, Charger, and Locker pin. The dataset contains 392034 records of benign data for Android programs , that are distributed as presented in Table III.

TABLE III. DISTRIBUTION OF RANSOMWARE DATASET

Attack Name	Number of Records
SVpeng	54161
PornDroid	46082
Koler	44555
Benign	43091
RansomBO	39859
Charger	39551
Simplocker	36340
WannaLocker	32701
Jisut	25672
Lockerpin	25307
Pletor	4715

B. Data Preprocessing

To analyze machine learning algorithms more accurately and reliably and to make sure there are no duplicate, wrong, or corrupted data in the dataset, it must be cleaned. This could lower the level of analysis and produce results that are inaccurate. Therefore, the cleaning procedure raises the data's quality. As can be seen in Table IV, methods have thus been used to enhance the data-cleansing process.

TABLE IV. DATA CLEANING OF SEL AND RANSOMWARE DATASETS

Process	SEL Dataset	Ransomware Dataset
Data Duplication	The dataset is of high quality and does not contain duplicate data	The dataset is of high quality and does not contain duplicate data
Unnecessary Data	-	Unnecessary data are eliminated
Missing Values	Removing missing values from the columns	-
Validation	The data has been validated	The data has been validated
Data Conversion	-	The dataset is converted into binary classification

C. Selection of ML Algorithms

This paper explains varieties of ML algorithms that can be used for ransomware detection as follows:

1) Naïve Bayes (NB): Ransomware detection is one of the many classification tasks that can be performed using the straightforward yet effective machine learning method known as Naive Bayes (NB). Based on the likelihood that each feature in a given data point belongs to a particular class, NB determines the likelihood that a given data point belongs to that class [24].

2) Support Vector Machine (SVM): Another effective machine learning approach for ransomware detection is SVM. Finding a hyperplane in the feature space that divides the data points into two classes (harmless and malevolent) is how SVMs operate. You would first need to compile a dataset containing both benign and dangerous software in order to employ SVMs for ransomware detection [24]. The file type, file size, file permissions, and file contents should all be included in this dataset. The model can be used to categorize fresh data points as benign or malicious after it has been trained. The model would determine the distance between the new data point and the hyperplane in order to accomplish this. The data are only used if the distance exceeds a predetermined threshold.

3) Decision Tree (DT): A supervised machine learning approach called decision trees (DT) is useful for both classification and regression tasks. DTs divide the feature space recursively into smaller and smaller sections until each zone only contains data points from one class [22]. After the dataset has been gathered, a DT model would need to be trained using the information. In order to achieve this, the feature space is recursively divided into smaller and smaller sections, until each zone only contains data points from a single class.

4) K-nearest neighbors (KNN): It is a simple and effective machine-learning algorithm that can be used for classification and regression tasks. KNN works by finding the K most similar data points to the new data point and assigning the new data point to the class of the majority of the K most similar data points [21].

5) Random Forest (RF): An ensemble learning approach called random forests (RFs) combines the predictions of various decision trees to create a forecast that is more accurate [22]. A huge number of decision trees are built using random selections of the data using RFs, and their predictions are then averaged. After gathering your dataset, you would need to use the information to train an RF model. To do this, many decision trees are built using random subsets of the data, and their predictions are then averaged.

6) Logistic Regression (LR): A machine learning approach for classification tasks is logistic regression (LR). By applying a logistic function to the data, LR operates [22]. A real integer is entered into the logistic function, a sigmoid function that returns a probability between 0 and 1. After gathering your dataset, you would need to use the information to train an LR model. In order for the model to forecast the likelihood that a data point would be malicious given its characteristics, the data must be fitted using a logistic function.

V. Experimental Results

The experimental results on two ransomware datasets are promising and suggest that ML algorithms can be used to develop effective ransomware detection systems. The accuracy, precision, recall, and F1-score are measured in both SEL and Ransomware datasets to explore the main performance of each dataset with different ML algorithms.

The accuracy is used to measure the performance of a ML model in predicting the correct class TP_c of a new data point. It is defined as the percentage of correct predictions made by the model as given in Formula (1).

$$Accuracy = \frac{TP_c+TN_c}{TP_c+FP_c+TN_c+FN_c} \quad (1)$$

A measure of precision in ML is the percentage of positive predictions that are in fact accurate. It is calculated by dividing the total number of accurate positive forecasts by the number of true positives as given in Formula (2).

$$Precision = \frac{TP_c}{TP_c+FP_c} \quad (2)$$

Recall is a metric used in ML that evaluates the percentage of real positives that are properly expected. It is calculated by dividing the total number of real positives by the number of true positives as given in Formula (3).

$$Recall = \frac{TP_c}{TP_c+FN_c} \quad (3)$$

The precision and recall measures for ML are combined into a single statistic called the F1-score. Given that it is defined as the harmonic mean of the precision and recall scores, both precision and recall are given equal weight as given in Formula (4).

$$F1-score = 2 \times \frac{Precision \times Recall}{Precision+Recall} \quad (4)$$

A. Results of SEL Dataset

The experimental results are executed for training and testing the dataset using the predefined ML algorithms. The dataset is split based on two ratios 80:20 and 70:30. For the dataset split ratio of 80:20, the 80% is applied for training and the 20% is applied for testing. For the dataset split ratio of 70:30, the 70% is applied for training and the 30% is applied for testing. As presented in Table V the data is split to 20% for testing 80% for training and the performance of different machine learning is measured based on the accuracy, recall, and F1-score.

TABLE V. Performance Analysis of ML Algorithms with 80:20 Splitting for SEL Dataset

ML Alg.	Accuracy	Recall	F1-score
SVM	99.26%	99.43%	99.61%
RF	97.68%	99.89%	98.79%
NB	95.02%	**100%**	97.44%
KNN	99.06%	99.48%	99.50%
DT	97.48%	97.97%	98.66%
LR	**99.31%**	99.63%	**99.63%**

As presented in Fig. 2, the LR algorithm achieved the highest accuracy of 99.31% on the SEL dataset, while the SVM algorithm recorded 99.26%. The KNN algorithm recorded the third-highest accuracy, with 99.06%. It is followed by the RF algorithm with an accuracy of 97.68%, while the DT algorithm recorded an accuracy of 97.48%. The NB algorithm achieved 95.02%, which is considered the lowest accuracy on the SEL dataset.

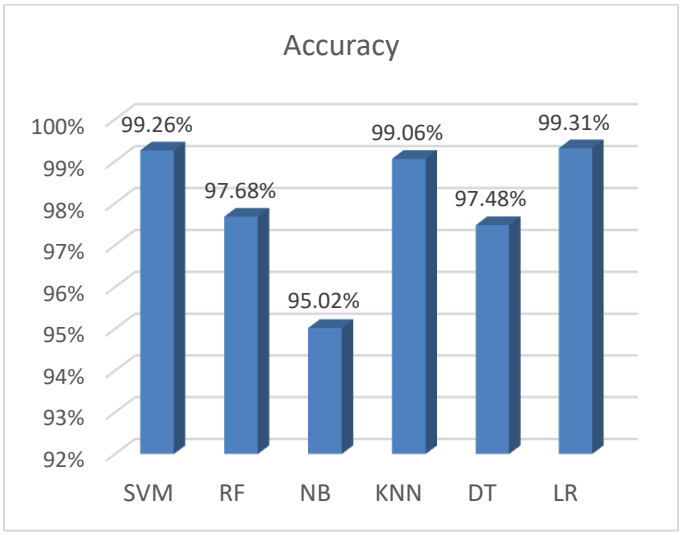

Fig. 2. Accuracy of different ML algorithms on SEL dataset with splitting ratio of 80:20.

As presented in Fig. 3, the NB algorithm achieved the highest recall of 100% on the SEL dataset, while the RF algorithm recorded 99.89%. The LR algorithm recorded 99.63%. It is followed by the KNN algorithm with a recall of 99.48%. The SVM algorithm recorded a recall of 99.43%, while the DT algorithm achieved 97.97%, which is considered the lowest recall on the SEL dataset.

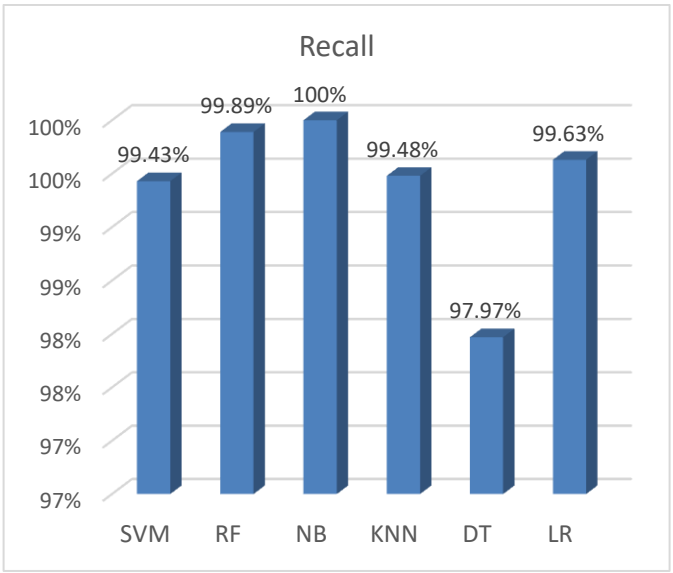

Fig. 3. Recall of different ML algorithms on SEL dataset with splitting ratio of 80:20.

As presented in Fig. 4, the LR algorithm achieved the highest F1-score of 99.63% on the SEL dataset, while SVM recorded 99.61%. The KNN algorithm recorded 99.50%, while the RF algorithm achieved an F1-score of 98.79%. The DT algorithm recorded an F1-score of 98.66%, while the NB algorithm achieved 97.44%, which is considered the lowest F1-score on the SEL dataset.

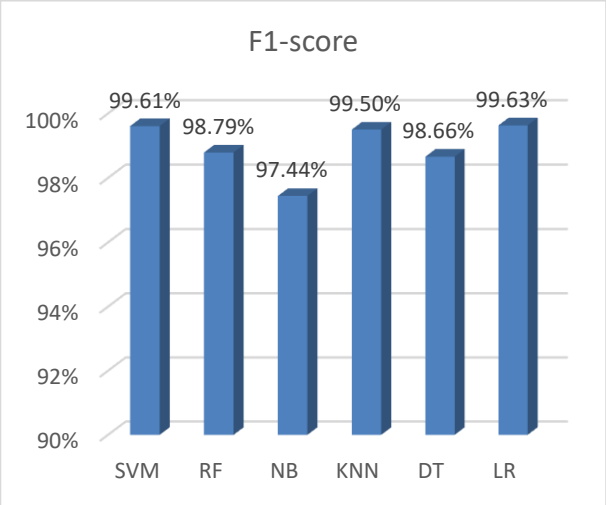

Fig. 4. F1-score of different ML algorithms on SEL dataset with splitting ratio of 80:20.

As presented in Table VI, the data is split to 30% for testing 70% for training and the performance of different machine learning is measured based on the accuracy, recall, and F1-score.

TABLE VI. PERFORMANCE ANALYSIS OF ML ALGORITHMS WITH 70:30 SPLITTING FOR SEL DATASET

ML Alg.	Accuracy	Recall	F1-score
SVM	99.24%	99.41%	99.60%
RF	98.32%	99.89%	99.12%
NB	95.27%	**99.96%**	97.5%
KNN	99.31%	99.65%	99.63%
DT	93.30%	93.17%	96.36%
LR	**99.47%**	99.72%	**99.72%**

As presented in Fig. 5, the LR algorithm achieved the highest accuracy of 99.47% on the SEL dataset, while the KNN algorithm recorded 99.31%. The SVM algorithm recorded the third-highest accuracy, with 99.24%. It is followed by the RF algorithm with an accuracy of 98.32%, while the NB algorithm recorded an accuracy of 95.27%. The DT algorithm achieved 93.30%, which is considered the lowest accuracy on the SEL dataset.

As presented in Fig. 6, the NB algorithm achieved the highest recall of 99.96% on the SEL dataset, while the RF algorithm recorded 99.89%. The LR algorithm recorded 99.72%. It is followed by the KNN algorithm with a recall of 99.65%. The SVM algorithm recorded a recall of 99.41%, while the DT algorithm achieved 93.17%, which is considered the lowest recall on the SEL dataset.

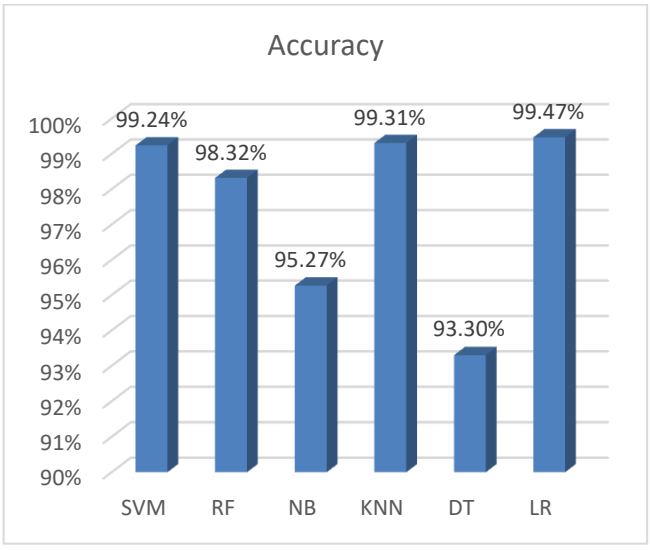

Fig. 5. Accuracy of different ML algorithms on SEL dataset with splitting ratio of 70:30.

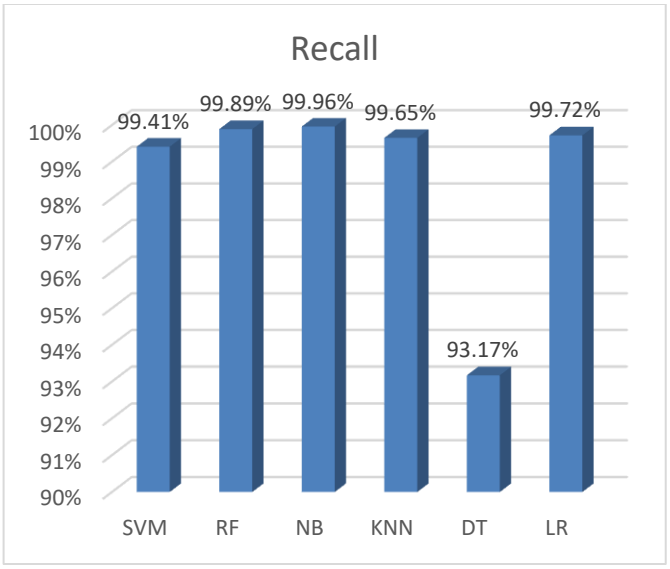

Fig. 6. Recall of different ML algorithms on SEL dataset with splitting ratio of 70:30.

As presented in Fig. 7, the LR algorithm achieved the highest F1-score of 99.72% on the SEL dataset, while KNN recorded 99.63%. The SVM algorithm recorded 99.60%, while the RF algorithm achieved an F1-score of 99.12%. The NB algorithm recorded an F1-score of 97.50%, while the DT algorithm achieved 96.36%, which is considered the lowest F1-score on the SEL dataset.

B. Results of Ransomware Dataset

The experimental results are conducted again on the Ransomware dataset to reevaluate the overall performance of the detection methodology. The Ransomware dataset is also split to 80:20 and 70:30 ratios to check whether the performance will be enhanced or not. As presented in Table VII, the data is split to 20% for testing 80% for training and the performance of different machine learning is measured based on the accuracy, recall, and F1-score.

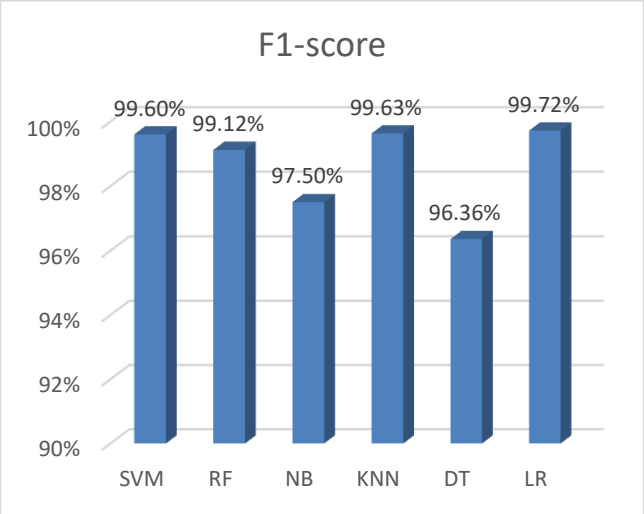

Fig. 7. F1-score of different ML algorithms on SEL dataset with splitting ratio of 70:30.

TABLE VII. PERFORMANCE ANALYSIS OF ML ALGORITHMS WITH 80:20 SPLITTING FOR RANSOMWARE DATASET

ML Alg.	Accuracy	Recall	F1-score
RF	90%	96.4%	94.7%
NB	89.01%	**100%**	94.18%
KNN	**93.25%**	97.12%	**96.24%**
DT	79.31%	84%	88%
LR	89.49%	96.9%	94.2%

As presented in Fig. 8, the KNN algorithm achieved the highest accuracy of 93.25% on the Ransomware dataset, while the RF algorithm recorded 90.00%. The LR algorithm recorded the third-highest accuracy, with 89.49%. It is followed by the NB algorithm with an accuracy of 89.01%. The DT algorithm achieved 79.31%, which is considered the lowest accuracy on the Ransomware dataset.

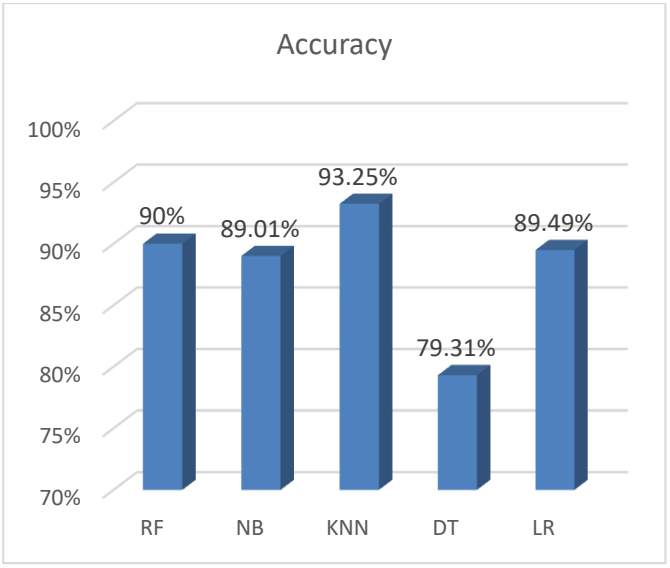

Fig. 8. Accuracy of ML algorithms on Ransomware dataset with splitting ratio of 80:20.

As presented in Fig. 9, the NB algorithm achieved the highest recall of 100% on the Ransomware dataset, while the KNN algorithm recorded 97.12%. The LR algorithm recorded the third-highest recall, with 96.90%. It is followed by the RF algorithm with a recall of 96.40%. The DT algorithm achieved 84%, which is considered the lowest recall on the Ransomware dataset.

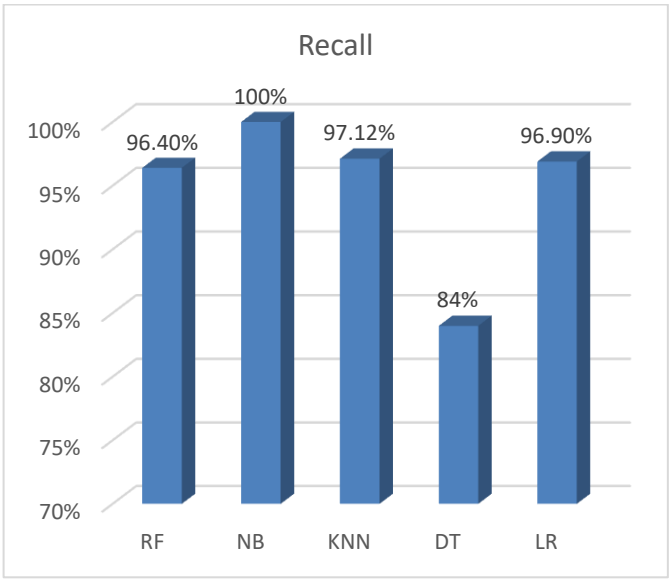

Fig. 9. Recall of ML algorithms on Ransomware dataset with splitting ratio of 80:20.

As presented in Fig. 10, the KNN algorithm achieved the highest F1-score of 96.24% on the Ransomware dataset, while the RF algorithm recorded 94.70%. The LR algorithm recorded the third-highest F1-score, with 94.20%. It is followed by the NB algorithm with an F1-score of 94.18%. The DT algorithm achieved 88%, which is considered the lowest F1-score on the Ransomware dataset.

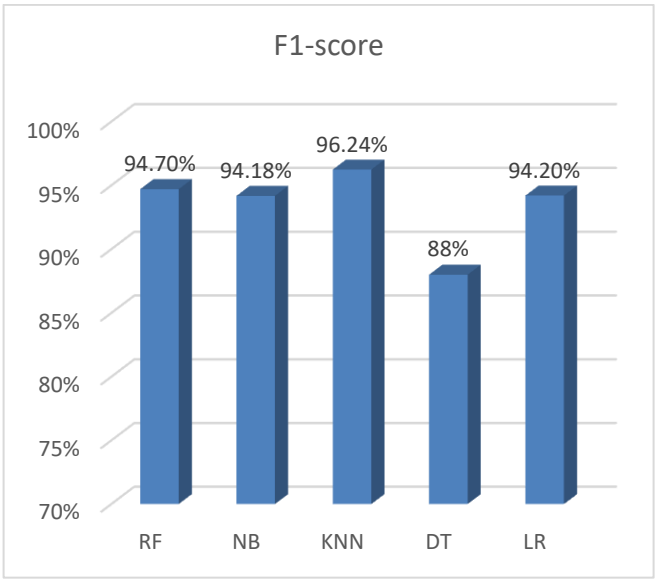

Fig. 10. F1-score of ML algorithms on Ransomware dataset with splitting ratio of 80:20.

TABLE VIII. PERFORMANCE ANALYSIS OF ML ALGORITHMS WITH 70:30 SPLITTING FOR RANSOMWARE DATASET

ML Alg.	Accuracy	Recall	F1-score
RF	89.32%	97.77 %	94.21%
NB	88.96%	**99.97%**	94.15%
KNN	**93.12%**	97.11%	**96.16%**
DT	82.88%	87.79%	90.12%
LR	89.45%	96.95%	94.24%

As presented in Table VIII, the data is split to 30% for testing 70% for training and the performance of different machine learning is measured based on the accuracy, recall, and F1-score.

As presented in Fig. 11, the KNN algorithm achieved the highest accuracy of 93.12% on the Ransomware dataset, while the LR algorithm recorded 89.45%. The RF algorithm recorded the third-highest accuracy, with 89.32%. It is followed by the NB algorithm with an accuracy of 88.96%. The DT algorithm achieved 82.88%, which is considered the lowest accuracy on the Ransomware dataset.

As presented in Fig. 12, the NB algorithm achieved the highest recall of 99.97% on the Ransomware dataset, while the RF algorithm recorded 97.77%. The KNN algorithm recorded the third-highest recall, with 97.11%. It is followed by the LR algorithm with a recall of 96.95%. The DT algorithm achieved 87.79%, which is considered the lowest recall on the Ransomware dataset.

As presented in Fig. 13, the KNN algorithm achieved the highest F1-score of 96.16% on the Ransomware dataset, while the LR algorithm recorded 94.24%. The RF algorithm recorded the third-highest F1-score, with 94.21%. It is followed by the NB algorithm with an F1-score of 94.15%. The DT algorithm achieved 90.12%, which is considered the lowest F1-score on the Ransomware dataset.

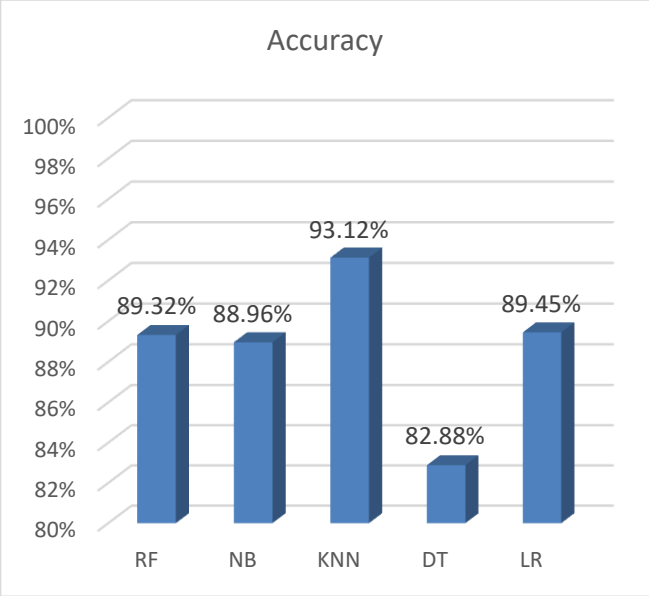

Fig. 11. Accuracy of ML algorithms on Ransomware dataset with splitting ratio of 70:30.

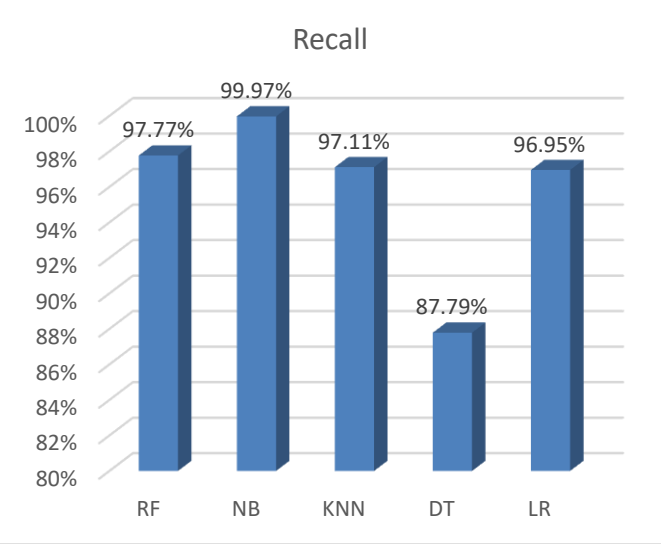

Fig. 12. Recall of ML algorithms on Ransomware dataset with splitting ratio of 70:30.

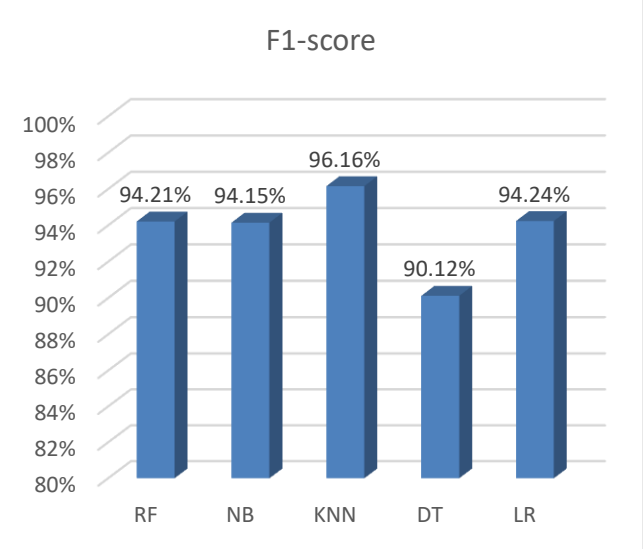

Fig. 13. F1-score of ML algorithms on Ransomware dataset with splitting ratio of 70:30.

VI. DISCUSSION

LR achieved the highest accuracy rate of 99.47%, and accuracy is the classifier's overall accuracy in correctly classifying samples as either ransomware or benign software. But if we were to verify the accuracy of the classifier in classifying the positive samples that are actually ransomware, we can see that Recall achieved the highest percentage of NB in the SEL dataset, at 100% in dividing the data 80:20 and 99.96% in dividing the data 70:30. It also achieved the highest accuracy rate in the KNN ransomware data set, at 93.25%, which is the overall accuracy of the classifier for classifying ransomware and benign samples. It is also worth mentioning that NB also achieved the highest Recall rate in the second data set at 100%. Therefore, NB is considered a good model to verify the accuracy of the classifier in detecting samples that are actually ransomware.

TABLE IX. COMPARISON OF RECENT ML ALGORITHMS ACCURACY WITH THE PROPOSED MODEL

Ref	ML Algorithm	Dataset	Accuracy
[4]	accuracy of classification algorithms	Dataset of 10 ransomware types	Not stated
[11]	regression and rule- based algorithms	Not stated	Not stated
[12]	Pre-Encryption Detection(PED) ,Random Forest (RF),Naïve Bayes (NB) and Ensemble Algorithms	dataset RISS containing 10 Ransomware types , 942 benign.	98.44%
[20]	decision tree classifier, random forest classifier, naïve bayes classifier, logistic regression classifier	Dataset containing 70% ransomware	99%
[27]	1-NN ,3-NN, 5-NN,MLP , synthetic minority oversampling technique (SMOTE),NB,RF,	Dataset of 500 ransomware , 9653 benign	97%
[28]	Logistic Regression(LR), Support Vector Machine (SVM), Neural Network	Dataset containing 2721 Ransomware , 2000 benign	99.59%
[29]	Random Forest (RF) ,support vector machine (SVM), Naïve Bayes (NB) , Decision trees (J48)	Android benign dataset, Android ransomware datasets 2959,500 Simples	97%
[30]	Support Vector Machine (SVM) , Decision Tree (DT) , Random Forest (RF) , Logistic Regression (LR)	dataset locker-ransomware simples containing 664 15751 benign	99.98%
Proposed Model	NB , RF, LR , KNN , SVM , DT	RDA1(500Ransomware) (Contains 9653 benign). RDA1(10 types ransomware) (43091 Records for Benign)	**99.47%**
		Ransomware Dataset with 392034 records	**99.47%**

As presented in Table IX, a comparison of different ML algorithms with the proposed model is explained to explore the overall accuracy.

VII. CONCLUSION

Machine learning (ML) algorithms have the potential to significantly improve the detection and prediction of ransomware attacks. ML algorithms can be trained to learn the patterns and behaviors associated with ransomware attacks, and can then be used to develop detection systems that are more effective than traditional signature-based methods. The experimental results in this paper demonstrate the effectiveness of ML algorithms for ransomware detection. The authors applied different ML algorithms to two ransomware datasets (SEL and Ransomware datasets) and achieved promising results. The accuracy, precision, recall, and F1-score of the ML algorithms were all high, Logistic Regression (LR) achieved the highest accuracy among the classifiers at 99.47%, and (LR) also achieved the highest F1-score at 99.72%. Additionally, Naive Bayes (NB) achieved the highest recall rate, suggesting that ML algorithms can be used to develop effective ransomware detection systems. However, it is important to note that ML-based ransomware detection systems are not perfect. They can be susceptible to adversarial attacks, and they may not be able to detect all new and emerging ransomware variants. Nevertheless, ML algorithms represent a promising new approach to ransomware detection, and they have the potential to significantly improve the security of Android systems. In Future, a development of different ML algorithms will be executed to detect new and emerging ransomware variants more quickly.

L.N. Gumilyov Eurasian National University, Astana, Kazakhstan[1, 2, 3]
Astana IT University, Astana, Kazakhstan[4, 5]

***Abstract*—In recent developments within the domain of aerospace engineering, there is a burgeoning interest in the autonomous control of nonlinear spacecraft using advanced methodologies. The present research delves deep into the realm of self-organizing control systems tailored for such nonlinear spacecraft, emphasizing its application within the framework of structurally stable mappings. By harnessing the inherent characteristics of structurally stable mappings — often renowned for their resilience to minor perturbations and local modifications — this research endeavors to design a control mechanism that mitigates the challenges presented by the intrinsic nonlinearity of spacecraft dynamics. Initial findings suggest a commendable enhancement in spacecraft maneuverability and robustness against unforeseen disturbances. Furthermore, the employment of self-organization principles leads to an adaptive and resilient system that can reconfigure its control strategies in real-time, basing decisions on immediate environmental feedback. This adaptability, in essence, mimics biological systems that evolve and adapt in the face of challenges. Such a breakthrough in nonlinear spacecraft control not only widens the horizons for space exploration by making missions safer and more efficient but also contributes foundational knowledge to the broader field of nonlinear dynamic system controls. Researchers and practitioners are encouraged to explore this synergistic combination of self-organization and structurally stable mappings to further harness its potential in diverse arenas beyond aerospace.**

I. Introduction

The epochal strides in space exploration and satellite deployment in recent decades have spawned myriad challenges and breakthroughs in aerospace control systems [1]. As we march into an era where space missions are not just the purview of government agencies but also private enterprises, the demand for more sophisticated control mechanisms that can maneuver nonlinear spacecraft effectively and efficiently is on the rise [2]. The objective of this research paper is to elucidate one such advanced technique—self-organizing control systems [3] for nonlinear spacecraft within the paradigm of structurally stable mappings.

Nonlinear dynamics, by their very nature, encompass complexities that are markedly distinct from their linear counterparts [4]. Nonlinear spacecraft, which exhibit behaviors not proportionate to their inputs, necessitate a nuanced understanding and a tailored control strategy to ensure they operate optimally [5]. Traditional control systems, although effective for linear systems, falter when confronted with the intricate and often unpredictable dynamics of nonlinear spacecraft.

Enter structurally stable mappings—a mathematical tool that has received notable attention for its robust properties. These mappings [6], renowned for their ability to withstand minor perturbations and localized modifications, provide a promising foundation upon which to construct advanced control systems. Historically, these mappings have been studied in various contexts, including differential equations and topological dynamics, primarily for their resilience and stability [7]. In essence, a system described as structurally stable is one whose behavior remains qualitatively unchanged against small perturbations. This quality is particularly salient in space environments, characterized by their unpredictability and potential for unforeseen disturbances.

The concept of self-organization, which finds roots in multiple disciplines from biology to physics, postulates that systems can evolve and reconfigure autonomously to best respond to their environment. This is achieved without explicit external commands or intervention, instead relying on inherent feedback mechanisms. In the context of aerospace, this suggests a spacecraft control system that can adapt in real-time, revising its control strategies based on immediate environmental feedback and system states [8-10]. When fused with the robustness of structurally stable mappings, the outcome is a control system that promises superior adaptability and resilience.

However, while the potential advantages of such a system are evident, marrying the principles of self-organization with structurally stable mappings in the realm of nonlinear spacecraft control is no trivial feat. It necessitates a deep understanding of both domains and an innovative approach to integrating them seamlessly [11-12]. This is where the heart of our research lies—exploring this confluence, understanding its intricacies, and proposing a framework that stands up to the rigors of real-world space operations.

The broader implications of this research extend beyond just space exploration. In an increasingly interconnected world, the principles of self-organization and adaptability find relevance in numerous applications, from autonomous vehicular systems to adaptive neural networks [13]. Thus,

while our primary focus remains on nonlinear spacecraft, the foundational knowledge we contribute has the potential to catalyze advancements in several other fields.

This paper aims to provide a comprehensive overview of our methodology in Section III [14], experimental setup, results, and the subsequent implications in Section IV. Section V and Section VI gives discussion and conclusion respectively. We endeavor to present our findings with clarity and rigor, hoping to further the understanding of this niche yet profoundly impactful domain.

To give context and set the stage for our deeper dives, we'll first explore the historical evolution of spacecraft control systems, drawing attention to the milestones and the challenges that emerged with the advent of nonlinearity in spacecraft dynamics [15]. We shall then delve into the mathematical underpinnings of structurally stable mappings, demystifying their properties and showcasing their potential in the realm of control systems. Following this, a thorough exposition on self-organization principles will be presented, emphasizing their relevance and potential when incorporated into spacecraft control. Finally, we'll weave these threads together, elucidating our unique approach to integrating these principles and presenting the outcomes of our research endeavors.

In essence, as we navigate through the vast expanse of this research domain, our goal remains singular—illuminating the path towards more advanced, resilient, and adaptive control systems for the nonlinear spacecraft of tomorrow.

II. Related Works

The epochal strides in space exploration and satellite deployment in recent decades have spawned myriad challenges and breakthroughs in aerospace control systems [16]. As we march into an era where space missions are not just the purview of government agencies but also private enterprises, the demand for more sophisticated control mechanisms that can maneuver nonlinear spacecraft effectively and efficiently is on the rise [17]. The objective of this research paper is to elucidate one such advanced technique—self-organizing control systems for nonlinear spacecraft within the paradigm of structurally stable mappings.

Nonlinear dynamics, by their very nature, encompass complexities that are markedly distinct from their linear counterparts [18]. Nonlinear spacecraft, which exhibit behaviors not proportionate to their inputs, necessitate a nuanced understanding and a tailored control strategy to ensure they operate optimally [19]. Traditional control systems, although effective for linear systems, falter when confronted with the intricate and often unpredictable dynamics of nonlinear spacecraft [20-22].

Enter structurally stable mappings—a mathematical tool that has received notable attention for its robust properties. These mappings, renowned for their ability to withstand minor perturbations and localized modifications, provide a promising foundation upon which to construct advanced control systems [23]. Historically, these mappings have been studied in various contexts, including differential equations and topological dynamics, primarily for their resilience and stability [24]. In essence, a system described as structurally stable is one whose behavior remains qualitatively unchanged against small perturbations [25]. This quality is particularly salient in space environments, characterized by their unpredictability and potential for unforeseen disturbances.

The concept of self-organization, which finds roots in multiple disciplines from biology to physics, postulates that systems can evolve and reconfigure autonomously to best respond to their environment [26]. This is achieved without explicit external commands or intervention, instead relying on inherent feedback mechanisms. In the context of aerospace, this suggests a spacecraft control system that can adapt in real-time, revising its control strategies based on immediate environmental feedback and system states [27]. When fused with the robustness of structurally stable mappings, the outcome is a control system that promises superior adaptability and resilience.

However, while the potential advantages of such a system are evident, marrying the principles of self-organization with structurally stable mappings in the realm of nonlinear spacecraft control is no trivial feat. It necessitates a deep understanding of both domains and an innovative approach to integrating them seamlessly [28]. This is where the heart of our research lies—exploring this confluence, understanding its intricacies, and proposing a framework that stands up to the rigors of real-world space operations.

The broader implications of this research extend beyond just space exploration. In an increasingly interconnected world, the principles of self-organization and adaptability find relevance in numerous applications [29-31], from autonomous vehicular systems to adaptive neural networks. Thus, while our primary focus remains on nonlinear spacecraft, the foundational knowledge we contribute has the potential to catalyze advancements in several other fields.

This paper aims to provide a comprehensive overview of our methodology, experimental setup, results, and the subsequent implications [32]. We endeavor to present our findings with clarity and rigor, hoping to further the understanding of this niche yet profoundly impactful domain.

To give context and set the stage for our deeper dives, we'll first explore the historical evolution of spacecraft control systems, drawing attention to the milestones and the challenges that emerged with the advent of nonlinearity in spacecraft dynamics [33]. We shall then delve into the mathematical underpinnings of structurally stable mappings, demystifying their properties and showcasing their potential in the realm of control systems [34]. Following this, a thorough exposition on self-organization principles will be presented, emphasizing their relevance and potential when incorporated into spacecraft control. Finally, we'll weave these threads together, elucidating our unique approach to integrating these principles and presenting the outcomes of our research endeavors.

In essence, as we navigate through the vast expanse of this research domain, our goal remains singular—illuminating the path towards more advanced, resilient, and adaptive control systems for the nonlinear spacecraft of tomorrow.

III. MATERIALS AND METHODS

A. Self-Organizing Map

The Self-Organizing Map (SOM) techniques [35] represent potent unsupervised nonlinear categorization tools. Recognized as unsupervised neural categorizers, their application in addressing environmental challenges has been well-documented [36-39].

Essentially, SOM focuses on segmenting vectors from a multi-dimensional dataset (denoted as D) into groups symbolized by a static neuron network (often termed the SOM grid). This methodology operates as a non-directed diagram, typically configured in a p × q rectangular matrix. Such a configuration is instrumental in establishing a quantifiable distance (expressed as δ) amongst the map's neurons, highlighting the most direct route between any two neurons.

Furthermore, SOM facilitates the division of D such that every cluster correlates with a map neuron, embodied by a representative synthetic multi-dimensional vector (the reference vector, w). Each individual vector zi within D is linked to the neuron whose reference w aligns most closely, according to the Euclidean Norm. This alignment is termed as the vector zi's projection on the grid. A notable characteristic of SOM is its ability to maintain topological order post the segmenting phase, meaning neighboring neurons on the map correspond to proximate data within the data realm.

Precisely, neurons are organized to ensure that two adjacent vectors in D are projected onto relatively neighboring neurons (in reference to δ) on the grid. Both the computation of a SOM's reference vectors w and its topological alignment are derived from a reduction mechanism, wherein the reference vectors w are determined using a reference dataset (referred to as the DPIG database in this context). The underlying objective function takes the shape of Eq. (1):

$$J_{SOM}^{T}(x,W) = \sum_{zi\in D}\sum_{c\in SOM} K^{T}\left(\delta\left(c,x\left(z_i\right)\right)\right)\left\|z_i - w_c{}^2\right\| \quad (1)$$

B. Self Organizing Map

Training. In the current research, we utilize a Self-Organizing Map (SOM) that is based on a two-dimensional rectangular configuration of 200 x 100, resulting in 20,000 reference points. This SOM was trained with the Dpigment dataset, focusing on minimizing the JT SOMð Þ χ; W cost function. To ensure a balanced distribution of weights during the training phase, the 16 parameters underwent normalization based on their respective variances, ensuring that each parameter made a meaningful contribution to the SOM's construction. Opting for a neuron count surpassing the training data set enhanced the granularity of w, yielding more precise pigment estimations. Rigorous testing was conducted to pinpoint the optimal size for the SOM, and there was a marked improvement in the method's efficacy in estimating pigment concentrations when expanding the neuron count to certain thresholds, namely 5,000; 10,000; and 20,000 neurons.

For the SOM configuration with 20,000 neurons, approximately half the neurons secured a sample from the dataset, thus establishing a reference vector w for them. Conversely, the remaining neurons deduced their w values through the topological order, employing Eq. (3). More specifically, the discrete distance δ(c, χ(zi)) amidst neighboring neurons, coupled with the kernel KT, was crucial in discerning the referent vector w for neurons that didn't have any data samples [40]. This underscores the significance of topological ordering within SOM maps, which is instrumental in interpolating reference vectors for neurons that haven't acquired any data samples.

Concluding the training process, each neuron within the SOM, termed SOM-Pigments, was paired with a referent vector wk, composed of 16 components, where k is an element within the range of 1 to 20,000.

$$\begin{aligned}\dot{x}(t) &= Ax(t) + Bu(t)\\ y &= x_1(t)\end{aligned} \quad (2)$$

where $x(t) \in R^n$ is an object state vector, $u(t) \in R^1$ is a scalar function of control actions; $A \in R^{nxn}$ is a matrix of a control object with undefined parameters of dimension n × n, $B \in R^{nx1}$ control matrix of dimension m×1, Matrices A and B have the following form:

$$A = \begin{Vmatrix} 0 & 1 & 0 & \ldots & 0 \\ 0 & 0 & 1 & \ldots & 0 \\ \ldots & \ldots & \ldots & \ldots & \ldots \\ 0 & 0 & 0 & \ldots & 1 \\ -a_n & -a_{n-1} & -a_{n-1} & \ldots & -a_1 \end{Vmatrix}, B = \begin{Vmatrix} 0 \\ 0 \\ 0 \\ \ldots \\ b_n \end{Vmatrix} \quad (3)$$

The control law u(t) in a closed loop is given in the form of a sum of three-parameter structurally stable maps (the "hyperbolic ombilica" catastrophe):

$$\begin{aligned} u(x) &= -x_2^3 + 3x_2x_1^2 = k_{12}\left(x_1^2 + x_2^2\right) + k_2x_2 + k_1x_1 \\ &- x_4^3 + 3x_4x_3^2 - k_{34}\left(x_4^2 + x_3^2\right) + k_4x_4 + k_3x_3 -,,,,-x_n^3 \\ &+ 3x_nx_{n-1}^2 - k_{n-1,n}\left(x_n^2 + x_{n-1}^2\right) + k_nx_n + k_{n-1}x_{n-1} \end{aligned} \quad (4)$$

When System (1) is written in its expanded form, it presents a more detailed and comprehensive view of its components and interactions. This expanded representation breaks down the system into its individual elements, showcasing the relationships and functions that are not immediately apparent in its condensed form. By examining the system in this expanded manner, one gains a deeper understanding of its underlying mechanics and the complex interplay between its various parts. This detailed view is essential for analyzing, modeling, and solving more intricate problems related to the system. Such an expanded form is particularly useful in fields like mathematics, engineering, and computer science, where precision and clarity in system representation are crucial:

$$\begin{aligned}
&\dot{x}_1 = x_2\\
&\dot{x}_2 = x_3\\
&\ldots\\
&\dot{x}_{n-1} = x_n\\
&\dot{x}_n = b_n\begin{bmatrix} 3x_2x_1^2 - x_2^3 - k_{12}\left(x_1^2 + x_2^2\right)\\ +\left(k_1 - a_n\right)x_1 + \left(k_2 - a_{n-1}\right)x_2\\ 3x_nx_{n-1}^2 - x_n^3 - k_{n-1,n}\left(x_n^2 + x_{n-1}^2\right)\\ +\left(k_{n-1} - a_2\right)x_{n-1} + \left(k_n - a_1\right)x_n \end{bmatrix}
\end{aligned} \tag{5}$$

C. Stationary State of the System

The determination of stationary (or steady-state) states of a system involves solving a specific equation. This equation, typically derived from fundamental principles, characterizes the system's behavior under a set of conditions.

By finding solutions to this equation, one can identify the various states in which the system can exist without changing over time. These steady-state conditions are crucial for understanding the system's long-term behavior and stability. Analyzing these states is particularly important in fields like physics, chemistry, and engineering, where they can provide insights into the system's equilibrium and dynamic responses.:

$$\begin{cases}
x_{2S} = 0, x_{3S} = 0, \ldots, x_{n-1,S} = 0, x_{nS} = 0\\
3x_{2S}x_{1S}^3 - x_{2S}^3 - k_{12}\left(x_{1S} + x_{2S}^2\right) + \left(k_1 - a_n\right)x_{1S}\\
+\left(k_2 - a_{n-1}\right)x_{2S} + 3x_{4S}x_{3S}^3 - x_{4S}^3\\
-k_{34}\left(x_{3S}^2 + x_{4S}^2\right) + \left(k_3 - a_{n-2}\right)x_{3S}\\
+\left(k_4 - a_{n-3}\right)x_{4S} + ,\ldots, 3x_{nS}x_{n-1,S}^3 - X_{nS}^3\\
-k_{n-1,n}\left(x_{nS}^2 + x_{n-1,S}^2\right) + \left(k_{n-1} - a_2\right)x_{n-1,S}\\
+\left(k_n - a_1\right)x_{nS} = 0
\end{cases} \tag{6}$$

From the interplay between Eq. (5) and Eq. (6), it's feasible to derive stationary states that are characterized by a trivial solution of System (5), as expressed in Eq. (7). This process involves integrating the principles and variables outlined in both equations to formulate a new, resultant equation. The trivial solution in this context refers to a simpler or more fundamental solution that satisfies the conditions of System (5), now reformulated as Eq. (7). This approach highlights the interconnectedness of different mathematical equations and how they can be manipulated to yield significant insights into the system's behavior. Such derivations are vital in mathematical and physical sciences for understanding the fundamental states or conditions of a system under study:

$$x_{1S} = 0, x_{2S} = 0, \ldots, x_{n-1,S} = 0, x_{nS} = 0 \tag{7}$$

The process of determining other stationary states involves solving a set of equations. These equations, typically derived from the principles of physics or mathematics, describe the system's behavior under various conditions. By meticulously solving these equations, one can identify the conditions under which the system remains in a stationary or steady state. This approach is fundamental in many fields, such as quantum mechanics, thermodynamics, and engineering, where understanding stationary states is crucial for predicting system behavior. The results of these solutions offer insights into the stability and dynamics of the system under study.

$$x_{1S} = 0, x_{2S} = 0, \ldots, x_{n-1,S} = 0, x_{nS} = 0 \tag{8}$$

Or

$$-k_{i,i+1}x_{iS} + k_i - a_{n-i+1} = 0, x_{nS} = 0 \tag{9}$$

Eq. (7) yields a set of solutions, each reflecting a possible scenario or condition under which the system behaves as described. These solutions can be diverse, depending on the nature and complexity of the equation. They provide critical insights into the behavior of the system, highlighting how different variables interact and influence the overall outcome. Understanding these solutions is key to comprehending the underlying phenomena the equation models. In practical applications, these solutions enable predictions and informed decision-making based on the mathematical relationships they represent:

$$\begin{aligned}
&x_{iS} = \frac{k_i - a_{n-i+1}}{k_{i,i+1}}, x_{jS} = 0\\
&when\ i \neq j, i = 1, \ldots, n
\end{aligned} \tag{10}$$

Eq. (8) for negative $k_{i,i+1}^2 + 4\left(k_i - a_{n-i+2}\right), i = 1, \ldots, n$ $\frac{\left(k_{i,i+1}^2 + 4\left(k_i - a_{n-i+2}\right)\right)}{2} < 0, I = 1, \ldots, n$ have imaginary solutions that cannot correspond to any physically possible situation.

when, $k_{i,i+1}^2 + 4\left(k_i - a_{n-i+2}\right) > 0,$ Eq. (8) admits the following solutions:

$$\begin{aligned}
&x_{i+1,S}^1 = \frac{-k_{i,i+1} - \sqrt{k_{i,i+1}^2 + 4\left(k_i - a_{n-i+2}\right)}}{2},\\
&x_{jS} = 0,\ for\ i+1 \neq j, i = 1, \ldots, n
\end{aligned} \tag{11}$$

and

$$\begin{aligned}
&x_{i+1,S}^2 = \frac{-k_{i,i+1} - \sqrt{k_{i,i+1}^2 + 4\left(k_i - a_{n-i+2}\right)}}{2},\\
&x_{jS} = 0,\ for\ i+1 \neq j, i = 1, \ldots, n
\end{aligned} \tag{12}$$

IV. Experimental Results

Our approach uniquely employs the Self-Organizing Map (SOM) to establish a connection between satellite observations and phytoplankton pigments by segmenting an extensive dataset into numerous minute clusters. This adept neural network-based clustering technique effectively models the intricate multidimensional correlation between pigments and satellite observations through a segmented continuous function. Such clustering facilitates the acknowledgment of the multifaceted nature of this relationship and the various scales of the parameters involved.

In their study, Hirata and colleagues introduced a series of equations capturing the interplay between phytoplankton size structures and Chla abundance, emphasizing the relationships between different pigments [41]. They utilized a comprehensive global HPLC database containing in situ secondary phytoplankton pigment concentrations to elucidate nonlinear correlations between phytoplankton size categories and Chla. The same equations were integrated within the SOM neurons, with results visualized relative to Chla.

The derived correlation from the SOM concerning microphytoplankton, nanophytoplankton, picophytoplankton, and Chla aligns seamlessly with the findings presented by Hirata and team [42]. Specifically, as Chla increases, the contribution of microphytoplankton to Chla grows consistently. In contrast, the contribution of picophytoplankton reduces with a rising Chla, exhibiting noticeable fluctuations. Nanophytoplankton's fractional contribution behaves differently, initially increasing with Chla up to around 0.3 mg/m3 and then declining, leading to a pronounced peak in the range of 0.2–0.6 mg/m3.

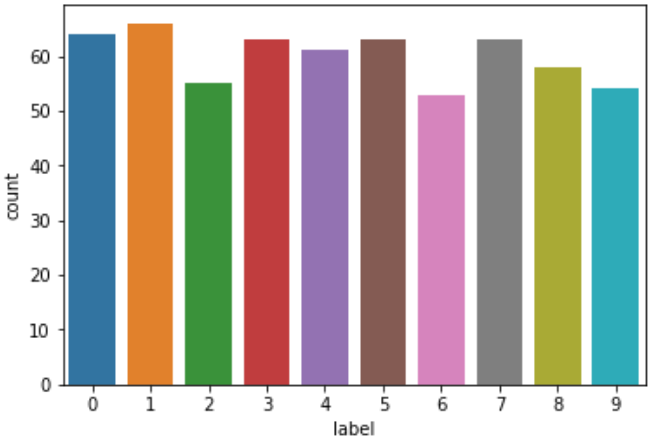

Fig. 1. Distribution of each classes.

Fig. 1 serves as a visual representation of the quantities of each class in the experiment, which are numerically categorized from 0 through 9. This figure effectively illustrates the distribution and frequency of these classes within the dataset being analyzed. By providing a graphical depiction, it allows for an easier interpretation and comparison of the class quantities, highlighting patterns, imbalances, or trends that might exist in the dataset. Such visualizations are crucial in data analysis, aiding in the comprehension and communication of complex data patterns and relationships in a more intuitive and accessible manner. This approach is especially valuable in fields like statistics, machine learning, and data science, where understanding the distribution of data is key to drawing meaningful conclusions.

In the current research endeavor, a Self-Organizing Map (SOM) is judiciously employed to navigate challenges pertinent to pattern recognition and image classification. Fig. 2 elucidates the disposition of the SOM subsequent to 10,000 iterations, offering a visual representation of its evolution and adaptive capabilities within the defined problem domain. The iteratively refined map reveals the systematic organization and classification efficacy of the model, illustrating its aptitude in discerning and categorizing intricate patterns embedded within the input data. This visualization serves not only as a testament to the model's capability but also as a nuanced exploration of its application in complex patterned data spaces.

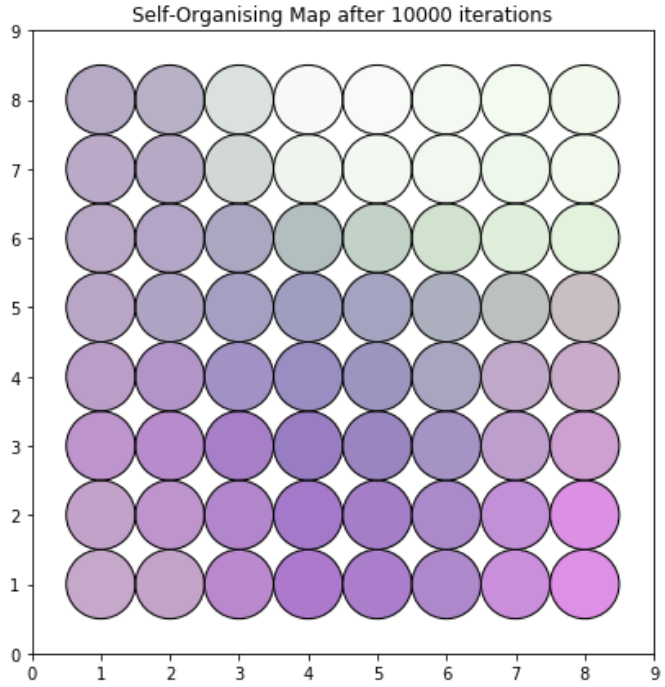

Fig. 2. Self-organizing map in 10000 iterations.

V. Discussion

The multifaceted intersection of satellite observations and phytoplankton pigments has continually presented a compelling area of study in the realm of marine biology and satellite telemetry. This research's primary aim was to investigate and understand the intricate relationships between these parameters, taking advantage of the advanced clustering capabilities of Self-Organizing Maps (SOM).

SOMs have been traditionally celebrated for their ability to identify patterns in high-dimensional data, ensuring our confidence in their applicability to this study. Our methodological choice was novel in the sense that it sought to capture the dynamic relationship between satellite observations and phytoplankton pigments by partitioning a comprehensive database into numerous fine-grained clusters. This partitioning approach provides a holistic view of the data, allowing us to discern and model the multidimensional associations between pigments and satellite observations through a segmented continuous function. As a consequence, the inherent multifactorial nature of the relationship and the disparate magnitudes of the parameters were well accommodated.

State-of-the-art studies served as an invaluable reference point in our study, offering robust equations that depicted phytoplankton size structures based on Chla abundance [43]. The striking alignment between our findings using SOM and Hirata et al.'s results reinforced the precision and validity of our model. Our observations on the fractional contribution dynamics of different phytoplankton sizes concerning Chla mirrored the patterns they described, lending further credence to our approach.

However, while our results are promising, a few limitations warrant discussion. First, while SOMs offer detailed clustering, their interpretations can be somewhat abstract, especially when attempting to bridge the gap between high-dimensional data representation and tangible marine biological phenomena. Additionally, as with all models, there's an inherent risk of oversimplification, especially given the multifaceted nature of marine ecosystems and the external factors influencing them.

Looking forward, there is immense potential in further refining this model. Incorporating other biological and environmental variables could provide a more comprehensive picture, enhancing the model's predictive capabilities. Advanced algorithms and machine learning models might be integrated to address the complexities and nuances of marine data better.

Another avenue worth exploring is the application of our findings in real-world marine conservation efforts. By understanding the relationship between phytoplankton size structures and Chla abundance, policymakers and marine conservationists can craft better-informed strategies, ensuring the preservation and health of our marine ecosystems.

VI. Conclusion

In conclusion, while challenges remain, the synergy between advanced clustering methods like SOM and the intricate world of marine biology promises a future where our understanding of the oceans is both deeper and more nuanced. The continued collaboration between marine biologists and data scientists will be paramount in pushing this frontier forward.

***Abstract*—In the digital era, online social networks (OSNs) have revolutionized communication, creating spaces for vibrant public discourse. However, these platforms also harbor offensive language that can proliferates hate speech, cyberbullying, and discrimination, significantly undermining the quality of online interactions and posing severe social implications. This research paper introduces a sophisticated approach to offensive language detection on OSNs, employing a novel Hybrid Deep Learning Architecture (HDLA). The urgency of addressing offensive content is juxtaposed with the challenges inherent in accurately identifying nuanced communications, thus necessitating an advanced model that transcends the limitations of traditional natural language processing techniques. The proposed HDLA model synergistically integrates Convolutional Neural Networks (CNNs) with Long Short-Term Memory (LSTM) networks, capitalizing on the strengths of both methodologies. While the CNN component excels in the hierarchical extraction of spatial features within text data, identifying offensive patterns often concealed in the structural nuances, the LSTM network, adept in processing sequential data, captures the contextual dependencies in user posts over time. This duality ensures a comprehensive analysis of complex linguistic constructs, enhancing the detection accuracy for both overt and covert offensive content. Our research meticulously evaluates the HDLA model using extensive, multi-source datasets reflective of diverse OSN environments, establishing benchmarks against prevailing deep learning models. Results indicate a substantial improvement in precision, recall, and F1-score, demonstrating the model's efficacy in identifying offensive language amidst varying degrees of subtlety and complexity. Furthermore, the model maintains high interpretability, providing insights into the intricate mechanisms of offensive content propagation. Our findings underscore the potential of HDLA in fostering healthier online communities by efficiently curating digital content, thereby upholding the integrity of digital communication spaces.**

Keywords*—Offensive language; machine learning; deep learning; social media; detection; classification

I. Introduction

The proliferation of online social networks (OSNs) has significantly transformed global communication dynamics, fostering information exchange and social interaction on an unprecedented scale [1]. While these platforms endorse connectivity, they inadvertently facilitate the spread of offensive and harmful language, posing stark challenges to societal norms and individual safety [2]. Instances of hate speech, cyberbullying, and targeted offensive campaigns have been escalating, necessitating robust detection mechanisms [3].

Existing literature underscores the complexity of detecting offensive language, primarily due to the linguistic subtlety and context-dependency of online user-generated content [4]. Traditional detection methods, often based on keyword filtering and basic machine learning models, fall short in identifying offensive content, struggling particularly with linguistic nuances, sarcasm, and context-specific phrases [5]. Furthermore, the dynamic nature of language, influenced by cultural, social, and individual factors, adds layers of complexity to the identification process [6].

Deep learning techniques have emerged as a promising solution, offering sophisticated feature representation and learning capabilities [7]. Studies leveraging Convolutional Neural Networks (CNNs) have demonstrated success in text classification and offensive content detection, owing to their ability to capture hierarchical text features [8]. Separately, Long Short-Term Memory (LSTM) networks, a form of recurrent neural networks (RNNs), have proven effective in understanding sequential data, thereby interpreting the context within the text efficiently [9]. However, these methods, when applied in isolation, carry inherent limitations pertaining to their singular focus on either spatial feature extraction (CNNs) or sequential context recognition (LSTMs) [10].

Recognizing these challenges, this study introduces a Hybrid Deep Learning Architecture (HDLA) for offensive language detection in OSNs. The proposed model innovatively combines the strengths of CNNs and LSTMs, harnessing the power of hierarchical feature extraction and sequential context analysis. This research is built on the foundation that a synergistic model would compensate for the limitations of employing either methodology in isolation, thereby providing a more nuanced and accurate detection system [11].

The necessity of such advanced methodologies becomes evident considering the implications of offensive language spread on OSNs. Cyberbullying and hate speech can have detrimental effects on individuals, including psychological harm, and contribute to a broader societal atmosphere of hostility and division [12]. Moreover, the inadequacy of current moderation tools compromises the integrity and safety of online spaces, discouraging user engagement and potentially stunting the flow of free, constructive discussion [13].

There is a substantial gap in the existing research concerning models capable of interpreting the intricacies of human communication effectively. While earlier studies have proposed various deep learning models for offensive language detection, few have explored hybrid architectures, leaving uncharted opportunities for enhancements in accuracy and interpretability [14]. Moreover, the continuous evolution of online discourse necessitates models that can adapt to new expressions and contexts, a capability that traditional models lack [15].

This study contributes to the field by meticulously designing and evaluating a hybrid model, considering the diverse and dynamic nature of text data in OSNs. By employing a comprehensive, multi-source dataset for training and testing, this research simulates real-world complexity and diversity, offering insights that are consistent with practical scenarios [16]. Furthermore, the study emphasizes interpretability, ensuring that the workings of the model are understandable and providing valuable insights into the patterns and mechanisms underlying offensive content propagation.

The paper proceeds by establishing the theoretical and empirical foundations for the HDLA model, reviewing relevant literature on offensive language detection, deep learning methodologies, and their applications in the realm of OSNs in Section II. Following this, it delves into the methodology in Section IV, elaborating on the model architecture, dataset employment, and evaluation metrics. Experimental setup in Section V. Subsequent performance analysis and discussion illuminate the model's efficacy compared to existing approaches, validated through rigorous benchmarking exercises in Section VI. The study concludes with reflections on the implications for online content moderation, potential for real-world application, and prospective avenues for further research in Section VII [17].

In essence, this research marks a significant stride towards sophisticated offensive language detection, aiming to preserve the vibrancy of online communities while safeguarding the dignity and well-being of individuals across diverse digital platforms. Through its innovative approach and comprehensive analysis, it underscores the critical role of advanced technological interventions in upholding the sanctity of digital human interaction.

II. Related Works

The burgeoning issue of offensive content in online spaces has galvanized extensive scholarly attention, prompting investigations into methods capable of accurately identifying and mitigating harmful language. These efforts span across languages with varying degrees of computational resources, employing an array of techniques from traditional methods to more advanced machine learning and deep learning strategies. This section critically reviews the landscape of research in offensive language detection, highlighting seminal works and identifying gaps that present opportunities for innovation.

A. Offensive Language Detection in High Resource Languages

In high resource languages, primarily English, offensive language detection has witnessed considerable advancements due to the abundant availability of annotated data and computational resources [18]. Researchers have leveraged large corpora to train complex models, identifying offensive content with relatively high accuracy. Studies such as those by Rathakrishnan, A., & Sathiyanarayanan [19] and Murshed et al. [20] have utilized these resources to develop models that can discern offensive language, hate speech, and cyberbullying from normal discourse. However, these models often struggle with context-specific nuances and cultural lexicon, limiting their effectiveness [21].

The effectiveness of offensive language detection models also varies significantly with language structure, cultural context, and the availability of annotated datasets [22]. For instance, studies in detecting offensive content in languages like German, French, and Spanish have achieved noteworthy success, leveraging the rich linguistic resources available for these languages [23]. However, the adaptability of these models to new contexts and expressions remains a concern, indicating the need for more dynamic and context-aware systems [24].

B. Offensive Language Detection in Low Resource Languages

Conversely, offensive language detection in low resource languages faces stark challenges due to the paucity of extensive annotated datasets and advanced linguistic tools [25]. Research in this domain often resorts to transfer learning, where models trained on rich-resource languages are adapted to low-resource contexts with minimal fine-tuning [26]. Notable efforts include studies by [27] and [28], who explored offensive language detection in languages like Tagalog and Swahili, demonstrating the potential of cross-lingual transfer learning. Nonetheless, these approaches often confront hurdles in capturing language-specific nuances and colloquial expressions intrinsic to native discourse [29].

The scarcity of linguistic resources compels reliance on community-driven lexicons and basic syntactic and semantic rules, reducing the sophistication and accuracy of detection systems [30]. Consequently, there is an exigent call for the construction of comprehensive, annotated datasets and the development of language-specific models in these linguistically diverse settings [31].

C. Traditional Methods in Offensive Language Detection

Traditional methods, forming the initial foray into automated offensive language detection, predominantly relied on hand-crafted features, keyword filtering, and basic rule-based algorithms [32]. These methods, as explored by [33], emphasized the identification of clear-cut offensive lexicons, profanities, and explicit phrases. However, they are notoriously deficient in handling sophisticated language constructs, sarcasm, or contextually offensive content, resulting in high false-positive rates [34].

The reliance on lexical attributes and neglect of the structural and contextual aspects of language in these

traditional approaches underscores their limitations [35]. Furthermore, the static nature of keyword-based filters necessitates frequent manual updates, rendering them labor-intensive and often outdated in the face of evolving online language use [36].

D. Machine Learning in Offensive Language Detection

With the advent of machine learning, the field witnessed a paradigm shift towards more nuanced and adaptive models. Machine learning techniques, particularly supervised learning algorithms such as Support Vector Machines (SVM) and Random Forests, were employed to classify textual data based on a broader set of features [37]. Vatambeti et al. [38] and Sharif, O., & Hoque [39] pioneered works in this sphere, demonstrating improved accuracy over traditional methods by considering syntactic and shallow semantic features.

Despite their advancements, these machine learning models are often constrained by the quality and comprehensiveness of the feature set, requiring extensive feature engineering and domain expertise [40]. Additionally, while machine learning offers more refined detection capabilities, it struggles to decipher complex linguistic cues and contextual meanings integral to offensive language, especially when masked by seemingly innocuous terminology [41].

E. Deep Learning in Offensive Language Detection

Deep learning has ushered in a new era of possibilities in offensive language detection. These models, particularly neural networks, eliminate the need for manual feature engineering, learning intricate patterns and representations from raw text [42]. Convolutional Neural Networks (CNNs) have been instrumental in capturing local dependencies and recognizing offensive patterns within the text data [43]. Work by [44] established the CNN's efficacy in text classification tasks, inspiring subsequent research in offensive language detection.

Moreover, Recurrent Neural Networks (RNNs) and their advanced variant, Long Short-Term Memory networks (LSTMs), have gained prominence for their aptitude in handling sequential data, offering a deeper understanding of contextual information in sentences [45]. This attribute is crucial in deciphering offensive content embedded in conversational threads or sentences reliant on context for interpretation [46]. Next study [47] on using LSTMs for offensive language detection in Twitter data underscores the model's success.

However, deep learning models, while powerful, are not without their challenges. They demand extensive annotated data, are often perceived as "black boxes" due to their complex architectures, and can falter in the face of ambiguous or creatively disguised offensive content [48]. Recent research has started addressing these challenges by proposing hybrid models, combining the strengths of CNNs and LSTMs, or integrating attention mechanisms to enhance model interpretability and performance [49].

Despite these significant strides, the literature collectively points to persistent challenges in balancing high detection accuracy with context sensitivity, especially in linguistically diverse online environments. The nuances of language, ever-evolving use of lexicon, and cultural variations continue to complicate the landscape of offensive content detection [50]. This research gap necessitates continued exploration into advanced model architectures, like the proposed HDLA, that promise enhanced performance by synergizing various aspects of deep learning technology.

In conclusion, while substantial progress has been made, the quest for highly accurate, context-aware, and language-sensitive offensive language detection systems remains an active and exigent field of research. The current study positions itself within this ongoing discourse, aspiring to contribute a nuanced detection approach that acknowledges linguistic diversity and the sophisticated manifestations of offensive language in digital communication [51]. By introducing a hybrid deep learning approach, this research seeks to address the identified gaps and limitations evident in the current body of literature, marking a step forward in the realm of safer and more respectful online interactions [52].

III. Problem Statement

The challenge of promptly detecting cyberbullying within online social networking platforms potentially operates independently from the intricacies involved in categorizing various forms of such digital harassment. Within the context delineated for this study, we encounter a set of social media interactions, herein designated under the collective term "S." It is plausible to consider that within this aggregation, certain exchanges manifest characteristics of cyberbullying.

The dynamic interactions occurring within these social media platforms can be conceptualized and subsequently articulated through a series of networking sessions. These sessions, characterized by their sequential nature, can be mathematically represented, facilitating a systematic analysis. The representation of such a sequence within the network sessions can be encapsulated in Eq. (1), expressed below:

$$S = \{s_1, s_2, ..., s_{|S|}\} \quad (1)$$

where, S refers to the total number of sessions, "i" indicates the current session.

This formal representation serves as a foundational framework in our endeavor to identify patterns indicative of cyberbullying activities within the vast, interconnected realms of social networking sites. By establishing a mathematical basis for these interactions, we enhance the precision and objectivity of subsequent analyses, thereby refining the processes underlying the early detection and classification of cyberbullying instances.

The order of submissions within a given session exhibits variability, dynamically altering across temporal junctions. This fluidity in sequence progression is influenced by a constellation of determinants that govern the interactive patterns observable during these specific temporal frames. This inherent non-static nature of user engagement underscores the complexity of behavioral patterns within online platforms, necessitating a nuanced understanding and approach to studying interaction dynamics in digital communication environments.

$$P_s = \left(\left\langle P_1^S, t_1^S \right\rangle, \left\langle P_2^S, t_2^S \right\rangle, ..., \left\langle P_n^S, t_n^S \right\rangle\right) \quad (2)$$

In this context, the tuple 'P' epitomizes the kth entry within a particular social network session, while 's' designates the precise chronological marker denoting the publication instance of post 'P'. This formulation underscores the temporal dimension by associating each discrete communicative act, represented by 'P', with a specific moment, identified by 's', thereby capturing the sequential dynamics integral to interactions within the session's framework.

Concurrently, a distinctive array of attributes is employed to characterize each individual post, ensuring a representation that is unequivocally unique. This methodological approach underscores the utilization of a feature vector, articulating a multidimensional space that encapsulates the singularities of each entry within the communicative exchange. Through this, every post is afforded a distinct identification schema, enabling nuanced differentiation and detailed analysis within the collective dataset.

$$P_k^S = \left[f_{k_1}^S, f_{k_2}^S, ..., f_{k_n}^S\right], k \in [1, n] \quad (3)$$

Consequently, the endeavor's focal point is the assimilation of requisite expertise for the formulation of a function, denoted as 'f', with the capability to discern the presence or absence of hate speech affiliations within a given text. This intellectual pursuit involves not only the understanding of linguistic and contextual intricacies inherent in hate speech but also the computational mechanisms necessary for the accurate operationalization of 'f'. The ultimate aspiration is to engineer a methodological apparatus that, through 'f', can reliably navigate the subtleties of language, thereby flagging content that aligns with the characteristics of hate speech, while minimizing false positives that can stem from misinterpretation or lack of contextual consideration.

IV. Materials and Methods

A. The Proposed Framework

A schematic illustration of the constructed model, tailored for the detection of cyberbullying instances is given in this section. Fig. 1 demonstrates a sample of LSTM network. This model is meticulously architected through several cardinal phases: the preprocessing stage, wherein the data is refined and primed for analysis; the feature extraction stage, responsible for distilling relevant attributes from the data; the classification stage, which employs certain criteria for predictive delineation; and finally, the assessment stage, which critically evaluates the outcomes.

In the ensuing discussion, each phase of the model is subjected to an exhaustive analytical scrutiny. This rigorous exploration is pivotal in elucidating the nuanced methodologies employed at each juncture, thereby highlighting their collective contribution to the model's overall precision and effectiveness. Through this, the paper seeks to accentuate the underlying complexities and the methodical considerations incumbent in developing a robust computational model capable of identifying cyberbullying with high accuracy. A schematic illustration of the constructed model, tailored for the detection of cyberbullying instances, is depicted in Fig. 2.

B. Feature Extraction

1) Term frequency-inverse document frequency. Within the scope of this research, the Term Frequency-Inverse Document Frequency (TF-IDF) methodology is employed as a crucial vectorization technique, instrumental in the transformation of textual data into feature vectors that can be efficaciously processed by machine learning algorithms. This subsection delves into the systematic application and theoretical underpinnings of TF-IDF in the context of identifying cyberbullying instances on online platforms.

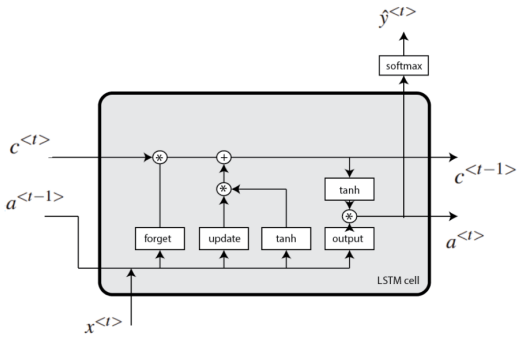

Fig. 1. LSTM network.

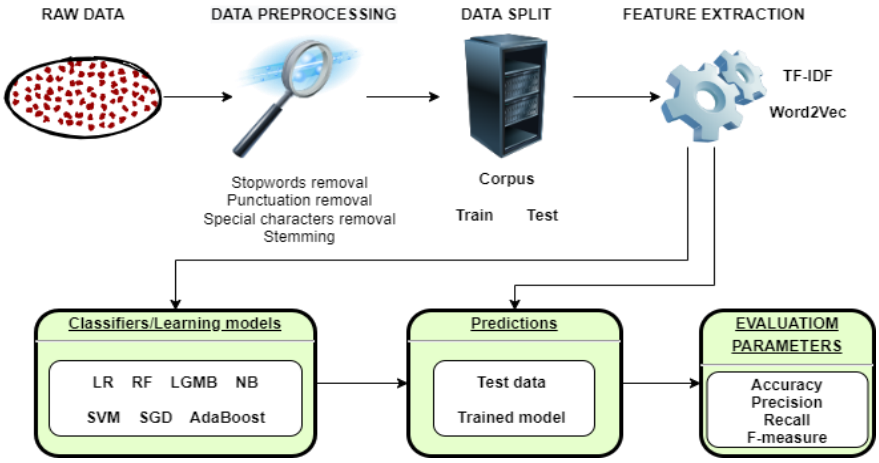

Fig. 2. Proposed framework.

TF-IDF, a renowned technique in text mining and information retrieval, quantifies the importance of specific terms within a corpus, contextualized by their frequency in individual documents and rarity across the entire dataset [53]. This technique is bifurcated into two primary components: Term Frequency (TF) and Inverse Document Frequency (IDF).

a) Term Frequency (TF): This component computes the recurrence of a term within a single document, positing that the relevance of the term augments proportionally with its frequency of occurrence [54].

b) Inverse Document Frequency (IDF): Complementing TF, IDF ascertains the scarcity of a term across the corpus, assigning more weight to terms that provide higher discriminatory power due to their infrequency. The mathematical formulation of IDF mitigates the prominence of terms that are ubiquitous across documents, thus offering a balanced view of term significance [55].

2) Word2Vec embedding. The complexity of detecting offensive language within the vast spectrum of human interaction necessitates an approach that transcends mere keyword spotting techniques, demanding a deeper understanding of contextual linguistic relationships. This research incorporates the Word2Vec model, known for its efficiency in capturing semantic relations between words, offering an advanced linguistic parsing mechanism vital for offensive language detection.

In the context of offensive language detection, Word2Vec plays a crucial role during the feature extraction phase. Here, textual data, laden with potential offensive content, is converted into vectors. This vectorization process is not arbitrary but is reflective of the words' semantic relationships within the dataset, informed by the context in which they appear.

The Skip-Gram model processes each word and its contextual neighbors, adjusting the vectors to closely represent the relational semantics in a multi-dimensional space. This approach is particularly pertinent to offensive language detection, as language nuances, euphemisms, and community-specific lexis often used in offensive content are contextually bound and not readily identifiable through conventional keyword detection methods [56].

In the present research, the selected method for weighting is the term frequency-inverse document frequency (tf-idf) system. To compute the tf-idf weight associated with the ith term within the jth document, the subsequent equation is employed:

$$w_{i,j} = TF_{i,j} \times \log\left(\frac{N}{DF_i}\right) \tag{4}$$

3) Bag of Words. Within the scope of computational linguistics, the Bag of Words (BoW) model stands as a simplified representation, used to preprocess the text by transforming it into a set of distinguishable words, or "tokens," thereby constructing a dictionary of the language used in the entire text corpus [57].

In the context of offensive language detection, the BoW model serves a fundamental role. By disregarding the syntactic relationships between words and focusing solely on the occurrence frequency, BoW facilitates a form of "token-based" analysis. Each unique word in the text is interpreted as a feature, and the value corresponds to the frequency of that word in the document. Despite its simplicity, this model offers considerable utility in scenarios where the structural complexity of text is less consequential compared to the relevance of word occurrences [58].

$$\arg\max_{\theta} \prod_{w \in T} \left[\prod_{c \in C} p(c \mid w; \theta) \right] \tag{5}$$

C. Machine Learning Methods

In the realm of hate speech detection, several machine learning algorithms have gained prominence due to their efficacy in classifying and predicting offensive content. Each algorithm's unique computational approach aids in the nuanced identification of hate speech within various digital communications.

1) Decision trees: Representing a form of supervised learning, Decision Trees create a framework that categorizes input data into specific output classes based on their statistical properties, effectively forming a tree of decisions [59]. These trees offer a highly interpretable model and adeptly manage non-linear relationships. Within hate speech detection, they function by analyzing features extracted from the text, such as the frequency of particular words or the presence of certain lexical items, thereby facilitating nuanced content-based decision-making processes.

2) Naïve bayes classifiers: These are grounded in the principles of Bayes' theorem and operate under the assumption of independence among predictors [60]. Despite its inherent assumption of feature independence, which oversimplifies linguistic relationships, the Naïve Bayes algorithm often yields robust performance in text classification. In the specific context of hate speech detection, it evaluates the probability of a message being categorized as hate speech, considering the presence of indicative terms or phrases.

3) K-Nearest Neighbors (K-NN): Functioning as a non-parametric method, K-NN employs instance-based learning, classifying data points based on the characteristics of neighboring instances [61]. Within hate speech detection paradigms, K-NN leverages the comparative analysis of feature similarities, utilizing representations like word embeddings or TF-IDF vectors, to classify textual data. This method hinges on identifying the most common classification among the 'K' nearest references in the feature space.

4) Support Vector Machines (SVM): SVMs operate through supervised learning, designed to discern the optimal boundary between multiple classes, effectively managing scenarios with high-dimensional spaces [62]. They are

adaptable through the use of diverse kernel functions to handle non-linear feature spaces. In hate speech detection, SVMs are instrumental in discerning boundaries in feature representation, relying on text attributes like word frequencies, n-grams, or sentiment indicators, thereby enhancing the precision of classification tasks.

Each of these algorithms, with their distinct methodological underpinnings, contributes to the more extensive framework of hate speech detection, providing comprehensive analytical capabilities essential for effectively navigating the complexities of digital communication landscapes.

D. Deep Learning Methods

1) LSTM (Long Short-Term Memory): Long Short-Term Memory (LSTM) networks, a variant of recurrent neural networks (RNNs), specifically address the challenges of learning long-term dependencies, thereby mitigating the vanishing gradient problem inherent in traditional RNNs. This is crucial for tasks such as text analysis, where understanding the sequence and context is essential [63]. Fig. 3 demonstrates architecture of LSTM network.

The unique component of LSTMs is their cell state, often conceptualized as the network's "memory," adjusted through structures called gates. The cell state C_t at time t is modified by three gates: the input gate (i_t), the forget gate (f_t), and the output gate (o_t), calculated as follows:

$$\begin{aligned} i_t &= \delta\left(W_{xi}x_t + W_{ht}h_{t-1} + b_i\right) \\ f_t &= \delta\left(W_{xf}x_t + W_{hf}h_{t-1} + b_f\right) \\ o_t &= \delta\left(W_{xo}x_t + W_{ho}h_{t-1} + b_o\right) \end{aligned} \quad (6)$$

where x_t is the input at time t, h_{t-1} is the previous hidden state, W and b are the weight matrices and bias terms, respectively. The crucial cell state update is then performed as:

$$C_t = f_t * C_{t-1} + i_t * \tan g\left(W_{xc}x_t + W_{hc}h_{t-1} + b_c\right) \quad (7)$$

This architecture allows LSTMs to selectively enhance or diminish the information passed along the sequence, making them particularly adept at modeling sequential data with complex dependencies.

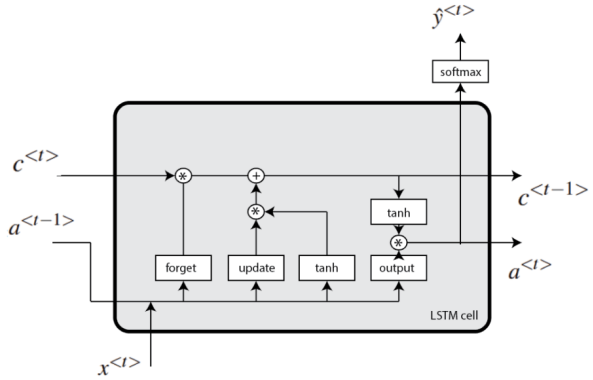

Fig. 3. Architecture of LSTM network.

2) BiLSTM (Bidirectional Long Short-Term Memory): Bidirectional Long Short-Term Memory (BiLSTM) networks augment the architecture of traditional LSTM by processing the data in both forward and backward directions, offering enhanced understanding through a two-way sequence representation [64]. This approach ensures that the information from both past and future contexts is utilized during the learning process, thus enriching the representation of each point in the sequence.

The BiLSTM model incorporates two layers of LSTMs: one processes the sequence from start to end (forward LSTM), and the other from end to start (backward LSTM). The final representation of each sequence point is the concatenation of the forward and backward information:

$$H_t = \left[\overrightarrow{H_t}; \overleftarrow{H_t}\right] \quad (7)$$

where, $\overrightarrow{H_t}$ and H_t are the hidden states of the forward and backward LSTMs at time t respectively.

For each direction, the LSTM computations are similar to the unidirectional case, with the same gating mechanisms and cell state updates:

$$\overrightarrow{H_t} = \overrightarrow{LSTM}\left[x_t, \overrightarrow{H_{t-1}}\right] \quad (8)$$

$$\overleftarrow{H_t} = \overleftarrow{LSTM}\left[x_t, \overleftarrow{H_{t-1}}\right] \quad (9)$$

By synthesizing context from both directions, BiLSTMs provide a richer, more comprehensive feature extraction, significantly improving the performance on tasks requiring an understanding of the entire data sequence, such as text classification and sentiment analysis. Fig. 4 demonstrates architecture of BiLSTM network.

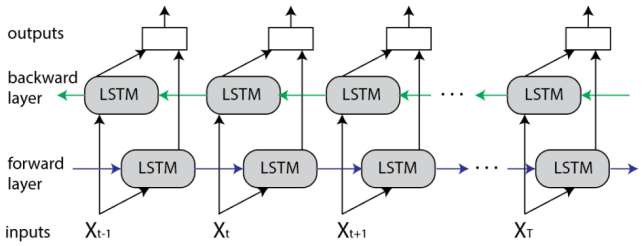

Fig. 4. BiLSTM network.

Convolutional Neural Networks (CNNs) are a class of deep neural networks highly effective in recognizing patterns directly from pixels of images, allowing hierarchical pattern recognition. They are especially powerful for tasks such as image classification, often producing superior results compared to traditional methods [65].

A key component of CNNs is the convolutional layer, which applies numerous learnable filters to the input. Each filter is used for the convolution operation, producing a feature map. Formally, for each spatial position, the convolution is computed as:

$$(F * G)(i, j) = \sum_m \sum_n F(m, n) \cdot G(i - m, j - n) \quad (10)$$

where, F is the filter matrix, G is a region of the input image, and $*$ denotes the convolution operation. The result is a feature map that undergoes a non-linear transformation (usually ReLU).

CNNs also include pooling layers, typically max pooling, which reduce the spatial dimensions (downsampling) of the input representation, decreasing the computational complexity and allowing for feature invariances. The layers of convolution and pooling operations are followed by fully connected layers that perform high-level reasoning on the features.

By learning hierarchies of features through backpropagation, CNNs construct increasingly complex representations of the input data, making them highly proficient at visual understanding. Fig. 5 demonstrates architecture of the convolutional neural network.

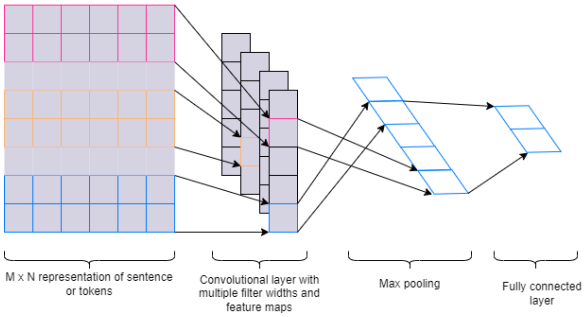

Fig. 5. Sample of a CNN architecture for offensive language detection.

V. Experimental Setup

A. Evaluation Parameters

In the realm of offensive language detection within digital platforms, the accuracy metric serves as a fundamental gauge for evaluation. Accuracy is quantified as the ratio of correctly identified instances—both offensive and non-offensive—to the total number of instances examined. Mathematically, it is expressed as [66]:

$$accuracy = \frac{TP + TN}{P + N} \quad (6)$$

While this metric provides an initial insight into the model's performance, relying solely on accuracy can be misleading, particularly in imbalanced datasets where non-offensive classes may significantly outnumber offensive ones. Therefore, accuracy is often employed alongside other metrics to furnish a more comprehensive evaluation landscape.

1) Precision: Precision is a critical metric in the evaluation of models tasked with offensive language detection, focusing specifically on the exactness of the classification. In this context, precision is the ratio of correctly predicted offensive instances to all instances predicted as offensive, whether rightly or wrongly identified. Formally, precision (P) is defined as [67]:

$$preision = \frac{TP}{TP + FP} \quad (7)$$

This metric is paramount in scenarios where the cost of false positives is high. For instance, incorrectly classifying content as offensive could impinge on free speech, making precision a vital measure of a model's reliability in distinguishing genuinely offensive content from the non-offensive.

2) Recall: Recall, in the context of offensive language detection, is an indispensable metric that quantifies the model's capacity to identify the entirety of offensive instances within a dataset. It is defined as the ratio of correctly predicted offensive comments (True Positives) to the total amount of offensive comments actually present in the data (True Positives + False Negatives), mathematically represented as [68]:

$$recall = \frac{TP}{TP + FN} \quad (8)$$

This metric is particularly crucial in scenarios where the implications of overlooking offensive content are severe, demanding a system sensitive enough to capture as many offensive instances as possible, thereby prioritizing the minimization of false negatives.

3) F-score: In offensive language detection, the F-score (or F1-score) is a crucial metric that balances precision and recall, providing a singular measure for the effectiveness of a classifier in identifying offensive content. The F-score is the harmonic mean of precision and recall, ensuring a robust metric that accounts for both false positives and false negatives. It is defined as [69]:

$$F1 = \frac{2 \times precision \times recall}{precision + recall} \quad (9)$$

Given that precision underscores the avoidance of over-policing while recall emphasizes the importance of not overlooking offensive content, the F-score harmonizes these aspects, offering a comprehensive measure of a model's performance.

4) ROC curve: The Receiver Operating Characteristic (ROC) curve is a fundamental tool for diagnostic test evaluation in offensive language detection systems. It graphically portrays the trade-off between true positive rate (sensitivity) and false positive rate (1 - specificity) across various threshold settings, highlighting the model's performance in terms of its discriminatory capacity. The area under the ROC curve (AUC-ROC) quantifies the overall ability of the model to discern between offensive and non-offensive content, irrespective of threshold. A perfect model scores an AUC of 1, while a score of 0.5 suggests no discrimination capability, equivalent to random guessing. This metric's resilience against class imbalance makes it essential for unbiased model evaluation.

B. Experimental Results

In the domain of cyberbullying detection research, several critical metrics are instrumental in evaluating model performance, including Accuracy, Precision, Recall, F-measure, and the Area Under the Receiver Operating Characteristic Curve (AUC-ROC). The elucidation of the effectiveness of various methodologies employed within this study is visually represented through confusion matrices, as depicted in Fig. 6. These matrices provide an insightful depiction of classification outcomes, distinctly presenting the distribution of predictions across different categories.

This investigation categorizes online interactions into three distinct classes, assigning them numerical representations for clarity and analytical rigor: 'cyberbullying' (scored as 1), 'non-cyberbullying' (scored as 0), and a 'neutral' category (scored as 2). Through this classification, the research not only underscores the nuanced nature of online discourse but also enhances the precision in quantifying the instances and nature of cyberbullying, facilitating a more robust and detailed analysis.

Fig. 7 critically contrasts the proposed model against a spectrum of extant machine learning and deep learning models, adjudging their efficacies. This rigorous assessment involves computing the area under the receiver operating characteristic curve (AUC-ROC), which encapsulates the totality of attributes extracted for each classification paradigm. Subsequently, Fig. 8 presents an exhaustive comparative analysis of the AUC-ROC curves emanating from each deployed strategy alongside the advocated methodology.

A salient observation from this visual representation indicates that deep learning frameworks, particularly the BiLSTM model, consistently outperform traditional machine learning counterparts. This assertion is corroborated by the superior AUC-ROC values exhibited by the BiLSTM model, commencing from the initial iteration and sustained throughout the subsequent procedural timeline, underscoring its predictive precision and reliability.

Table I delineates the classification outcomes pertinent to cyberbullying instances, derived through the application of various machine and deep learning algorithms across three distinct datasets. The evaluative criteria employed encompassed a range of metrics, including accuracy, precision, recall, and F1-score [70], offering a comprehensive perspective on the performance benchmarks of the machine learning and deep learning methods under scrutiny. This systematic approach ensures a holistic and nuanced understanding of each model's strengths and potential areas for enhancement in the context of cyberbullying detection.

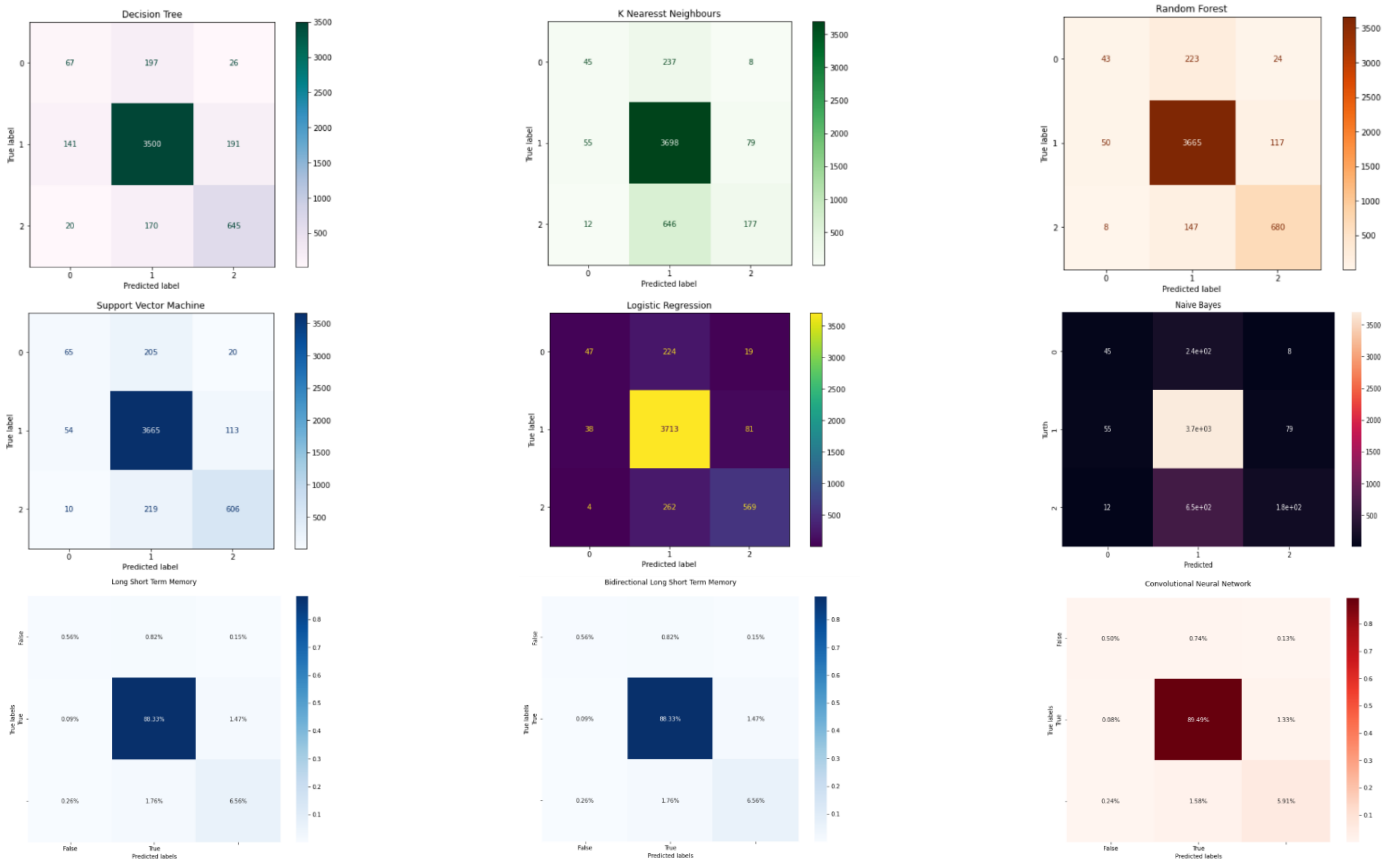

Fig. 6. Confusion matrices for hate speech detection using different machine learning methods.

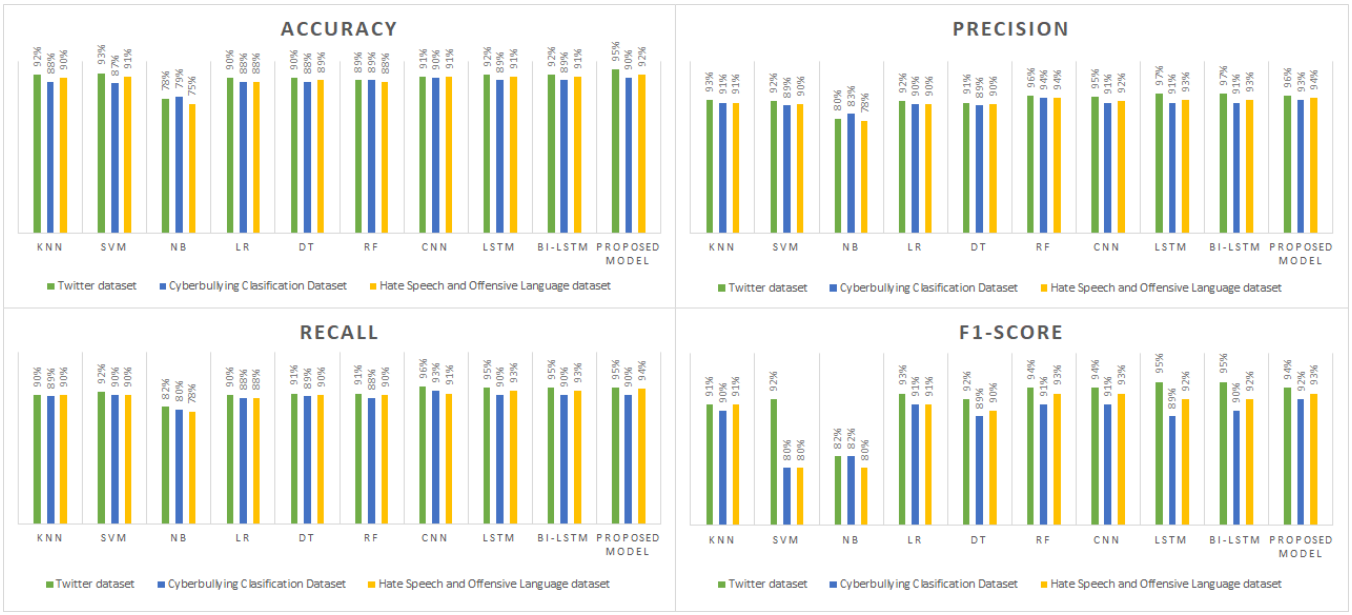

Fig. 7. Evaluation parameters for different datasets using machine learning and deep learning models.

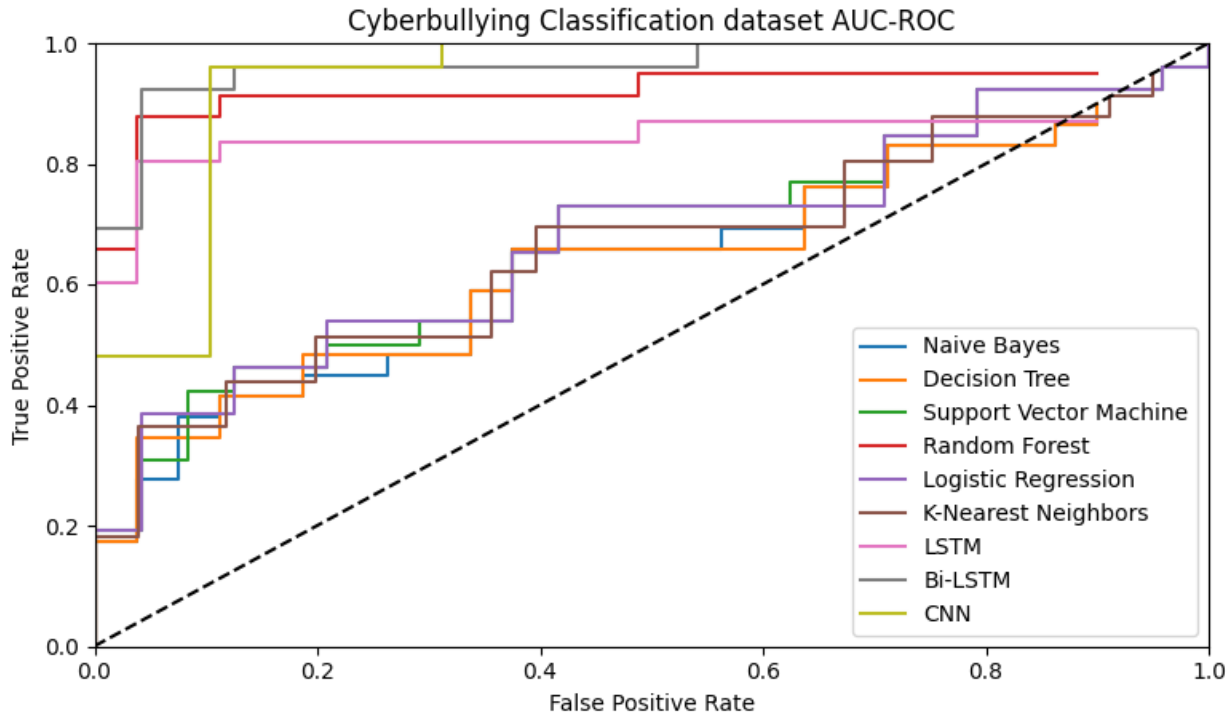

Fig. 8. ROC curve of applied machine learning and deep leaerning techniques for hate speech detection

TABLE I. COMPARISON OF THE OBTAINED RESULTS

Dataset	Approach	Model	Accuracy	Precision	Recall	F-score	ROC

In light of the compelling performance metrics attained, the proposed methodology emerges as a viable approach for the identification of cyberbullying activities within social networking platforms. Furthermore, when evaluated against all performance benchmarks, the introduced deep neural network stands paramount, particularly in discerning instances of cyberbullying.

The efficacy of the proposed deep neural network can be attributed not only to the refinement of weights and biases but also to its optimization leading to reduced training duration. This streamlined process, indicative of the method's robustness, fosters favorable outcomes, reinforcing the technique's applicability and effectiveness.

Crucially, the findings suggest that the innovative application of deep neural networks, as advocated in this study, exhibits a high degree of adaptability, capable of accommodating texts of varying lengths. This flexibility, intrinsic to the proposed model, signifies its potential for broader applicability and scalability within current digital communication contexts, thereby bolstering its practicality in real-world scenarios.

VI. DISCUSSION

This research ventured into the critical realm of cyberbullying detection within social networking sites, recognizing the profound impact that online harassment can have on individuals and communities. The study's underpinning was the development and assessment of a novel deep learning strategy designed to efficiently and accurately identify instances of cyberbullying, a task that traditional machine learning models have approached with varying degrees of success.

One of the salient aspects of this research was its emphasis on deep learning models, particularly BiLSTM, and their capacity to outstrip the performance of conventional machine learning approaches in this domain. These models, known for their proficiency in handling sequential data, proved adept at capturing the nuanced context embedded in human language, a critical factor in accurately detecting cyberbullying.

The superiority of the BiLSTM model, as evidenced through various performance metrics, underscores a pivotal shift in computational linguistics, highlighting the increasing relevance of models that understand the intricacies of language and context. This contextual understanding is paramount in the realm of cyberbullying, where the intent behind words can be just as harmful as the content itself. The model's ability to discern subtle nuances comes from its architectural advantage, allowing it to retain information over prolonged sequences and thereby understanding context better than its machine learning counterparts.

However, the journey to this point was not without its challenges. One of the primary obstacles was the variability of language used in cyberbullying. Slang, misspellings, regional dialects, and code-switching are rampant in online communications, presenting hurdles in training models that traditionally rely on standard language rules. The research navigated this by enriching the training data and iteratively refining the neural network parameters, which was pivotal in

enhancing the model's ability to understand and interpret the eclectic nature of online discourse.

Moreover, the ethical implications of automated cyberbullying detection were considered, acknowledging the delicate balance between flagging harmful content and preserving user privacy and freedom of speech. The model's design required careful consideration to respect users' digital rights while maintaining its commitment to creating safer online environments. This dual commitment is reflected in the model's methodology, emphasizing user protection while striving for comprehensive detection and minimal false positives.

Comparatively, the study's findings align with the current trajectory in cyberbullying research and technological advancements in artificial intelligence. They underscore the potential deep learning holds in transforming safety measures on social networking platforms. However, they also bring to light certain limitations that future studies will need to address.

Firstly, while the model showcased high efficiency, the question of scalability remains. As social media content continues to grow exponentially, the ability of this model to process vast quantities of data without compromising performance is something future research needs to explore. Additionally, the adaptability of the model in real-time detection scenarios are aspects that necessitate further investigation, considering the dynamic nature of online interactions.

Secondly, the diversity in data sets poses both a challenge and an opportunity. The model's performance across various demographics, cultures, and languages is a testament to its robustness. However, there's a recognized need for more diverse and inclusive data sets to ensure the model's efficacy across broader spectrums of society. This inclusivity extends beyond linguistic diversity to encompass different forms of cyberbullying, acknowledging that online harassment transcends overt language to include subtler, equally damaging forms.

Furthermore, the research's focus on deep learning, while justified, also highlights the need for interdisciplinary approaches in future studies. The psychological, sociological, and cultural dimensions of cyberbullying demand a holistic approach to technology-based solutions. Collaborations across various fields could enhance the technological frameworks proposed by this study, ensuring they are grounded in the multifaceted reality of cyberbullying.

In conclusion, this study marks a significant step forward in employing advanced AI technologies in the battle against online harassment. However, it also serves as a reminder of the work still required to perfect these systems. As we move forward, the goal remains clear: to harness the power of technology in creating online spaces where safety, respect, and freedom of expression coexist. The journey, though complex, holds the promise of achieving a more harmonious digital society, and this research serves as both a catalyst and a beacon in that quest.

VII. Conclusion

The journey through this research has underscored the intricate challenges and profound necessities within the realm of detecting and mitigating cyberbullying across social media platforms. In an era where digital interactions are an extension of our social fabric, ensuring the virtual environment's safety becomes paramount. This study ventured beyond traditional machine learning methodologies, embracing the nuanced capabilities of deep learning mechanisms, particularly through the adoption of the BiLSTM model. The findings reaffirm the assertion that understanding the sequential and contextual aspects of language is crucial in the accurate detection of cyberbullying. By leveraging the enhanced memory and processing capabilities of BiLSTM, the research demonstrated notable success in identifying offensive content, thereby holding significant implications for safeguarding online communities. However, it was observed that the battle against online harassment is an ongoing process, necessitating continuous advancements and iterations within technological applications.

As we envisage the future of cyber safety, the conclusions drawn here are not terminal but rather serve as a springboard for further exploration and innovation. The success of the proposed model underscores the potential within deep learning methodologies, offering a beacon of hope for substantial progress in this domain. Nonetheless, the complexities of human interaction, the ever-evolving nature of language, and the ethical considerations in digital monitoring present ongoing challenges that must steer future research directions. Collaborative, interdisciplinary approaches may also be essential in addressing these multifaceted issues, uniting technological prowess with psychological, cultural, and linguistic expertise. As we forge ahead, the objective remains steadfast: to refine and enhance these technological guardians to preserve the dignity, safety, and well-being of individuals in the digital sphere, ensuring that our virtual environments are reflective of the respect and security we strive for in our broader societies.

Automated Detection of Driver and Passenger Without Seat Belt using YOLOv8

Sutikno, Aris Sugiharto, Retno Kusumaningrum
Department of Informatics, Diponegoro University, Semarang, Indonesia

***Abstract*—The issue of traffic accident fatalities is a serious concern on a global scale, and one of the contributing factors is the failure of drivers to adhere to seat belt usage. A notable challenge arises from the limited availability of law enforcement personnel monitoring this particular issue. In this context, there is a compelling need to implement an automated detection system. The development of this system using YOLOv5 has been done. However, there are weaknesses related to the length of training and detection time. Therefore, this paper proposed a new system using the YOLOv8 method to detect drivers and passengers who violate seat belt regulations. The proposed system is divided into three subsystems: windshield detection, passenger classification, and seat belt classification. YOLOv8 is the latest version of the YOLO (You Only Look Once) method and has been proven to provide better performance than previous versions. Furthermore, this paper also compared five YOLOv8 models, namely YOLOv8n, YOLOv8s, YOLOv8m, YOLOv8l, and YOLOv8x. The proposed model is trained and tested using image data collected from several roads in Indonesia. The experiment results show that the YOLOv8s model produced the best mean Average Precision (mAP) of 0.960 for windshield detection. YOLOv8s-cls and YOLOv8l-cls models achieved the same accuracy of 0.8923 for passenger classification. The YOLOv8l-cls model produced the best accuracy of 0.8846 for seat belt classification. In addition, the proposed method can increase mAP and training time for windshield detection compared to YOLOv5.**

Keywords*—*Windshield detection; passenger classification; seat belt classification; YOLOv8

I. Introduction

Traffic accident fatalities are pressing global issues, ranking among the top 10 causes of mortality in low-income countries [1]. A key factor related to this issue is drivers' and passengers' non-adherence to seat belt usage. Even though the compulsory use of seat belts has been mandated, instances of non-compliance are alarmingly frequent. Using seat belts can significantly reduce the risk of severe injury or death in a traffic accident. Therefore, it is essential to raise public awareness among vehicle operators of the importance of wearing seat belts. Efforts are also needed to improve surveillance and enforcement of the regulations on the road.

In this context, monitoring of drivers and passengers in four-wheeled or larger vehicles is accomplished through direct observation. Several weaknesses have been reported in this approach since many violations remain undetected. This issue can be addressed by using Closed-Circuit Television (CCTV) cameras for surveillance on the road combined with automated detection based on computer vision. This automatic detection requires a method that produces high accuracy and speed. This application can help the police detect drivers and passengers not wearing seat belts. So their work becomes more efficient.

Research into computer vision-based detection of drivers' compliance with seat belt regulations commenced approximately a decade ago. Generally, this research can be divided into two types based on handcrafted and non-handcrafted features. The use of handcrafted features was shown by Qin et al., who combined Haar-like and Histogram of Oriented Gradient (HOG) descriptors to report efficiency and robustness [2]. Additionally, Elihos et al. used Fisher Vector [3]. Most research used non-handcrafted features, such as BN-AlexNet [4], Convolutional Neural Network (CNN) [5], A Nimble Architecture for Driver and Seat Belt Detection through Convolutional Neural Networks (NADS-Net) [6], YOLOv3 [7], and YOLOv5 [8], [9]. YOLOv5 achieved the best mean Average Precision (mAP) compared to other methods for detecting vehicle windshields, passengers, and drivers without seat belts [9]. However, there are weaknesses related to training and detection time. In addition, this method incorrectly detects low-quality data [10]. For this reason, a method is needed to increase detection accuracy and reduce detection time so that it can be applied in real-time.

YOLOv3 has also been used for other detections, for example, to detect pedestrians [11], vehicles [12], and road objects [13]. Another investigation compared YOLOv5, YOLOv6, and YOLOv7 for detecting small objects [14], while YOLOv7 was used for real-time weed detection [15]. Yung et al. compared YOLOv5, YOLOv6, and YOLOv7 to detect safety helmets workers wear [16]. The test results showed that YOLOv7 achieved better mAP than YOLOv5 and YOLOv6. Furthermore, YOLOv7 exhibited superior accuracy and speed compared to YOLOR, PP-YOLOE, YOLOX, Scaled-YOLOv4, and YOLOv5 algorithms.

The latest version of YOLO (You Only Look Once), YOLOv8, was more advanced than its predecessors. YOLOv8 produced high average accuracy. YOLOv8 scores much better than YOLOv5 [17]. Therefore, this paper developed a new system using the YOLOv8 to detect drivers and passengers without seat belts. The proposed system was divided into three subsystems: windshield detection, passenger classification, and seat belt classification. The main contribution of this paper is that the proposed method can produce relatively high accuracy so that it can potentially be applied to actual conditions.

The remainder of this paper is organized as follows: Section II is about related work. Section III describes the dataset, the proposed method, and the parameters used to

evaluate the performance of the proposed method. Section IV explains the test results and analysis of the windshield detection, passenger classification, and seat belt classification subsystems. Additionally, this section compares the proposed method with previous research. Finally, Section V explains the conclusions and research that will be carried out.

II. Related Work

Research on driver detection without seat belts based on computer vision started about a decade ago. Generally, this research can be divided into two types based on handcrafted and non-handcrafted features. Guo et al. used license plate and edge detection to determine the area of the driver's area and the position of the seat belt [18]. Li et al. also used Canny edge detection, with the driver's area determined by cutting the left half of the windshield [19]. Meanwhile, the windshield area's position was detected using the cascade Adaboost classifier.

Zhou et al. proposed Canny edge detection and salient gradient map for feature extraction and learning-based algorithms for binary classification [20]. Yang et al. determined the driver's area using face and seat belt detection through connected area methods [21]. Wu et al. introduced a methodology that includes ascertaining the driver's area through semantic segmentation, streamlined by a pruning process, and conducting classification using connected techniques [22]. Yongquan et al. focused on reducing computation time for driver detection without seat belts by designing a Graphics Processing Unit (GPU) acceleration method [23]. The driver's area was obtained using Squeeze-YOLO, while seat belt usage was determined using semantic segmentation algorithms and full convolution network pruning. Wang et al. used semantic segmentation but lightweight feature extraction and the Squeeze-YOLO algorithm to determine the driver's area [24].

In pursuit of enhanced accuracy, specific research endeavors have embraced a fusion of multiple descriptors. For instance, Qin et al. integrated Haar-like features and HOG [25]. Madake et al. combined feature extraction techniques such as Canny, FAST (Features from Accelerated Segment Test), and BRIEF (Binary Robust Independent Elementary Features) [26]. The test results showed that the proposed feature extraction combinations improved accuracy.

In recent years, most research has used CNN. Furthermore, Sajja et al. used this method and compared the concept to Support Vector Machine (SVM) [27]. Test results showed that the CNN method achieved better accuracy than SVM. Kapdi et al. adopted the MobileNetV2 model [28], which had the advantage of robustness in different weather conditions. Meanwhile, Chen et al. combined CNN and SVM for feature extraction and classification. This method was based on multi-scale feature extraction and applied to images with complex road backgrounds. In this context, the proposed method achieved better average detection than the Adaboost algorithm and CNN [5]. Kannadaguli proposed a detection method using Fully Connected One Shot (FCOS) and added prediction elimination with Non-Maximum Suppression (NMS) [29]. Additionally, Elihos et al. compared the Single Shot MultiBox Object Detector (SSD), VGG16 model, shallower CNN model, and Fisher vector model [3]. The test results showed that the SSD model achieved the highest accuracy.

Some versions of YOLO have also been used in this field. Luo et al. used YOLOv3 to determine the driver's area and CNN for the classification process [30]. The testing showed that the proposed method achieved high accuracy and robustness in complex environments. Wang and Ma also used YOLOv3 and a lightweight network structure [7]. In this context, increasing the number of lightweight templates improved accuracy but reduced speed.

Furthermore, Khalid and Hazela used YOLOv4 to determine the driver's area and the AlexNet model for classification [31]. Feng et al. proposed YOLOv5 to locate the driver's area and used the AlexNet deep convolutional network for classification [8]. This method saved memory and computational time compared to SVM. Hosseini and Fathi used YOLOv5 to detect car windshields and the ResNet32 model for classification [9].

Maduri et al. proposed a method for real-time driver detection without seat belts [32]. This method used deep learning and was embedded in a Raspberry Pi. Upadhyay et al. also focused on real-time conditions and implemented the concept in real-world scenarios to install a camera in a car cabin using YOLOv5 [33]. Zang et al. also proposed the SlimSSDMV2 and Line Segment Detector (LSD) models, which were applied to mobile devices [34].

Some researchers aimed to improve accuracy and speed with the development of the CNN model. Zhou et al. developed the Alexnet model by adding Batch Normalization (BN), known as BN-Alexnet [4]. The proposed method increased the average accurate detection and reduced training time compared to Alexnet, VGGNet-16, and GoogLeNet. Chun et al. developed the CNN model known as NADS-Net using the feature pyramid network (FPN) backbone and multiple detection heads method [6]. Additionally, Yang et al. proposed a method focused on the Central Processing Unit (CPU) and real-time implementation. The proposed method combined traditional operators (texture extraction), SSD MobileNet V2, and particle filter tracking algorithms [35].

III. Material and Method

A. Dataset

This research used three datasets, namely Dataset1, Dataset2, and Dataset3. The datasets were captured from video frame recordings on several roads, using CCTV and cameras in Bandung and Semarang City, Indonesia. Fig. 1 shows samples of images from Dataset1. This dataset contains video frame images with annotations of windshields used in the windshield detection subsystem.

Fig. 2 shows samples of images from Dataset2 used in the passenger classification. This dataset consists of a set of seating area images comprising two classes, namely 488 passenger images and 484 no-passenger images. These images are obtained from the right half of the windshield image.

Fig. 3 shows samples of images from Dataset3 used in the seat belt classification. This dataset contains images of drivers and passengers with and without seat belts. The number of

images of drivers or passengers wearing seat belts is 957, and the number of images of drivers or passengers not wearing seat belts is 727. Whereas Table I shows the number of training and testing data in each dataset. The distribution of training and testing data is carried out randomly, with a ratio of 80% for training data and 20% for testing data.

Fig. 1. Samples of dataset1.

Fig. 2. Samples of dataset2.

Fig. 3. Samples of dataset3.

TABLE I. NUMBER OF TRAINING AND TESTING DATA

Dataset	Image Number		
	Training	***Testing***	***Total***
Dataset1	2631	658	3289
Dataset2	777	195	972
Dataset3	1346	338	1684

B. Proposed System

This research built a system for detecting drivers or passengers without seat belts. The proposed system generally consists of three subsystems: windshield detection, passenger classification, and seat belt classification. Fig. 4 displays this proposed system.

1) Windshield detection: A car's driver and front passengers are visible through the car's windshield. Therefore, the initial step includes detecting each car's windshield position using the YOLOv8 method. YOLO predicts bounding boxes (Bbox) and class probabilities (Cls) through a single network. Furthermore, it excels in high accuracy even when using small model sizes and can be trained on a single GPU [17]. The method is cost-effective for machine learning practitioners with limited hardware resources or cloud computing. Ultralytics developed YOLOv8 as the latest model for object detection, image classification, and image segmentation. This method is an anchor-free model that directly predicts the object's center and augments images during online training. The model analyzes variations of the provided images in each epoch through mosaic augmentation. This augmentation has empirically been found to decrease performance when applied throughout the entire training routine. Fig. 5 shows the architecture of the YOLOv8 model divided into two main parts: the backbone and the head [36]. The backbone architecture consists of 53 convolutional layers and uses partial cross-stage connections to enhance information flow between different layers, promoting better feature representation and extraction based on CSPDarknet53. Meanwhile, the head of YOLOv8 consists of several convolutional and fully connected layers. These layers are used for object detection, including bounding box prediction, objectivity scores prediction, and class probabilities for image objects. The model uses a feature pyramid network to detect large and small objects accurately.

2) Passenger classification: The windshield detection subsystem results in the windshield area. This area has two seats: the driver (left) and the passenger (right). The driver's seat always has a driver, but the passenger's seat may or may not have a passenger. Therefore, the passenger classification subsystem classifies the presence of a passenger in the right seat. This subsystem comprises windshield cropping, division of the driver and passenger areas, and the classification process. The windshield cropping process is used to capture the windshield area of each car. Division of driver and passenger areas separates the area into the left and right sides for the driver and passenger areas. The classification process is conducted in two classes (seat with passenger and seat without passenger) using the YOLOv8 method.

3) Seat belt classification: The final subsystem is the seat belt classification, which determines whether the driver and passenger are wearing a seat belt. We used YOLOv8 method.

C. Performance Evaluation

Performance evaluation for windshield detection used the parameters of precision (P), recall (R), and mAP. Precision and recall are calculated using as in Eq. (1) and Eq. (2), respectively [37]. TP_{dec} represents correct detections of the ground truth bounding box, FP_{dec} is the false detections of objects, and FN_{dec} represents the undetected ground truth.

$$P = \frac{TP_{dec}}{TP_{dec}+FP_{dec}} \quad (1)$$

$$R = \frac{TP_{dec}}{TP_{dec}+FN_{dec}} \quad (2)$$

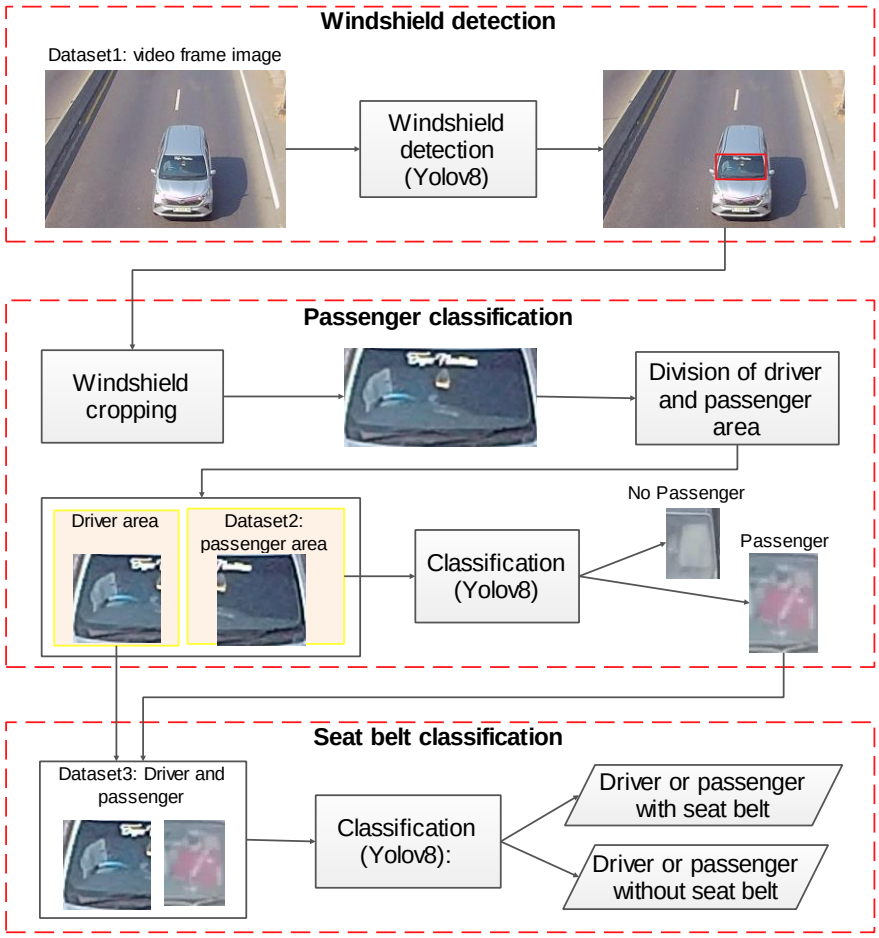

Fig. 4. Proposed system.

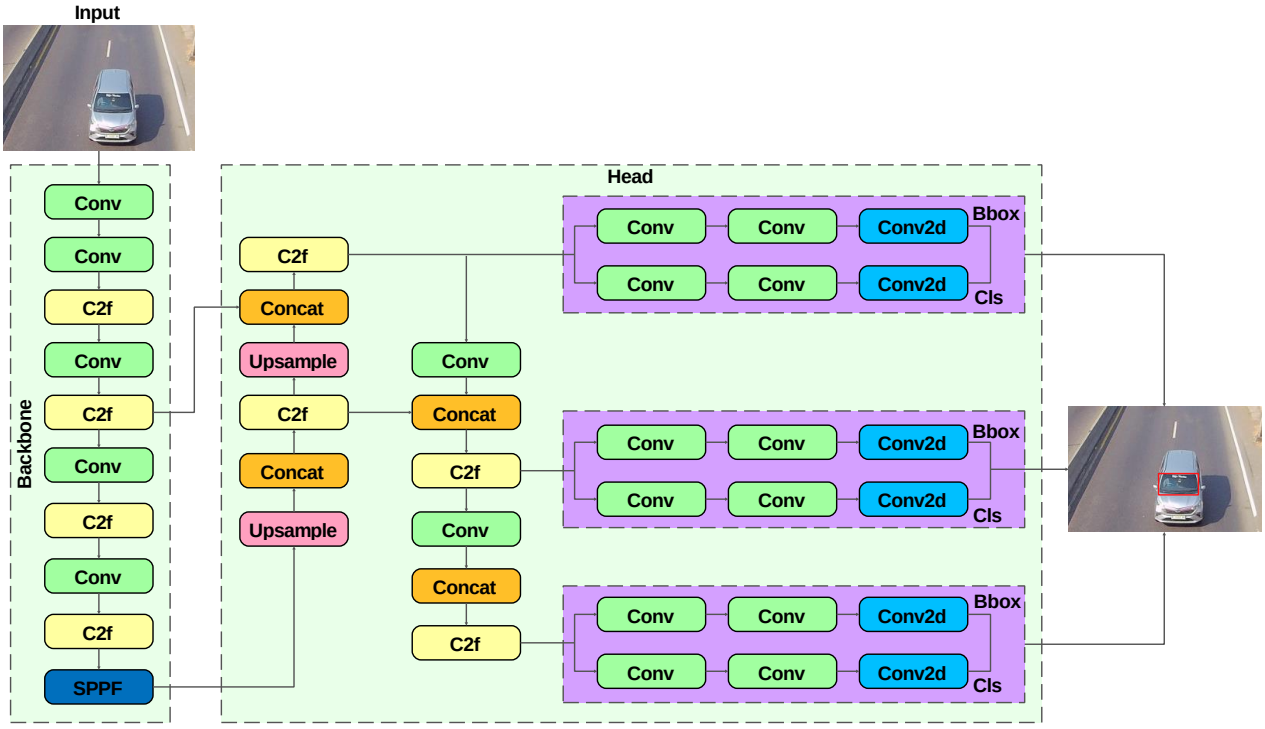

Fig. 5. The architecture of the YOLOv8 model.

Meanwhile, mAP is calculated as in Eq. (3) [37].

$$mAP = \frac{1}{N}\sum_{i=1}^{N} AP_i \quad (3)$$

AP_i is the average precision for each class, and N is the number of classes. AP for each class is calculated as in Eq. (4).

$$AP = \sum_n (R_{n+1} - R_n) P_i(R_{n+1}) \quad (4)$$

$P_i(R_{n+1})$ is calculated as in (5).

$$P_i(R_{n+1}) = \max_{\tilde{R}:\tilde{R}\geq R_{n+1}} P(\tilde{R}) \quad (5)$$

$P(\tilde{R})$ is the precision measured at the time of recall $\tilde{R}$.

The performance evaluation for passenger and seat belt classification used an accuracy parameter calculated as in Eq. (6). Table II displays a confusion matrix containing True Positive (TP_{cls}), False Positive (FP_{cls}), False Negative (FN_{cls}), and True Negative (TN_{cls}).

$$Accuracy = \frac{TP_{cls}+TN_{cls}}{TP_{cls}+TN_{cls}+FP_{cls}+FN_{cls}} \quad (6)$$

TABLE II. CONFUSION MATRIX

		Actual Value	
		Positive	**Negative**
Predicted	***Positive***	TP_{cls}	FP_{cls}
	Negative	FN_{cls}	TN_{cls}

IV. EXPERIMENTS AND RESULTS

The experiments were conducted on each subsystem using different datasets. The windshield detection, passenger classification, and seat belt classification subsystems used Dataset1, Dataset2, and Dataset3, respectively. The experiments were performed using YOLOv8, and the model was trained and tested on a Tesla T4 GPU.

A. Windshield Detection

The first experiment was conducted for windshield detection using five YOLOv8 models, including YOLOv8n, YOLOv8s, YOLOv8m, YOLOv8l, and YOLOv8x. All experiments used 640×640 pixels for input size, 16 for batch size, 100 for epochs, and Adam for optimizer. Table III shows the experiment result of windshield detection. The best precision and recall were achieved using the YOLOv8s and YOLOv8n models, respectively, while the fastest training time was obtained with YOLOv8s. Additionally, the best mAP was achieved using the YOLOv8m model at 0.960. Fig. 6, Fig. 7, and Fig. 8 display the precision-recall, precision-confidence, and recall-confidence curves of this experiment, respectively. Meanwhile, Fig. 9 displays examples of windshield detection results.

TABLE III. EXPERIMENT RESULT OF WINDSHIELD DETECTION

Model	P	R	mAP	Time (hours)
Yolov8n	0.878	**0.933**	0.959	1.659
Yolov8s	**0.882**	0.921	0.950	**1.628**
Yolov8m	0.879	0.913	**0.960**	2.391
Yolov8l	0.860	0.895	0.945	3.606
Yolov8x	0.847	0.893	0.943	5.718

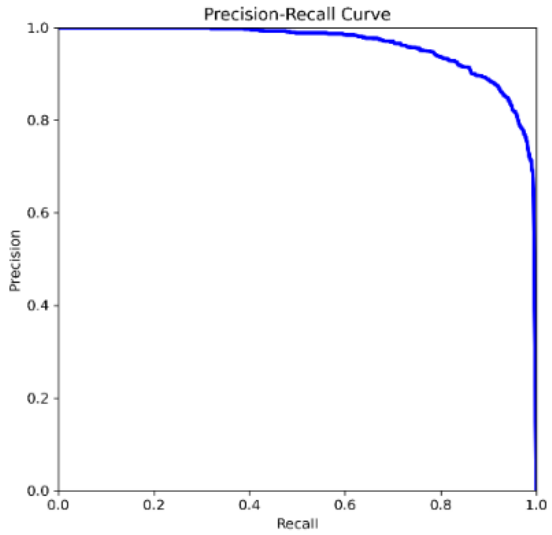

Fig. 6. Precision-recall curve of windshield detection.

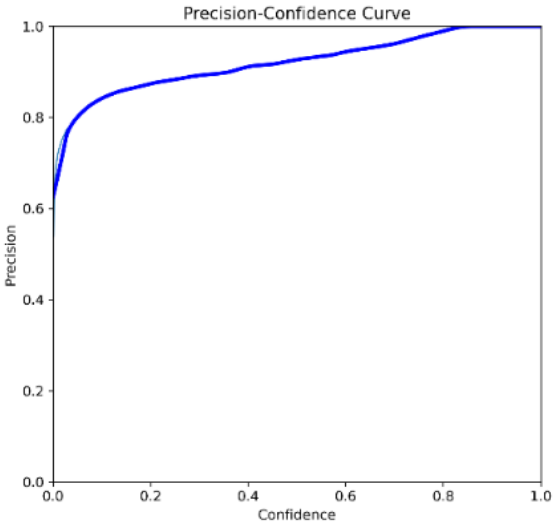

Fig. 7. Precision-confidence curve of windshield detection.

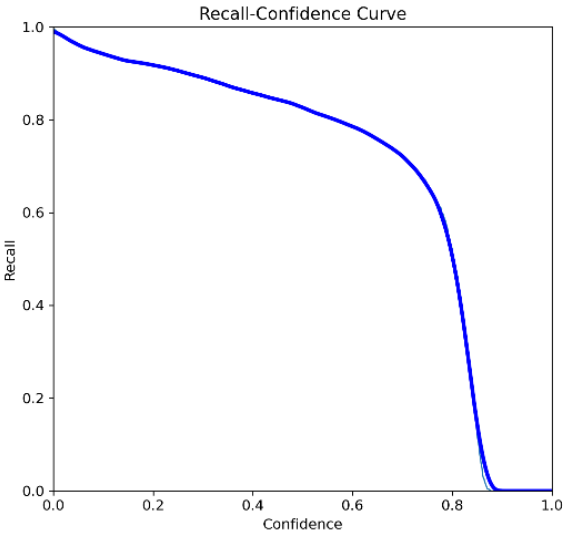

Fig. 8. Recall-confidence curve of windshield detection.

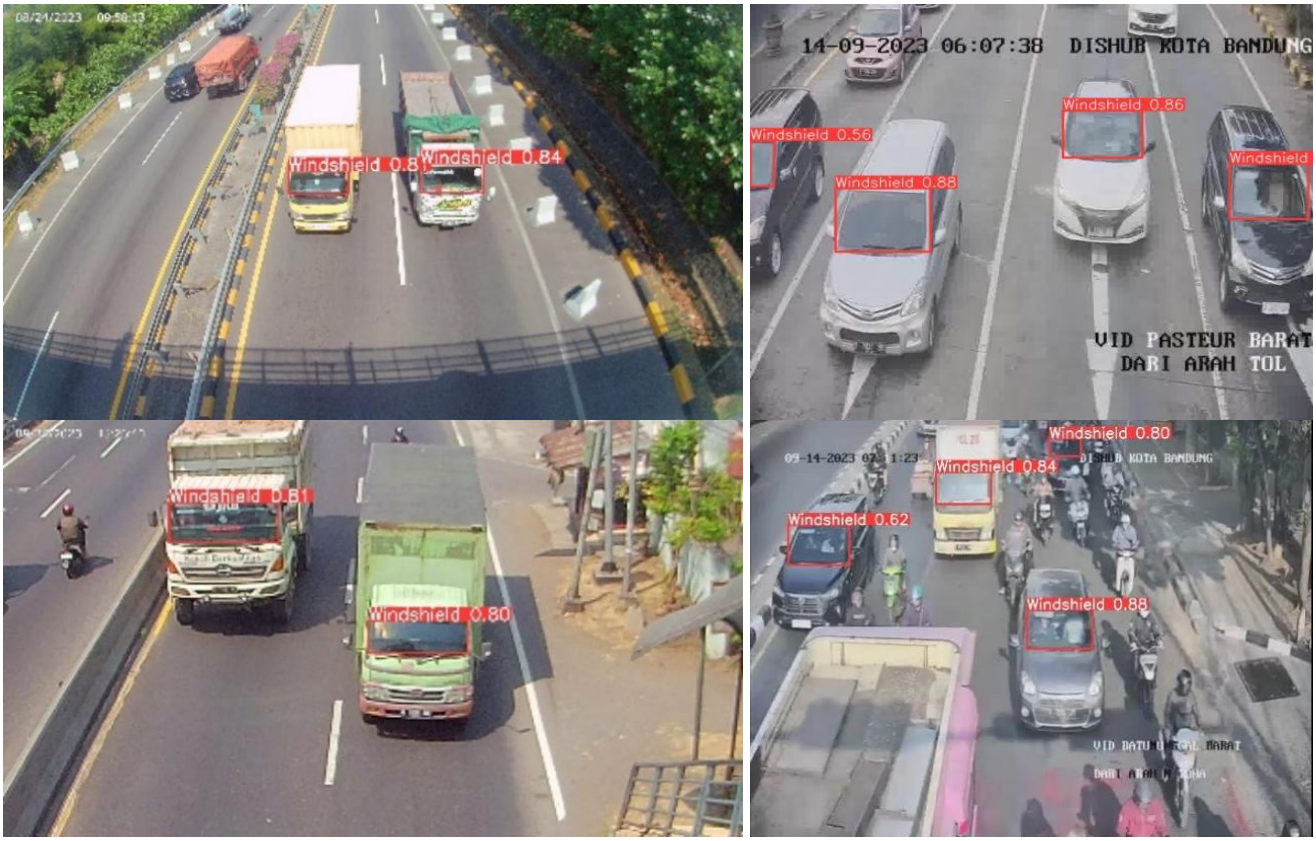

Fig. 9. Example of windshield detection from video frame images.

The proposed method was compared to the previous research, as shown in Table IV. Here, the study in [9] used the YOLOv5s model with 48 for batch size, 0.0001 for learning rate, and Adam for the optimizer. The table shows that the proposed method outperformed precision, recall, and mAP. The proposed method increases mAP by 2% and decreases training time by 0.54 times compared to the YOLOv5s model. Therefore, the proposed method is more suitable for real-time windshield detection.

TABLE IV. COMPARISON BETWEEN THE PROPOSED METHOD AND PREVIOUS RESEARCH METHOD (YOLOV5)

Model	P	R	mAP	Time (hours)
[9]	0.824	9.907	0.940	4.427
Proposed	**0.879**	**0.913**	**0.960**	**2.391**

B. *Passenger classification*

A passenger classification experiment was conducted using five models and three batch sizes. Those models are YOLOv8n-cls, YOLOv8s-cls, YOLOv8m-cls, YOLOv8l-cls, and YOLOv8x-cls and those batch sizes are 4, 8, and 16. All training used 224×224 pixels for image size input, 100 for epochs, Adam for optimizer, and 20 for early stopping. Table V shows the results of this experiment. The highest accuracy reaches 0.8923 using YOLOv8s-cls and YOLOv8l-cls. Table VI is a confusion matrix of the best result of passenger classification. Furthermore, the fastest epochs and training time are achieved using the YOLOv8n-cls model with 16 for the batch size.

TABLE V. EXPERIMENT RESULT OF PASSENGER CLASSIFICATION

Model	Batch size	Accuracy	Epoch	Time (hours)
Yolov8n-cls	4	0.8667	38	0.095
	8	0.8718	43	0.076
	16	0.8564	**33**	**0.051**

C. Seat Belt Classification

The seat belt classification experiment used five models and three batch sizes, the same as in the passenger classification experiment. Table VII shows the results of this experiment. In this context, the highest accuracy reaches 0.8846 using the YOLOv8l-cls model and 16 for batch size. Table VIII is a confusion matrix of the best experiment result. The fastest training time reaches 0.126 hours using the YOLOv8n-cls model and 16 for batch size.

TABLE VII. EXPERIMENT RESULT OF SEAT BELT CLASSIFICATION

Model	Batch size	Accuracy	Epoch	Time (hours)
Yolov8n-cls	4	0.8669	100	0.432
	8	0.8787	61	0.176
	16	0.8609	**52**	**0.126**
Yolov8s-cls	4	0.8669	100	0.410
	8	0.8698	100	0.281
	16	0.8550	86	0.201

	Seat belt	19	172

V. CONCLUSION

This research developed a system for detecting drivers and passengers who violate seat belt regulations. The proposed system consists of three subsystems: windshield detection, passenger classification, and seat belt classification. The proposed methods in each subsystem used YOLOv8. The experiment was conducted by comparing five models. Furthermore, three batch sizes were compared in passenger and seat belt classification. The results show that the proposed method achieved an mAP of 0.960 for windshield detection. An accuracy of 0.8923 and 0.8846 was reported for passenger and seat belt classifications. Moreover, the proposed method excelled in accuracy and training time compared to YOLOv5 for windshield detection. Therefore, the proposed method is more suitable for detecting drivers or passengers who violate seat belts in real-time. A license plate detection subsystem could be adopted for future research to identify vehicles.

ACKNOWLEDGMENT

The authors are grateful to the Ministry of Research and Higher Education of Indonesia through Diponegoro University, which has funded this research with contract numbers 017/E5/PG.02.00.PL/2023.

Enhancing Alzheimer's Disease Diagnosis: The Efficacy of the YOLO Algorithm Model

Tran Quang Vinh, Haewon Byeon*
Department of Digital Anti-Aging Healthcare (BK21), Inje University, Gimhae 50834, South Korea

***Abstract*—The diagnosis and early detection of Alzheimer's Disease (AD) and other forms of dementia have become increasingly crucial as our aging population grows. In recent years, deep learning, particularly the You Only Look Once (YOLO) architecture, has emerged as a promising tool in the field of neuroimaging and machine learning for AD diagnosis. This comprehensive review investigates the recent advances in the application of YOLO for AD diagnosis and classification. We scrutinized five research papers that have explored the potential of YOLO, delving into the methodologies, datasets, and results presented. Our review reveals the remarkable strides made in AD diagnosis using YOLO, while also highlighting challenges, such as data scarcity and research lacking. The paper provides insights into the growing role of YOLO in the early detection of AD and its potential to transform clinical practices in the field. This review aims to inspire further research and innovation to enhance AD diagnosis and, ultimately, patient care.**

***Keywords*—Machine learning; deep learning; YOLO; alzheimer's disease; dementia**

I. Introduction

There is a surging interest in the application of Artificial Intelligence (AI) within the realm of healthcare. Health care-related AI research has seen a rapid acceleration in publication growth since 2012, with a 45.1% increase in the past five years, driven by technological breakthroughs and is expected to continue doubling approximately every two years based on this growth trend [1]. AI has solidified its position as a transformative power in the healthcare sector, completely reshaping the approaches to diagnosis, treatment, and medical condition management. In recent years, AI has emerged as an indispensable asset in the healthcare industry, offering groundbreaking solutions to some of the most formidable challenges in medicine, particularly when addressing neurological diseases. Neurological diseases, encompassing a diverse spectrum of conditions, such as Alzheimer's disease (AD), stroke and Parkinson's disease, pose intricate challenges in terms of diagnosis and treatment [2,3]. AI has decisively altered the landscape in this context.

AI applications in the realm of neurological diseases are both diverse and promising. AI, particular machine learning (ML) and deep learning (DL) architecture have the capability to scrutinize extensive volumes of brain imaging data, encompassing magnetic resonance imaging (MRI), positron emission tomography (PET), and computed tomography (CT) scans, in order to unearth subtle anomalies that might elude human perception [4,5,6]. In contrast to conventional diagnostic and treatment methodologies, these AI-driven approaches address several limitations inherent in traditional methods, such as subjectivity, delayed diagnoses often resulting from inconspicuous early-stage symptoms, or findings imperceptible to human observers. This proficiency in early detection of neurological disorders offers the potential for swifter and more precise diagnoses.

In particular, the deep learning object detection algorithm known as You Only Look Once (YOLO) shows great promise in enhancing the accuracy, efficiency, and automation of diagnosing neurological diseases, with a special emphasis on Alzheimer's disease. The primary aim of this brief review is to investigate the present applications of YOLO in the classification of neurological diseases with a particular focus on Alzheimer's disease. Additionally, we will delve into the methods used and the challenges faced when applying AI to the diagnosis and treatment of neurological diseases.

II. Materials and Methods

A. Artificial Intelligence in AD Diagnosis

AD is a formidable and complex neurological condition that has captured the attention of scientists, healthcare professionals, and society at large. Named after Dr. Alois Alzheimer, who first described the disease in the early 20th century [7], Alzheimer's is a progressive and degenerative brain disorder that predominantly affects memory, cognitive function, and daily life activities. The impact of AD extends far beyond the affected individuals themselves, as it profoundly affects their families and caregivers, often placing an immense emotional and practical burden on them. It is the most common cause of dementia, a term that encompasses a range of cognitive impairments that interfere with an individual's ability to think, reason, remember, and communicate. AD is a devastating and relentless neurological disorder that presents a profound challenge to both the medical community and society as a whole [8]. It is estimated that over 50 million people worldwide are currently affected by AD [9]. As the global population ages, this number is projected to escalate significantly in the coming decades. This ailment has grown into one of the most prevalent and impactful health concerns of our time [10].

As is the case with numerous other neurological disorders [11], early diagnosis holds a crucial position in the care and strategic planning for Alzheimer's disease (AD). The classification of AD is based on different levels, which include Alzheimer's disease (AD), mild cognitive impairment (MCI), and cognitively normal (CN). Early identification in MCI level empowers individuals and their families to take proactive steps in addressing critical aspects of their future, encompassing healthcare preferences, support requirements, and financial and

*Corresponding Author.

legal considerations [12, 13]. Additionally, early detection allows for proactive safety measures to reduce the risk of wandering or disorientation-related incidents. Moreover, it opens up the possibility of participating in clinical trials for innovative treatments during the disease's early stages, contributing to advancements in research.

Despite recent advancements in clinical trials related to Alzheimer's disease, several challenges have emerged. These challenges include the difficulty of distinguishing AD from normal age-related cognitive changes, limited access to specialized diagnostic tools in certain geographic regions, and the growing number of individuals affected by the disease [14]. Consequently, the role of computer applications in AD diagnosis has become increasingly crucial. Among these, deep learning, which falls under the umbrella of machine learning and constitutes a pivotal element of artificial intelligence, has showcased impressive accomplishments in fields like object recognition and computer vision [15]. This has led to the extensive integration of deep learning in the realm of neuroimaging analysis, where its neural network architecture, featuring non-linear activation functions, plays a pivotal role in tasks like image classification [16], particularly in the domain of neuroimaging and AD neuroimaging [17]. This encompasses various modalities, including MRI, PET, CT, fMRI, and more [18].

B. Advanced in Machine Learning in Neuroimaging

Brain imaging can be categorized into distinct types based on various criteria. One such classification pertains to imaging modality, which can be categorized into structural and functional imaging. Structural imaging, exemplified by MRI, offers high-resolution images that unveil detailed brain anatomy, encompassing gray and white matter, as well as cerebrospinal fluid. It detects changes in brain volume and atrophy patterns, key indicators of Alzheimer's disease. While primarily used for functional studies, fMRI can also provide insights into structural connectivity through techniques like resting-state functional connectivity. Alterations in functional connectivity can be associated with structural changes in AD. In recent times, deep learning architectures have demonstrated the capability to handle complete 3D brain images seamlessly from start to finish (end-to-end) [19, 20, 21]. However, the foremost challenge is the high computational cost, which demands substantial processing power and can result in extended training times. Overfitting is another issue of concern, as is the need for ensuring model interpretability. Data preprocessing is a critical stage in preparing both 2D and intricate 3D data, albeit with the introduction of added complexities.

In more detail, data preprocessing is a fundamental process in the preparation of raw data for machine learning algorithms. Its significance stems from the fact that real-world data can be noisy, incomplete, or poorly formatted. By cleaning and structuring the data, data preprocessing significantly enhances the accuracy and effectiveness of machine learning models. Within the domain of neuroimaging analysis, the pivotal stages of data preprocessing and feature extraction hold an indispensable role. These critical components serve to enhance data quality, mitigate noise, establish data consistency, augment statistical power, facilitate data interpretation, and enhance research precision. Nevertheless, it is essential to recognize that data preprocessing may also introduce certain inherent limitations that warrant consideration in the research process.

C. Limitation of Deep Learning in Alzheimer's Disease Diagnosis

The increasing importance of deep learning in Alzheimer's Disease (AD) classification has become increasingly apparent, resulting in a notable upswing in research endeavors from 2017 onward [17]. These investigations have yielded a spectrum of reported accuracy levels, spanning from 70% to 99% [22]. Notably, Sarraf et al. (2016) achieved outstanding accuracy rates of 98.84% for MRI [23] and an impressive 99.99% for fMRI [24] pipelines, while Suk et al. (2013) [25] attained an accuracy of 98.8%. However, a common reliance on diverse MRI pre-processing techniques to attain optimal results and a predominant focus on Convolutional Neural Networks (CNN) have contributed to a distinct research gap in the domain of deep learning for object detection. Consequently, there exists a pressing need to explore new research avenues that minimize the dependence on these pre-processing techniques.

D. Advancement of YOLO for Alzheimer's Disease Diagnosis

The diligent efforts of numerous researchers have been dedicated to the deployment of deep learning models for object detection within the realm of medical imaging, particularly within the domain of Alzheimer's Disease diagnosis. This dedication has culminated in the emergence of the YOLO model and its various iterations, representing significant milestones in the development of this innovative approach.

E. Convolutional Neural Networks

A key technique within the domain of deep learning is the Convolutional Neural Network (CNN) [26]. These networks take inspiration from the human system and are designed to conduct hierarchical learning using sophisticated algorithms. This process involves the modeling of features at various levels, allowing the extraction of abstract representations from the input data. CNNs are constructed with multiple layers, including convolutional, activation, and pooling layers. To produce final output predictions, one or more Fully-Connected layers (FC) are added to the network. Ang et al. (2017) illustrated the architecture of a CNN using a diagram (see Fig. 1).

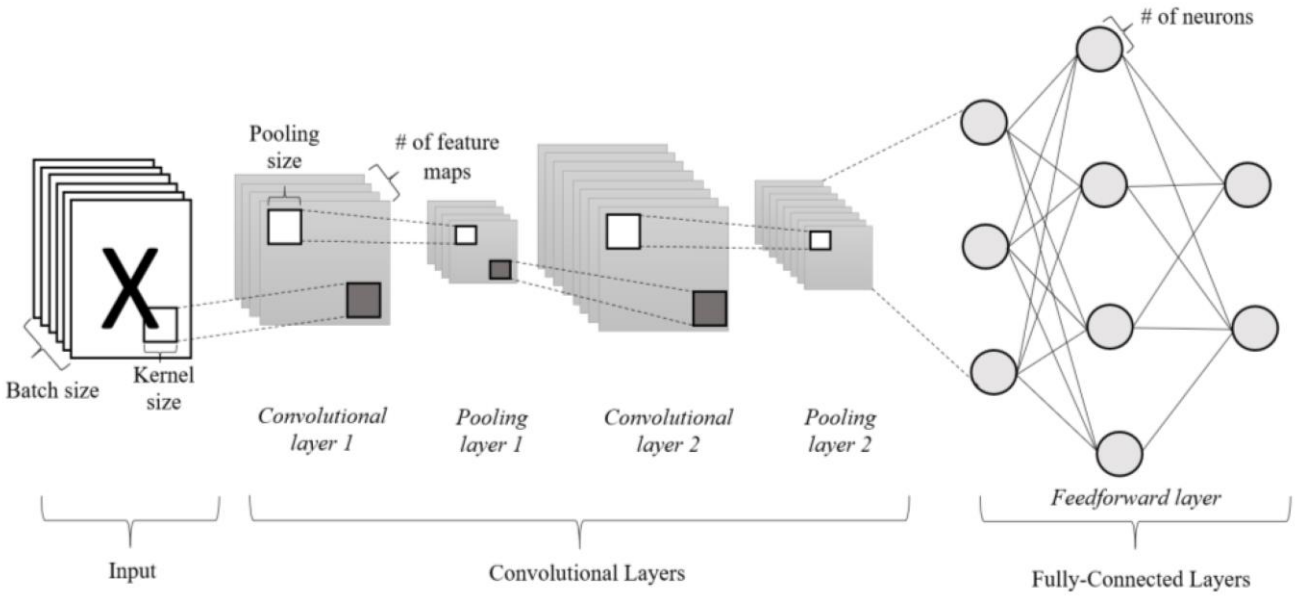

Fig. 1. The concept of a sequential convolutional neural network [27].

Various notable variations in the field of deep learning have been developed, with some well-known models leading the way. These models include LeNet [28], AlexNet [29], ResNet [30], and GoogLeNet [31]. Moreover, these models can be categorized into two main types: one-stage architectures and two-stage architectures. In a two-stage CNN, such as the Faster R-CNN (Region-based Convolutional Neural Network) [32], the object detection process is divided into two distinct steps: region proposal and classification. Initially, the model generates region proposals, which are essentially candidate regions within an image where objects might be situated. Once these region proposals are generated, each one is passed through a classifier to determine if it contains an object and, if so, to identify the class of the object. On the other hand, one-stage CNNs are designed for a more streamlined approach, where object detection occurs in a single step, without the need for a separate region proposal stage. These models directly predict bounding boxes and class labels for objects within an image, making them efficient and suitable for real-time object detection. However, it's worth noting that they may not always achieve the same level of accuracy as two-stage models in certain situations. Examples of one-stage CNNs include YOLO and the Single Shot MultiBox Detector (SSD).

F. LeNet Architecture

LeNet, a condensed form of "LeNet-5," represents an architectural framework introduced by LeCun et al. in 1998 [28] as depicted in Fig. 2. This landmark innovation has played an integral role in shaping the landscape of deep learning and CNN. It was one of the first successful applications of neural networks for computer vision tasks particular in handwritten digit recognition, specifically for recognizing digits in postal codes and zip codes.

LeNet's structure is distinctly organized into two core components: the Convolutional Part and the Fully-Connected Part. Within the Convolutional Part, three vital layer types are evident: an Input Layer designed to handle 32x32 grayscale images (though adaptability is included for zero-padding, as seen in datasets like MNIST), two Convolutional Layers (CL) employing 5x5 filters, and two Max-Pooling Layers tasked with efficient feature map downsampling. Meanwhile, the FullyConnected Part incorporates three FC, also known as Dense layers, responsible for capturing intricate data relationships, concluding with an Output Layer featuring a softmax function to categorize handwritten digits, as exemplified in the MNIST dataset, which consisted of images of numbers from 0–9 in black and white. Nevertheless, it was primarily designed for the specific task of recognizing handwritten digits, limiting its applicability to a broader range of image classification tasks.

G. AlexNet Architecture

In 2012, Krizhevesky et al. [29] introduced AlexNet, a pioneering convolutional neural network (CNN) that revolutionized deep learning. This innovation significantly enhanced the depth of CNNs and incorporated effective parameter optimization strategies, marking a breakthrough in the prestigious ImageNet Large Scale Visual Recognition Challenge (ILSVRC). AlexNet's remarkable achievement was evident in its top-5 error rate of just 15.3%, outperforming traditional computer vision methods and setting a new standard at the time. The concept of AlexNet is illustrated in Fig. 3.

AlexNet marked a significant milestone in the realm of deep convolutional neural networks by pioneering the training of complex models on an extensive dataset, comprising more than 15 million images and involving millions of model parameters. This achievement underscored the capacity of deep networks to extract intricate features from massive datasets. Moreover, AlexNet popularizedthe adoption of Rectified Linear Units (ReLU) [33] as an activation function,

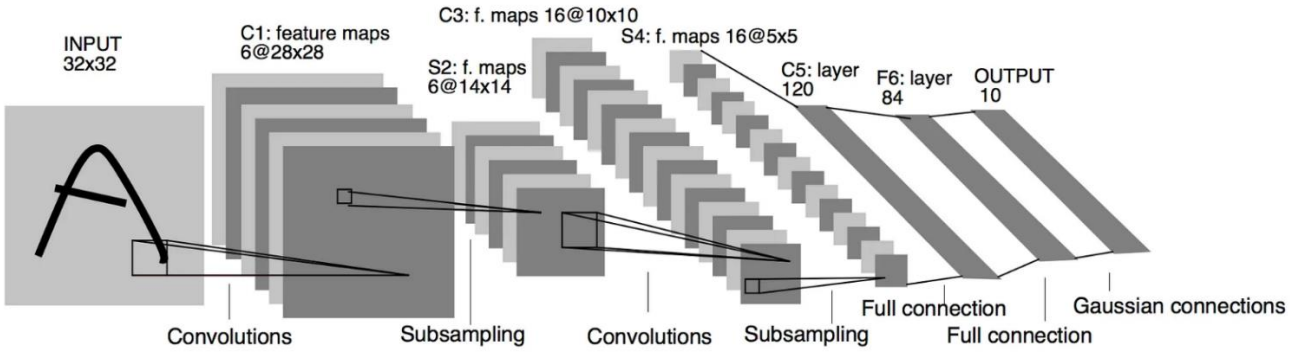

Fig. 2. The concept of LeNet [28].

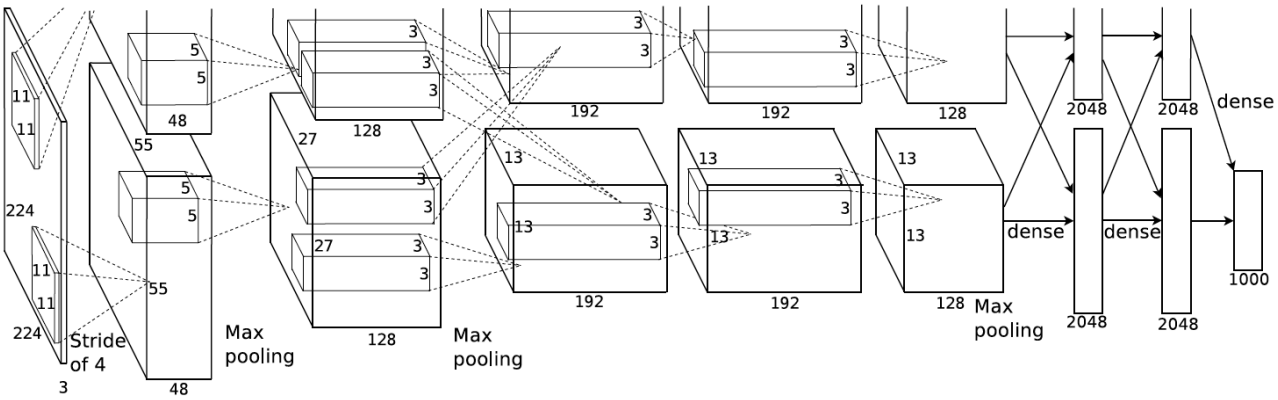

Fig. 3. The concept of AlexNet [29].

which not only improved computational efficiency but also expedited training convergence. Furthermore, to combat overfitting, a key concern in deep learning, the technique of dropout was introduced. This involved randomly setting 50% of the hidden neuron outputs to zero during training, effectively excluding them from the backpropagation process. These innovations not only contributed to AlexNet's success but also inspired the design of subsequent modern architectures.

H. GoogLeNet Architecture

In the 2014 ILSVRC, GoogLeNet, also known as Inception-V1, achieved first place [31] (Figure 4). A significant innovation of GoogLeNet lies in its use of inception modules, which are tailored to capture features at multiple spatial scales. These modules employ convolutional filters of different sizes, including 5x5, 3x3, and 1x1, to effectively integrate channel and spatial information across a range of spatial resolutions, enabling the network to extract features at both fine and coarse levels simultaneously. This design enhances feature learning efficiency.

Additionally, GoogLeNet incorporates 1x1 convolutions, which have the effect of reducing the dimensionality of feature maps, resulting in a computationally efficient architecture. This not only permits the construction of deeper networks but also significantly reduces the number of parameters to 5 million, as compared to AlexNet's 61 million. These designs make GoogLeNet well-suited for real-time and resource-efficient applications. However, GoogLeNet's limitations include its complexity, resource-intensive training, and reduced suitability for tasks beyond image classification.

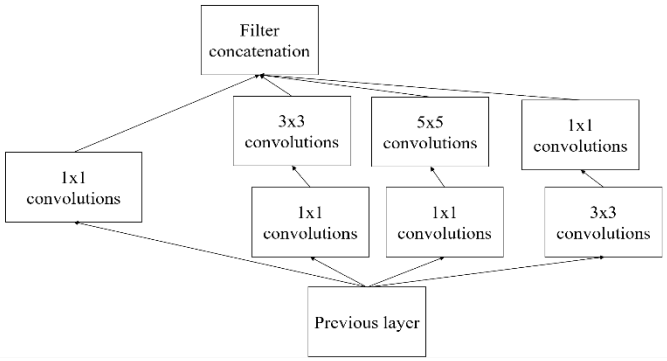

Fig. 4. GoogLeNet inception module [31].

I. ResNet Architecture

ResNet, introduced by He et al. [30], made a significant breakthrough in deep learning by winning the ILSVRC 2015 competition with a remarkably deep architecture of 152 layers, over 20 times deeper than AlexNet. The core challenge that ResNet addresses is the training of such deep neural networks, which previously suffered from issues like vanishing gradients and a decline in accuracy with increased depth. In order to overcome these challenges, ResNet introduces a groundbreaking concept known as residual connections, commonly denoted as skip connections. These ingenious connections serve to ease the training of exceptionally deep networks by promoting the efficient flow of gradients during the training process. Each residual block in a ResNet contains a

"shortcut connection" that bypasses one or more layers, enabling the network to learn residual functions. Essentially, this results in a combination of a traditional feedforward network and a residual connection. These residual functions capture the difference between the desired output and the current layer's output, making it easier for the network to learn identity mappings. ResNet models are available in various depths, including ResNet-50, ResNet-101, and ResNet-152, which are widely adopted for image classification tasks.

J. Faster R-CNN

Ren et al. [32] proposed Faster R-CNN algorithm, with the idea of introducing the idea of integrating region proposal generation within a deep neural network. Faster R-CNN introduces the RPN, also known as region proposal network, a neural network module designed to generate region proposals directly from the input image. This replaces the need for external algorithms like selective search or edge boxes.

The RPN take an image from any size and suggests candidate object bounding boxes based on learned features from the image. The RPN employs anchor boxes, which are pre-defined bounding box shapes at various scales and aspect ratios. These anchor boxes are used to propose object regions efficiently. Faster R-CNN uses a two-stage detection approach. In the initial stage, the Region Proposal Network (RPN) is responsible for generating region proposals. Subsequently, the second stage entails the involvement of another CNN, known as Fast R-CNN [34], which carries out object detection and precise bounding box regression based on the generated region proposals.

K. YOLO Architechture

The primary innovation in Faster R-CNN lies in its Region Proposal Network (RPN), which generates high-quality region proposals directly within the network. This advancement results in faster inference times while upholding the required accuracy for object detection tasks. However, Faster R-CNN's two-stage architecture introduces a complex pipeline, demanding precise tuning of each stage independently, resulting in a system with significant computational overhead.

In an attempt to simplify the process and make it more efficient, YOLO (see Fig. 5), created by Redmon and his team [35], takes a unique approach. YOLO partitions the input image into a grid$S \times S$ cells, grid cell is tasked with object detection if the object's center is located within it. These grid cells make predictions for B bounding boxes, complete with confidence scores and C class probabilities. These predictions are organized as a tensor with dimensions $S \times S \times (B \times 5 + C)$ .Within this framework, the input image is effectively partitioned into $S \times S$ sub-images, where 'five' signifies the detection of attributes like height, width, confidence score, and central coordinates (x, y) for each bounding box.

Moreover, YOLO consolidates the various aspects of object detection into a unified neural network, utilizing information from the entire image to make predictions for each bounding box. This integration enables YOLO to simultaneously forecast bounding boxes for all categories within a given image. YOLO's architecture offers the advantages of end-to-end training and real-time processing speed, all while upholding a high level of precision in object detection. Taking cues from the architectural advancements of GoogLeNet, YOLO is structured with a series of 24 CL, supplemented by 2 FC layers. In contrast to GoogLeNet's inception modules, YOLO follows a more straightforward approach, integrating 1×1 reduction layers followed by 3×3 CL. Additionally, YOLO exhibits certain similarities with R-CNN, particularly Faster R-CNN, where each grid cell generates potential bounding boxes and assigns scores to them. Subsequently, a Non-Maximum Suppression (NMS) mechanism is employed to eliminate redundant or overlapping bounding boxes after predictions are computed across all grid cells using convolutional features.

Since its initial introduction in 2016, YOLO has undergone a series of evolutionary iterations, adapting to the specific requirements of diverse fields within human life. Each subsequent version of YOLO has been meticulously refined to meet the ever-evolving challenges and demands of real-time object detection and various computer vision applications.

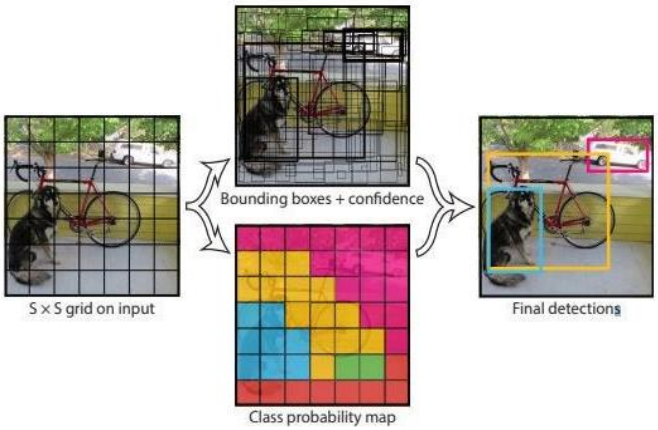

Fig. 5. The concept of YOLO [34].

III. RESULTS

While YOLO's recent trends have leaned towards real-time applications, its potential in the medical imaging field, particularly for diagnosing Alzheimer's disease (AD), has drawn significant interest. Originally developed for object recognition, the adoption of YOLO in AD diagnosis has shown promise. Nevertheless, the need for further research, as highlighted in Table I, emphasizes the importance of ongoing investigations to advance AD diagnosis and treatment.

TABLE I. SUMMARY OF ALZHEIMER'S DISEASE DIAGNOSIS STUDIES

Article	Data	DL Architecture	Results
Alon et al. (2020)[36]	1000 MRI images (70% for training, and 30% for validation) 20 images for testing	YOLOv3	80% testing accuracy
Islam et al. (2023)[37]	400 images for training and 100 images for validation	From YOLOv3 to YOLOv7	Illustrated in Table II.
Fong et al. (2021)[38]	500 raw MRI image	Faster R-CNN, YOLOv3, SSD	Illustrated in Table III.
Abd-Aljabar et al.[39]	300 raw MRI images	YOLOv2	98% accuracy
Uddin et al. (2022)[40]	6400 MRI images (Training and test in 4:1 ratio)	YOLOv4, AlexNet, Faster R-CNN	YOLOv4: 99% accuracy Faster R-CNN: 84% accuracy AlexNet: 99%

IV. DISCUSSION

Uddin et al. [40] conducted a comparative analysis of three distinct deep learning architectures, namely YOLOv4, AlexNet, and Faster R-CNN. Their research encompassed a substantial dataset comprising 6400 MRI images, making it the largest dataset among the studies reviewed. However, a notable aspect of their dataset was the relatively limited number of CN (cognitively normal) images, which stood at 2560 training images. This dataset composition, characterized by an abundance of CN images and a scarcity of AD (Alzheimer's disease) and MCI (mild cognitive impairment) images, raised concerns about the potential for overfitting. The resulting models exhibited a propensity to classify most images as CN due to the skewed distribution of classes. This highlights the need for improved dataset balance, including a more representative inclusion of AD and MCI images. Addressing this class imbalance could lead to more reliable and accurate classification results, reducing the risk of overfitting and enhancing the model's overall performance.

In a study conducted by Alon et al. [36], the YOLOv3 architecture demonstrated an accuracy rate of 80%, which was notably the lowest among the studies under review. It's important to highlight that this study employed a significant dataset comprising 1000 MRI images for training and validation, achieving impressive results with training accuracy reaching 98.617%, validation accuracy at 98.8207%, and a mean average precision (mAP) of 96.17%. However, it's crucial to consider certain factors that might impact the reliability and generalizability of these findings. One notable concern is the study's reliance on a relatively small subset of only 20 MRI images for testing. The limited size of the testing dataset introduces an element of uncertainty into the model's performance, as it may not fully capture the intricacies and variations present in a more extensive dataset. Additionally, the absence of information regarding any pre-processing procedures applied to the dataset raises questions about the data's quality and its readiness for deep learning analysis. To enhance the credibility of these findings and ensure their generalizability, it is advisable to conduct further evaluations on larger and more diverse datasets. This would not only provide a more comprehensive assessment of the model's robustness but also validate its performance across a broader range of MRI images.

In a concurrent research effort, Islam et al. [37] undertook a comprehensive investigation into the use of various YOLO versions for image classification. Their study aimed to evaluate the performance of different YOLO iterations in the context of object recognition. Comparatively, the findings revealed that YOLOv3 and YOLOv4 outperformed YOLOv5. This difference in performance was attributed to the adaptable Darknet3 backbone, a crucial component of YOLOv3 and YOLOv4, which excels in the task of object detection. The Darknet3 backbone's architecture and capabilities enhanced the accuracy and efficiency of these YOLO versions. A noteworthy advancement came in the form of YOLOv6 and YOLOv7, which surpassed the capabilities of YOLOv4. This improvement was achieved by passing the input through multiple (CNN) layers in the backbone, resulting in increased computational efficiency and better overall performance. However, it's important to note that these models primarily focused on single-class detection, which may limit their applicability in scenarios where multi-class detection is required. The detailed results are presented on Table II.

TABLE II. ISLAM ET AL. [37] STUDY RESULT

	AD-Level	Accuracy (%)	mAP 0.5
YOLOv3	AD	95	0.98
	MCI	90	0.92
	CN	93	0.93
YOLOv4	AD	87	0.99
	MCI	85	0.97
	CN	85	0.98
YOLOv5	AD	90	0.99
	MCI	85	0.99
	CN	84	0.99
YOLOv6	AD	92	0.96
	MCI	90	0.80
	CN	91	0.90
YOLOv7	AD	97	0.99
	MCI	96	0.99
	CN	97	0.99

TABLE III. FONG ET AL. [38] STUDY RESULT

Image Interference Size (IMF)	200^2	300^2	400^2	500^2	600^2	700^2
YOLOv3 Accuracy	99.66	99.66	99.83	99.83	99.49	99.66
SSD Accuracy	94.18	96.23	98.12	97.77	98.29	97.43
Faster R-CNN Accuracy	-	-	74.14	94.86	98.12	98.8

Concurrently, Fong et al. [38] (see Table III) embarked on an extensive investigation aimed at streamlining the pre-processing stage in the context of medical image analysis. They achieved this by implementing YOLOv3 and employing a dataset consisting of Abd-Aljabar et al. [39] also utilized YOLOv2 with a dataset of 300 raw MRI images, achieving a result of 98% accuracy, which is slightly lower than Fong et al.'s research at 99.8%. Nevertheless, this outcome reaffirms the effectiveness of YOLO variations in handling raw and unprocessed MRI images, offering an alternative approach to streamline the pre-processing stage in medical image analysis. These findings collectively emphasize the adaptability and robustness of YOLO-based models in handling diverse image data without the need for extensive pre-processing, potentially simplifying the workflow for neuroimaging analysis individual predictions.

In summary, YOLO has proven to be a promising tool for tasks related to Alzheimer's disease diagnosis and classification. However, it's crucial to acknowledge the persistent challenges that hamper progress in the field of neuroimaging research. These challenges encompass the scarcity of available data, a pronounced imbalance in class distribution within datasets, and a noticeable research gap. Addressing these issues through further data collection, careful dataset curation, and expanded research efforts is essential to fully unlock the potential of YOLO and other deep learning approaches in the critical domain of neuroimaging research.

V. Conclusion
