The training set, which accounts for the majority (80%) of the dataset, is utilized to train the YOLOv5 model. During training, the model learns from the annotated images, optimizing its parameters to improve pothole detection accuracy. By exposing the model to a diverse range of pothole images and their corresponding annotations, it becomes capable of recognizing and localizing potholes effectively. Training typically involves iterating through multiple epochs, gradually refining the model's performance.

The validation set, comprising 13% of the dataset, is utilized to appraise the performance of the model during training. It serves as a means to monitor the model's progress and assess its generalization capabilities. The model's performance metrics, such as detection accuracy and loss values, are measured on this set. The validation set aids in identifying potential issues like overfitting, where the model becomes overly specialized to the training data but fails to generalize well to new, unseen examples. If overfitting is observed, adjustments can be made to the model architecture, regularization techniques, or hyperparameters to improve accuracy and generalization.

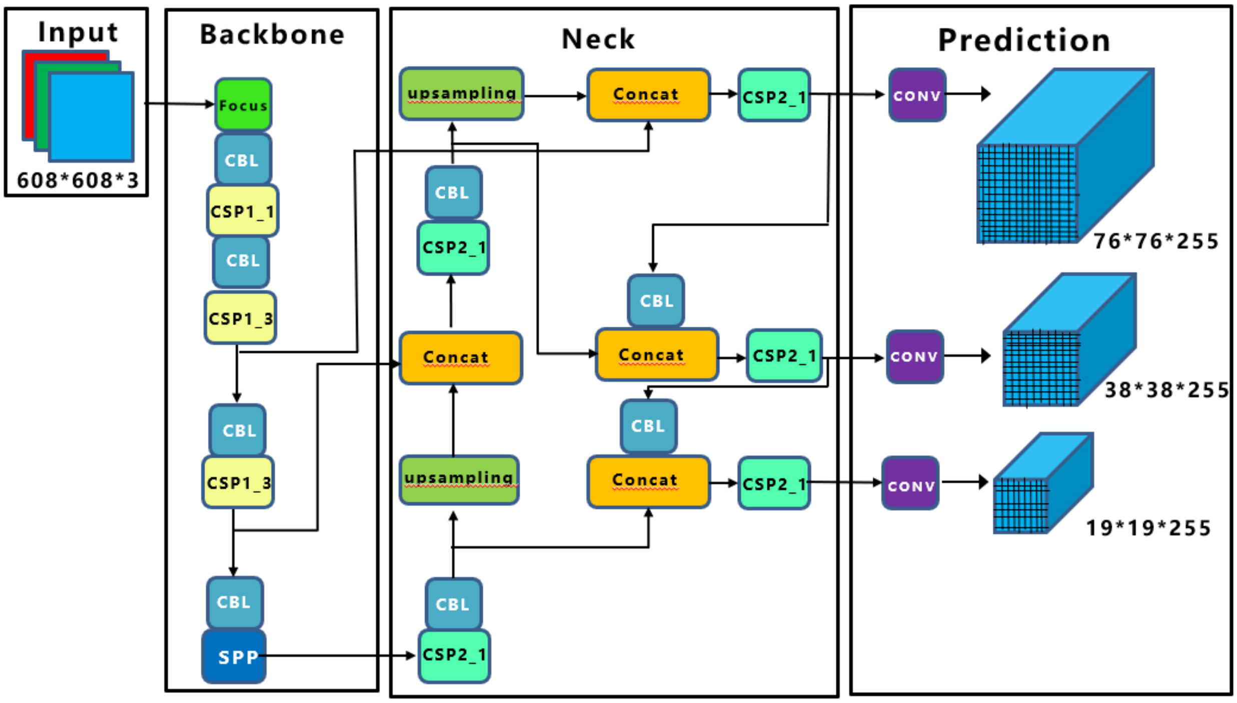

Fig. 2. The architecture of YOLOv5 [19].

Lastly, the testing set, which consists of 7% of the dataset, is reserved for the final evaluation of the trained YOLOv5 model. This set serves as an unbiased benchmark to assess the model's performance on unseen data. By applying the model to the testing set, we can measure its effectiveness in detecting potholes and evaluate its overall recall, accuracy, precision, and other relevant performance metrics. This evaluation helps to validate the model's capabilities as well as determine its readiness for deployment in real-world scenarios.

IV. Experimental Results

In this section, the YOLOv5 algorithm is compared to other algorithms. This comparison is presented to prove the YOLOv5 model enables to present better performance compared to another algorithm. Different versions of YOLOv5 and YOLO-Z models are compared in terms of the Mean Average Precision (MaP) metric. This comparison is inspired by the study in [20]. The comparison of the YOLOv5 and YOLO-Z versions is illustrated in Fig. 3.

Performance comparison between the YOLOv5 and YOLO-Z families of models, plotting mAP (top) is analysed. The superior average performance of YOLOv5 is achieved, while performance is stable and very close to 1 [20]. Performance comparison between the YOLOv5 and YOLO-Z families of models was conducted, with the mean average precision (mAP) plotted for evaluation. The results clearly indicate the superior average performance achieved by YOLOv5 compared to the YOLO-Z models. The mAP values for YOLOv5 remained stable and consistently close to 1, indicating a high level of accuracy and reliability in pothole detection. On the other hand, the YOLO-Z models exhibited slightly lower mAP scores, suggesting a relatively lower performance in terms of pothole detection accuracy.

The superior average performance of YOLOv5 can be attributed to several factors. Firstly, YOLOv5 benefits from architectural improvements and optimizations compared to the YOLO-Z models. These enhancements allow YOLOv5 to effectively capture and analyze visual features relevant to pothole detection, resulting in higher precision and recall rates. Secondly, YOLOv5 incorporates advanced training strategies and data augmentation techniques, enabling the model to generalize well to diverse road conditions and pothole appearances. This robustness contributes to its stable and consistently high performance across various scenarios.

A. Results of Yolov5 Models in Different Architectures

The performance of YOLOv5 models on Google Colab is well-established, but their performance on mobile devices remains uncertain. While the model's accuracy is unaffected by the execution platform, factors such as available resources and architecture can impact its performance and inference time. To assess the viability of using YOLOv5 models in real-time on mobile devices that inspired from study [21], several experiments are conducted using an iPhone 12 equipped with different system-on-a-chip (SoC) components. These components included an Apple Neural Engine (ANE), a graphical processing unit (GPU), and a central processing unit (CPU).

As shown in Fig. 4, we observed consistent patterns similar to those observed in the previous experiment. It is worth noting that the YOLOv5s model, which is the smallest in terms of size, exhibited the shortest inference time. However, as the complexity of the model increased, its inference speed decreased proportionally. Among the architectures we examined, it became clear that the ANE architecture demonstrated the fastest inference. This characteristic makes it particularly well-suited for running YOLOv5 models on the iPhone 12.

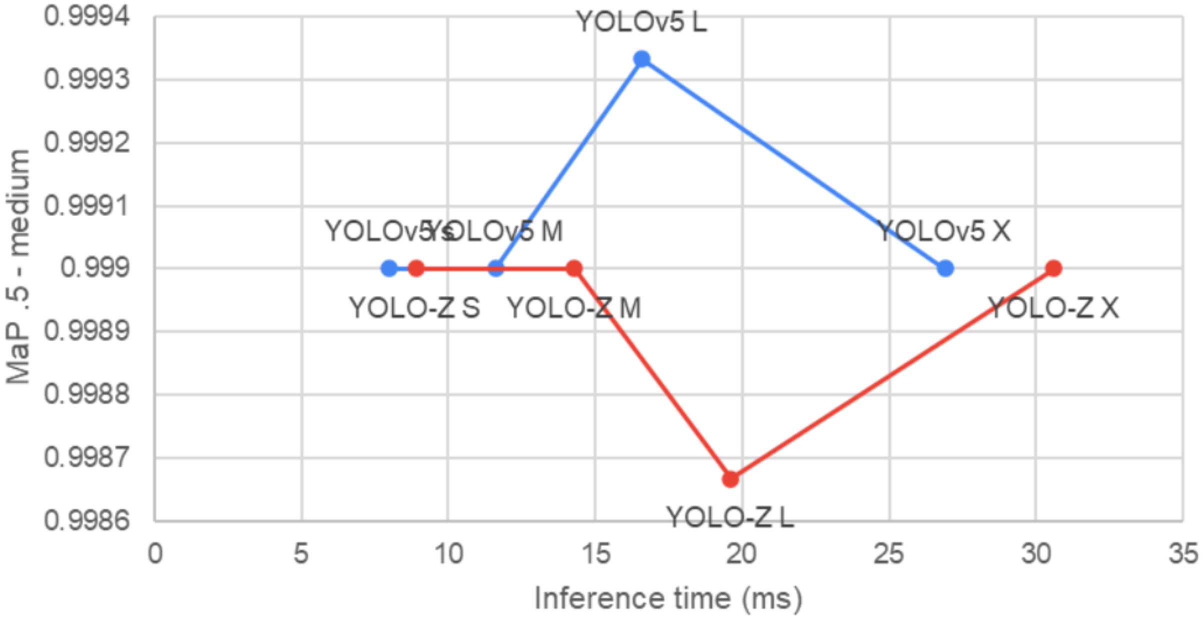

Fig. 3. Performance comparison between the YOLOv5 and YOLO-Z families of models [20].

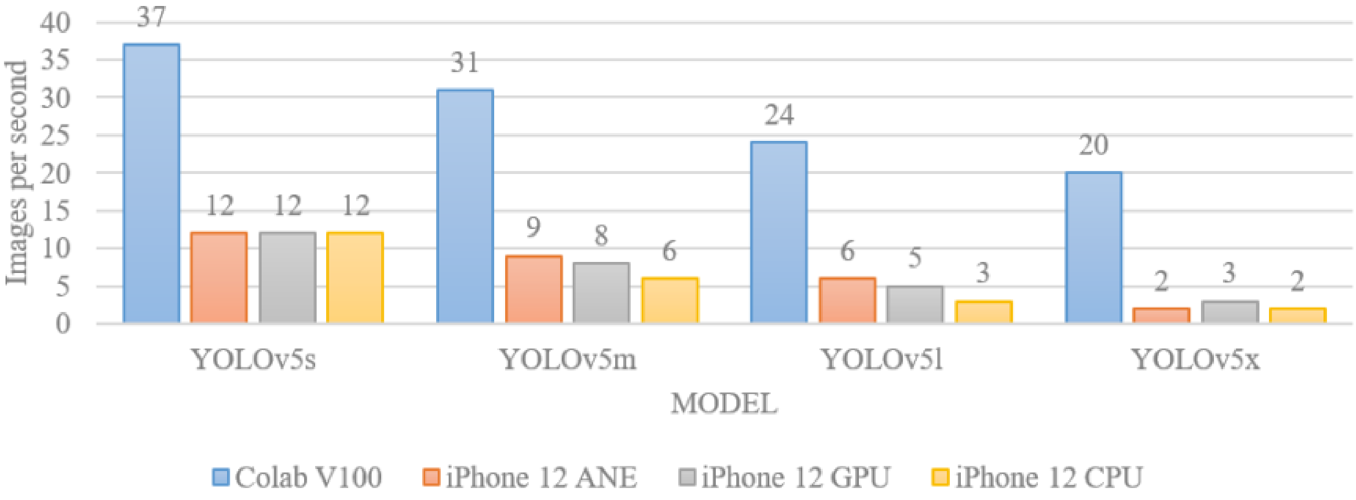

Fig. 4. Comparison of different architectures of YOLOv5 models [21].

Through the comparison of the different models, we encountered similar trends as in the previous experiment. The YOLOv5s model, due to its smaller size, required the least amount of time for inference. Conversely, as the model's complexity grew, its inference speed decreased accordingly. Notably, when considering the various architectures, the ANE architecture stood out for its superior performance in terms of inference speed. Consequently, for optimal execution of YOLOv5 models on the iPhone 12, the ANE architecture emerged as the most appropriate choice, as it consistently delivered the fastest inference results.

B. *Results of our Experiments*

In this study, the proposed YOLOv5 model, generated through our training and validation processes, is implemented and tested on various image sets. The experimental results, illustrating the performance of our model, are presented in Fig. 5. The figure provides a visual representation of the effectiveness and accuracy of our YOLOv5-based approach in detecting potholes. Through these experiments, we demonstrate the practicality and robustness of our model, highlighting its potential for real-world applications in pothole detection tasks.

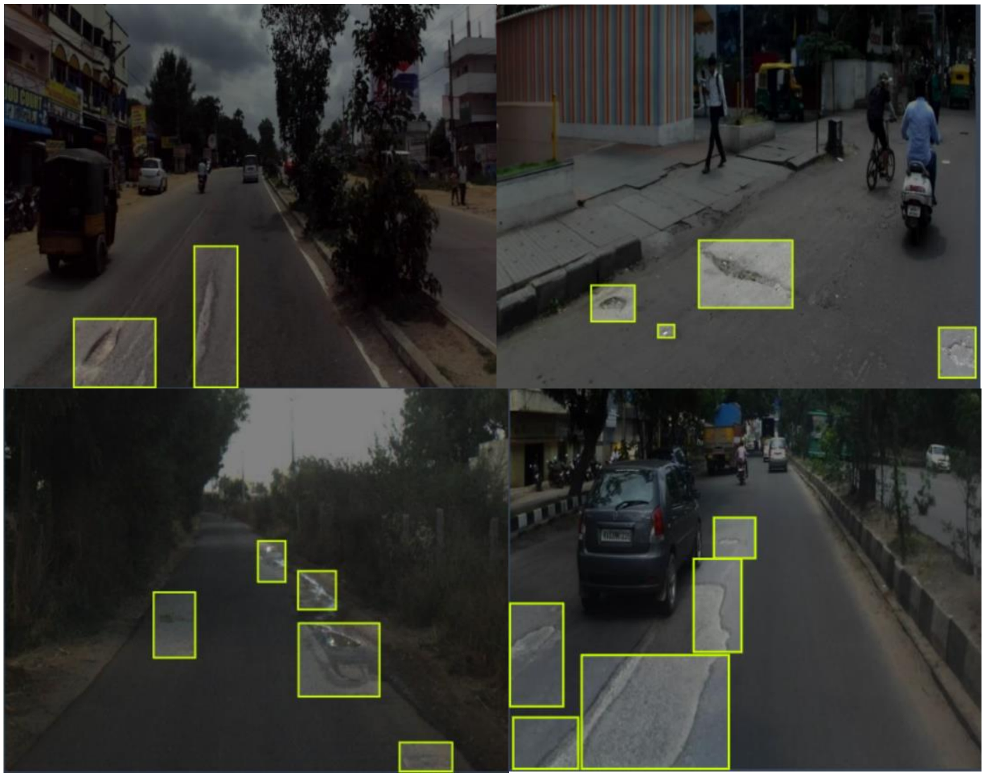

Fig. 5. Sample of experimental result.

C. *Performance Evaluation*

Performance evaluation of a generated YOLOv5 model is typically assessed by analyzing the training and validation losses. The training loss measures how well the model is learning during the training phase, while the validation loss evaluates its performance on unseen data. By examining these two metrics, one can gain insights into the model's ability to generalize as well as make accurate predictions. During the training process, the YOLOv5 model's training loss is monitored and analyzed. The training loss indicates the disparity between the forecasted bounding boxes and the ground truth labels for the training images. A lower training loss suggests that the model is effectively learning to detect objects and minimizing the error between its predictions and the actual objects present in the images. However, it is important to strike a balance between reducing the training loss as well as avoiding overfitting, where the model becomes too specialized to the training data and fails to generalize well to new data. Fig. 6 shows training/loss graphs of the generated model.

The validation loss is evaluated using a separate set of images that the model has not seen during training. This metric provides an estimate of how well the model is performing on new, unseen data. A low validation loss indicates that the model is generalizing well and making accurate predictions on unfamiliar images. If the validation loss is significantly higher than the training loss, it suggests that the model may be overfitting to the training data, highlighting the need for regularization techniques such as dropout or data augmentation to improve generalization. By closely monitoring the training and validation losses, researchers and practitioners can iteratively refine the YOLOv5 model to achieve better performance and enhance its object detection capabilities. Fig. 7 shows validation/loss graphs of the generated model.

In YOLOv5, the graphs involving "train/box_loss," "train/obj_loss," and "train/cls_loss" provide insights into the training process and help us achieve accuracy in the pothole detection model. Training a YOLOv5 model for pothole detection involves monitoring the "train/box_loss," "train/obj_loss," and "train/cls_loss" graphs. These graphs provide insights into the model's performance during training and are crucial for achieving accuracy.

A lower "train/box_loss" indicates that the model is accurately localizing potholes by predicting precise bounding box coordinates. Reducing the "train/obj_loss" demonstrates that the model is effectively distinguishing potholes from other objects or background areas. Minimizing the "train/cls_loss" suggests that the model is correctly classifying potholes. To achieve accuracy, data augmentation techniques, such as applying transformations to training data, help the model generalize better.

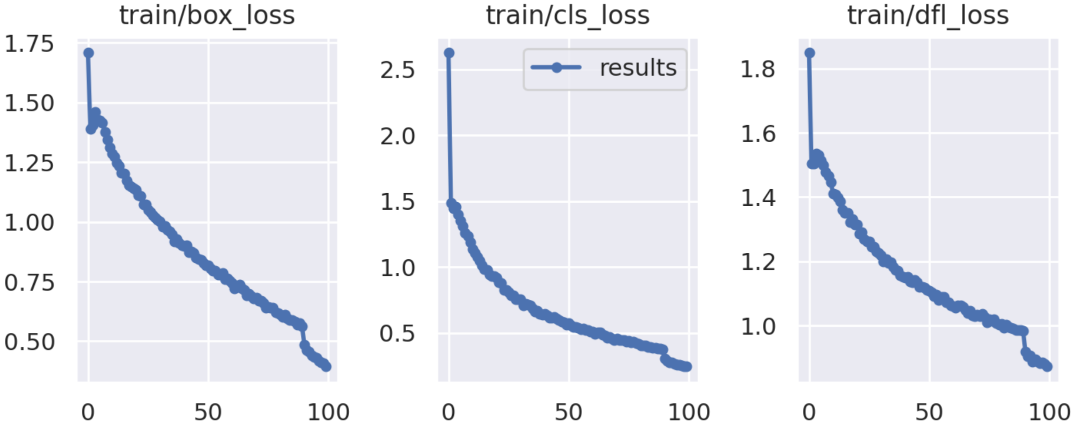

Fig. 6. Training/losses graphs of the generated model.

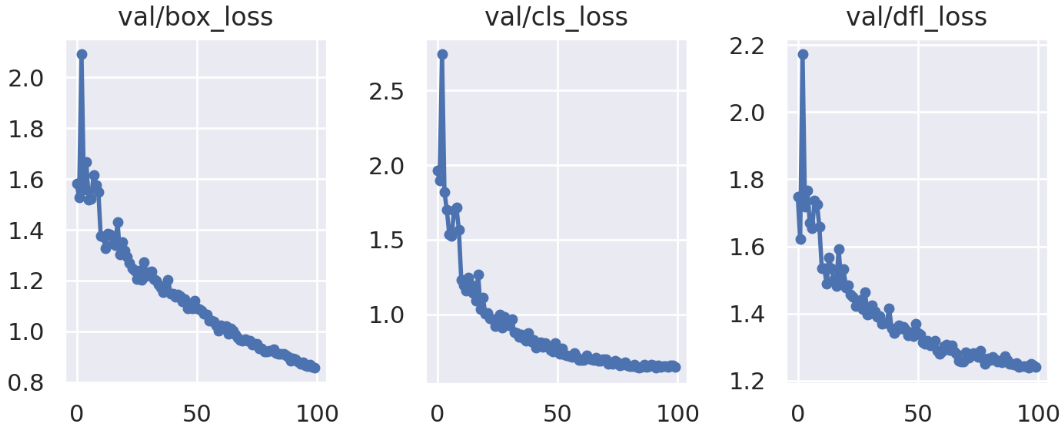

Fig. 7. Validation/loss graphs of the generated model.

Optimizing hyperparameters specific to YOLOv5, such as learning rate and weight decay, is crucial. Monitoring and analyzing the loss graphs during training is vital, allowing adjustments to be made if any loss value becomes stagnant or starts increasing. Through an iterative process of training, evaluation, and adjustment, the YOLOv5 model can learn and refine its pothole detection capabilities, ultimately achieving accuracy in identifying and classifying potholes.

In YOLOv5, the validation graphs involving "val/box_loss," "val/obj_loss," and "val/cls_loss" provide insights into the performance of the pothole detection model during the validation phase. These graphs help us evaluate and improve the accuracy of the model. In the following, we discuss each of these validation graphs and how they contribute to achieving an accurate model:

"Val/box_loss" graph: This graph represents the box regression loss during validation. Box regression loss measures the discrepancy between predicted bounding box coordinates and the ground truth coordinates of the potholes. A lower box loss indicates that the model is accurately localizing the potholes' positions. To achieve an accurate model, you would monitor the "val/box_loss" graph and aim to minimize it over the training iterations. Decreasing box loss signifies that the model is improving its ability to predict the bounding boxes around potholes precisely.

"Val/obj_loss" graph: This graph depicts the objectness loss during validation. Objectness loss measures the confidence of the model in detecting whether a pothole exists within a bounding box. It represents the ability of the model to discriminate between potholes and non-pothole regions accurately. To achieve accuracy, you would aim to reduce the "val/obj_loss" value. Lower objectness loss shows that the model is more proficient at distinguishing potholes from other objects or background areas.

"Val/cls_loss" graph: This graph represents the classification loss during validation. Classification loss measures the accuracy of the model in assigning the correct class label (e.g., "pothole") to the detected objects. To achieve accuracy, you would strive to minimize the "val/cls_loss" value. A lower classification loss shows that the model is correctly identifying potholes and effectively distinguishing them from other object classes.

In our generated model, to achieve an accurate model, you would typically iterate on the training process, adjusting various parameters and monitoring the validation graphs. The objective is to see a gradual reduction in losses over time, demonstrating that the model is learning and improving its ability to detect and classify potholes accurately.

As results, the application of deep learning is pivotal in overcoming the inherent challenges associated with pothole detection, with our primary objectives being the attainment of elevated accuracy, non-destructiveness, and real-time processing capabilities. A critical aspect of our approach involves the development of a meticulously curated dataset, tailored specifically for training our model. This dataset encompasses diverse road conditions and various instances of potholes, ensuring the robustness and adaptability of our detection system. Through a comprehensive evaluation process, involving stringent validation, training, and testing protocols, we establish the effectiveness of our proposed method. Leveraging the YOLOv5 algorithm, our model not only refines the precision and stability of pothole detection but also contributes significantly to the overall efficiency of intelligent transportation systems. The generated model using YOLOv5 advancements not only enhances the accuracy and stability of pothole detection but also contributes to the overall efficiency of intelligent transportation systems. The results emphasize the value of adopting state-of-the-art models like YOLOv5 for real-time pothole detection tasks, ensuring optimal performance and facilitating proactive maintenance and repair of road infrastructure.

V. Conclusion

In this research, we present a novel approach for detecting potholes using video analysis and deep learning techniques. By utilizing deep learning, our aim is to address the aforementioned research challenges and meet the requirements of achieving high accuracy, non-destructiveness, and real-time processing. To train our model effectively, we have created a custom dataset specifically tailored for the pothole detection task, which covers a wide range of road conditions and various instances of potholes. Through rigorous validation, training, and testing procedures, we demonstrate the efficacy of our suggested method. The developed model, employing the YOLOv5 algorithm, not only enhances the precision and stability of pothole detection but also contributes to the overall efficiency of intelligent transportation systems. These findings underscore the significance of adopting cutting-edge models like YOLOv5 for real-time pothole detection applications. This approach ensures optimal performance and facilitates proactive maintenance and repair of road infrastructure, promoting safer and more efficient transportation networks. For future research in the field of pothole detection, the integration of additional sensor modalities, such as LiDAR or infrared imaging, alongside vision-based methods can be explored to enhance the accuracy and robustness of pothole detection systems. Moreover, investigates the use of transfer learning techniques to leverage pre-trained deep learning models on large-scale datasets from related tasks, enabling efficient and effective pothole detection even with limited training data. Furthermore, the number of experiments can be increased to obtain more relevant and accurate results that can b e investigated for future works.

***Abstract*—Cloud service providers offer a trustworthy and resistant-based storage environment for on-demand cloud services to outsource clients' data. Several researchers and business entities currently adopt cloud services to store their data in remote cloud storage servers for cost-saving purposes. Cloud storage offers numerous advantages to users like scalability, low capital expenses, and data available from any place, anytime, regardless of location and device. However, as the users lose physical access and control over data, the storage service raises security and privacy issues, such as confidentiality, integrity, and availability of outsourced data. Data integrity is a primary concern for cloud users to confirm whether data integrity is intact or not. This paper presents a comprehensive review of cloud data auditing schemes and a comparative analysis of the desirable features. Furthermore, it provides advantages and disadvantages of the state-of-the-art techniques and a performance comparison regarding the communicational and computational costs of involved entities. It also highlights desirable features of different techniques, open issues, and future research trends of cloud data auditing protocols.**

Keywords—Cloud computing; proof of possession; data integrity auditing; proof of retrievability; public auditing; proof of ownership

I. Introduction

Cloud computing is a new, rapidly emerging technology paradigm [1, 2], which can resolve large-scale service issues in multiple industries, such as engineering, sciences, and e-commerce [3]. Currently, several Cloud Service Providers (CSPs), for example, Linode [4], Amazon EC2 [5], Google Cloud Platform [6], and Microsoft Azure [7], manage and distribute shared resources for cloud users [8, 9]. Cloud computing offers manageable shared resources like services, networks, servers, applications, and storage that can be accessed over the Internet and managed with minimal effort without the interaction of cloud service providers [10, 11]. Generally, the distributed shared resources of the CSPs are available to their clients based on the pay-as-you-go. The CSPs mainly offer services like Platform-as-a-Service, Software-as-a-Service, and Infrastructure-as-a-Service [12, 13], as shown in Fig. 1. The web applications we used years ago, for instance, YouTube, Facebook, Instagram, and Twitter, are examples of cloud computing services. Furthermore, Dropbox, Amazon web services, and Google applications are generally utilized for personal and business purposes to store and share information anywhere and anytime via the Internet.

The critical part of this business model is to outsource and share data for distributed computing. Cloud storage is an elastic on-demand service model that attains significant benefits; for example, it decreases storage administration burden and reduces infrastructure and software costs. Moreover, it helps to access data from various geographic locations, focusing on ease of maintenance, efficient computation [14], data storage, data archival disaster recovery, etc. [15]. Statista reported that the cloud computing business model persistently develops and is estimated to reach 379 billion US dollars by 2022, showing a tremendous increase in this service sector [16].

Even though the adoption and development of cloud computing businesses are growing every year, most corporations are not satisfied with using this business model due to some obstacles, like pricing, interoperability, vendor lock-in, reliability, and security [17]. Security is the most critical concern [17] because it can be compromised while transferring the data from one location to another by cloud administrators, dishonest CSPs, malware, or other malevolent users who can mutilate the data [18].

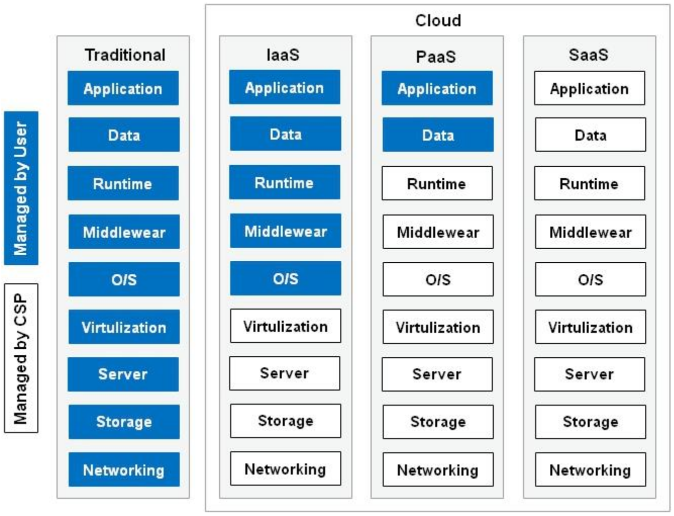

Fig. 1. Service-oriented architecture of cloud computing.

*Corresponding Author.

An insecure storage server can lead to data or privacy leakage if unauthorized users get access to data. For example, the infamous data breach incident of Microsoft's business cloud suit in which unauthorized users gained control of data [19, 20]. Statista shows that the total spending on IaaS is increasing every year [21], and with the increase in cloud demand [21], many security incidents were reported in the top CSPs [22]. The association of information audit systems defines data security as a combination of three fundamental components, i.e., confidentiality, integrity, and availability, also known as the CIA triad [23].

As contribution this paper highlight that cloud computing saves time and monitoring costs for any organization and turns technological solutions for large-scale systems into server-to-service frameworks.

A. *Background*

Cloud data storage related to IaaS is one of the critical business services offered by CSPs [24, 25]. It provides storage space for users or business organizations to host their personal or business data, as illustrated in Fig. 2. It is an ongoing trend for clients to host their data on remote storage servers. Besides the benefits, the CSPs also incorporate the critical apprehensions for the CIA security fundamentals of their client’s data. The main goal is to maintain the integrity of hosted data in the Cloud Storage Servers (CSS) [26, 27].

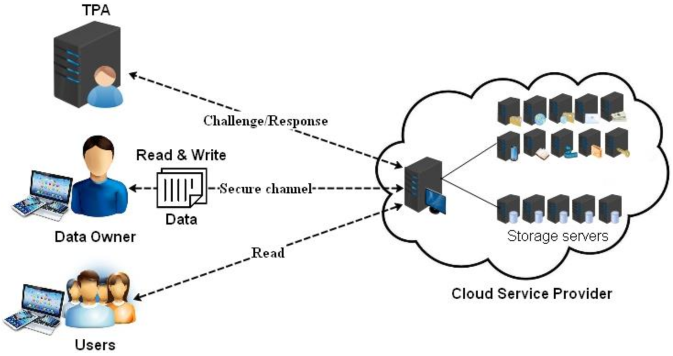

Fig. 2. The architecture of data integrity auditing protocol.

The security of remote data storage is essential because the user loses physical control of their data. One of the solutions to ensure data integrity is to utilize the fundamental cryptographic strategies based on signature and data hashing methods. However, these types of techniques need to store a local copy. Besides, it is unreasonable for the clients to retrieve all the hosted data to confirm its integrity, which incurs high communication overhead over the networks and clients and increases the communication cost. Hence, clients need auditing services for remote data storage to authenticate data integrity periodically.

Currently, researchers are focusing more on verifying the data integrity of the cloud storage servers. However, the cloud server is labelled as an adversary, and the Third-party Auditor (TPA) might see the data contents during the data auditing phase. To overcome these issues, several researchers have proposed different data security techniques. These security techniques can be mainly classified into three categories, namely Proof-of-Data Possession (PDP), Proof-of-Retrievability (PoR), and Proof-of-Ownership (PoW).

1) PDP: These techniques allow the storage server to confirm to its users that the CSPs control the hosted data with probabilistic-based assurance. However, it cannot support the recovery of data exploitation, and the data damage is irrecoverable. This causes serious concerns among cloud users, such as data loss, trust loss, financial damage, etc.

2) PoR: These techniques ensure data integrity and address the limitation of PDP techniques by supporting data exploitation recovery with Error Correction-code (ECC).

3) PoW: In these schemes, the storage servers focus on ownership of data, know which is owned by which user, and prevent downloading remote data by malicious or illegal users.

B. *Contributions*

In this article, we comprehensively studied several data integrity auditing techniques. The main contributions of this work are mentioned as follows:

1) Briefly discuss system models, basic notations, and security preliminaries used in RDA schemes.

2) Presents a comprehensive review and basic requirements of several cloud data auditing schemes.

3) Comparative analysis with desirable security features of efficient and secure data auditing protocols has been presented.

4) Provides advantages and disadvantages of the state-of-the-art data auditing schemes.

5) Evaluate the performance in terms of communication and computational cost for different entities and the data structures involved in the RDA schemes.

6) Identifies different challenges and future research trends of RDA schemes.

C. *Organizations*

Section II presents the fundamentals of Remote Data Auditing (RDA) techniques, including system models, notations, and preliminaries used to design RDA protocols. Section III presents state-of-the-art data auditing schemes with basic security requirements. The comparative analysis along desirable security parameters to ensure data integrity and overcome the privacy leakage of RDA protocols is presented in Section IV. Later, Section V presents a comparison and evaluates the performance of different protocols and data structures involved in schemes. Section VI highlights open research issues to design efficient data auditing protocols, and Section VII describes possible future research trends. Finally, we conclude the paper in Section VIII.

II. Fundamentals of RDA Techniques

This section briefly describes the system models, necessary notations, and security preliminaries used for data integrity auditing protocols.

A. System Models

Cloud data storage related to IaaS is one of the critical business services offered by CSPs [24, 25]. It provides storage space for users or business organizations to host their personal or business data, as illustrated in Fig. 2. It is an ongoing trend for clients to host their data on remote storage servers. Besides the benefits, the CSPs also incorporate the critical apprehensions for the CIA security fundamentals of their client's data. The main goal is to maintain the integrity of hosted data in the Cloud Storage Servers (CSS) [26, 27].

The outsourced data integrity auditing services generally include four entities, particularly in public data auditing (see Fig. 3); for instance, (i) Data Owner (DO): is an entity that pre-processed and outsources data to cloud storage servers; it is also capable of performing dynamic data updates through the insert, delete, and update procedures, (ii) the CSP: the entity that offers on-demand shared cloud services and responsible for storing the user data to release the storage burden of its registered users, and it is needed to react the challenges request by the auditor, (iii) Third-party Auditor (TPA): provides audit services, without downloading entire data, with high computational and communicational capabilities to the registered user who delegates his audit task, and (iv) the users: any other user or enterprise who is registered on behalf of the DO and allowed to read the outsourced data.

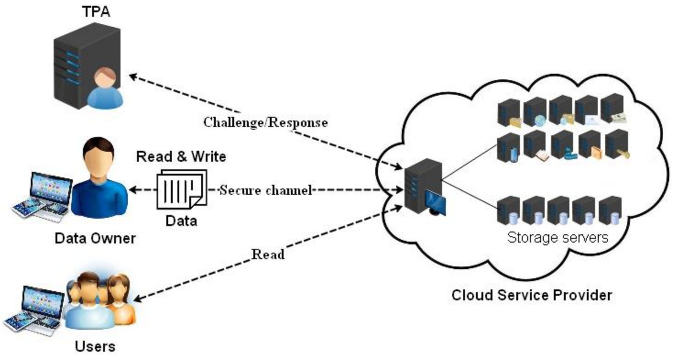

Fig. 3. Public data auditing

On the other hand, in private data auditing, a third-party auditor is not included (see Fig. 4). The outsourced data auditing technique is a challenge-response mechanism, and its comprehensive process is as follows. (i) The users initially pre-compute their data files, utilizing cryptographic, coding, or data block, and afterwards produce some metadata for all data. At that point, they transfer the data files and related metadata to the cloud storage servers. While verifying the data integrity of the hosted data, they send a challenge request to the auditor and wait for the notice of the outcome. (ii) The auditor produces an arbitrary challenge after getting the user's request and sending it to the storage servers. We regularly expect that the user approves the auditor before any activity with cloud storage servers. (iii) after getting the challenge request, the storage server produces corresponding evidence identified with the challenge and responds to the auditor. (iv) to verify the data integrity, the auditor confirms the receiving evidence. If the authentication fails, the auditor responds with a “rejected” notification to the user. Otherwise, the auditor responds “success” notice to the user, which means the outsourced data is secure.

B. Notations and Preliminaries

Homomorphic Verifiable Tag (HVT) is the foundation of current data integrity verification techniques. It can aggregate different data blocks into one value and save substantial communication costs. For enhancing audit phase proficiency, the signature mechanism is integrated with HVT to create a homomorphic signature method to verify the integrity of big data outsourced in existing data auditing techniques. As per the review of current RDA techniques, most of the data storage auditing protocols are constructed using Message Authentication Code (MAC) [28], RSA, BLS, Homomorphic Linear-authenticator (HLA) [18, 29], Identity (ID), and Certificate-less (CL) homomorphic methods. Cryptographic systems utilize these algorithms to build security primitives and cryptographic groups. Cryptographic operations are the security primitives to create the audit process, including key, tag, challenge, and proof generation phases. Nevertheless, the TPA can learn the user's data during the audit phase, which puts the data at risk [18]. To protect the privacy and integrity of data, user-initiated key, tag, or signature generation algorithms. In contrast, the cloud server and TPA execute the challenged and proof generation algorithms using public and private key security parameters.

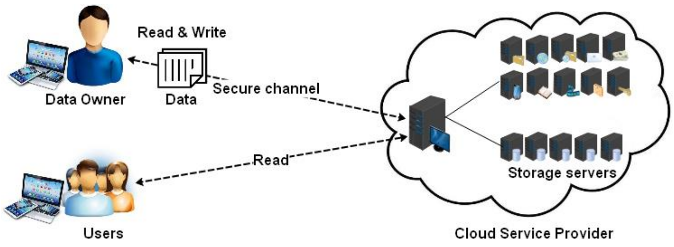

Fig. 4. Private data auditing.

A commonly utilized security parameter in a cryptosystem, denoted as n, describes the length of public and secret keys. The security parameters must be computed viably, and the implementation of the cryptographic system must be polynomial in time. When the user increases the key size, the encryption and decryption time will also be increased. It is harder for an adversary to break the system in polynomial time, generally addressed as 1n. The cryptographic procedures and keys generation for the audit reliability of the cloud storage services, and 80, 128, or 160 bits are the commonly used problem's input size security parameters [30]. The remotely stored file F is addressed as an arrangement of finite sets of memory blocks like m1, m2, m3…mn. It is essential to verify that the security parameter is not lesser than the data blocks because the user needs to encrypt the data with a relevant key [31].

The pairing function is another cryptographic method for security systems, such as let $\mathbb{G}_1$ and $\mathbb{G}_2$ be two groups belonging to similar prime order $\mathbb{q}$, where $\mathbb{G}_1$ and $\mathbb{G}_2$ are additive and multiplicative groups, respectively. A bilinear map $e: \mathbb{G}_1 \times \mathbb{G}_2 \to \mathbb{GT}$ has the following properties:

- Non-degeneracy: suppose $\mathbb{P}$ is a creator of $\mathbb{G}_1$, so $e(\mathcal{P},\mathcal{P})$ is a creator of $\mathbb{G}_2$. Therefore, $e(\mathcal{P},\mathcal{P}) \neq 1$; and e proficiently computable;
- Bilinearity: $e(a\mathcal{P}, b\mathcal{Q}) = e(\mathcal{P},\mathcal{Q})^{ab}$, for all $\mathcal{P} \in \mathbb{G}_1$, $\mathcal{Q} \in \mathbb{G}_2$ and $a, b \in \mathbb{Z}_{\mathbb{q}}$, where $\mathbb{Z}_{\mathbb{q}}$ is a prime order.
- Computability: The map ‘e’ is efficiently computable.

1) Message Authentication Codes (MAC): The MAC ensures non-repudiation of the origin, validates the owner’s identity, and preserves data integrity. The hash functions need to generate the MAC codes for validation, including hash value and data block. The receiver utilizes the shared secret key known by both parties to decode and get the original message. It is easy to use MAC in the data audit phase; the user generates data blocks and their respective metadata (MACs) of data file F, uploads it to storage servers and sends the security keys to TPA. Nonetheless, this methodology needs to release the data blocks to the auditor [18]. So, cloud users can perform the integrity verification process (private audit) to prevent the TPA from validating their data. Even though the MAC authenticates the data integrity, data privacy is lost. Moreover, data integrity is at risk because attackers can modify or share the message with other users. The subsequent algorithms can be utilized in the cloud data audit phase [18]:

- generateKey($\mathcal{K}$): $\mathcal{K} \overset{\mathcal{S}}{\leftarrow} \mathcal{K}$
- generateCode: $tag \overset{\mathcal{S}}{\leftarrow} MAC_K(M)$
- verifier: $\mathcal{D} \leftarrow VF_K(M, tag)$ where $\mathcal{D} \in \{0,1\}$

The MAC uses a deterministic and state-less key generation algorithm, so it is not required a tag authentication algorithm because the receiver can create a tag by executing $MAC_K(M)$. The receiver can verify the message if the generated tag is matched to the received tag; otherwise, it fails to authenticate. Instead, using the MAC in data auditing can cause significant security issues, including the following [32]:

- It provides static data only and is unable to support dynamic data operations.
- If the user needs to update data, it requires regenerating the security keys and uploaded to the storage servers and auditor.
- The auditor should keep MAC keys because cloud users can modify their data from any geographical location.

2) Homomorphic Authentication (HA): The study in [30] was the first to introduce homomorphic linear authenticators. The HA allows the user to generate the data tag α by using the data blocks $\{M_i\}$ along with secrete keys, where $i = \{1,2,3 \dots n\}$ and store it on the cloud servers. After that, the CSP generates the data blocks $\{M_i\}$ with relative data tag by using publically accessible functions. So, the HA permits anyone to validate the output derived from the verified datasets using complex computational procedures with data tag α. Moreover, this approach also allows users to combine data stream bits of several files without revealing data contents to others.

Consider the case of supply chain management, the transactions of each department carried out for production, sales, and retail, without revealing information to other departments. The HA can be categorized as (1) partially homomorphic cryptography, which can be additive or multiplicative, and (2) fully homomorphic encryption that supports both additive and multiplicative operations [33]. The procedure to perform the storage authentication can be briefly described as follows:

- The data file φ is represented as an N vector.
- Then generated the tags τ of every data block φ.
- The user randomly generates a challenge request c and sends it to the cloud storage servers.
- The server responds as data verification proof by using:

$$\mu = \sum_j c_j, \varphi_j$$

The homomorphic provable tag has been utilized in data audit procedures. They have flexibility and Blockless authentication properties. Blockless authentication permits the cloud servers to authenticate the integrity of data deprived of computing the data and metadata of the data block. Metadata (tags) and the distinctive index are created and stored as inclusive counters for every data block. Later, the storage servers generate a proof and allow users to authenticate data integrity with linear summation of tag values [34]. The HA provides cumulative signatures, where ƞ signatures related to ƞ messages for ƞ number of users [35]; support homomorphic signature [36] and batch authentication [37].

The following four algorithms are included in the homomorphic authentication [30]:

$(\rho\kappa, s\kappa) \leftarrow (1^k)$: The data owner initiates this algorithm for the setup phase to verify data storage. It requires security parameters to compute public $\rho\kappa$ and secret $s\kappa$ keys.

$(\vec{t}, st) \leftarrow Tag_{sk}(\vec{f})$: It is also a probabilistic algorithm executed by the user to tag a file. It uses a private key $s\kappa$ and a file $\vec{f} \in [\mathbb{B}]^n$ as an input security parameter and computes the tags’ vector and state information st.

$\tau := Auth_{pk}(\vec{f}, \vec{t}, \vec{c})$: The cloud storage servers executed this deterministic method by computing a tag. It uses public-key $\rho\kappa$, a data block $\vec{f} \in [\mathbb{B}]^n$, a tag $\vec{t}$, and a challenge request $\vec{c} \in \mathbb{Z}_p^n$ as an input security parameter and computes a proof τ.

$b := Verify_{\rho\kappa}(st, \mu, \vec{c}, \tau)$: It is also a deterministic algorithm that is run by the verifier; it uses security parameters public-key $\rho\kappa$, state info st, an element $\mu \in \mathbb{N}$, challenge request $\vec{c} \in \mathbb{Z}_p^n$, a proof τ as an input, and generates a bit ‘1’ or ‘0’, accept or reject, respectively.

We determine that the private key is not required during authentication in the algorithms mentioned above. Moreover, linear data block combinations expose sufficient information to the auditor for downloading the complete file f [32, 37]. The state info belongs to $\{0,1\}^k$ which is just a security parameter resulting from tag or encode a file f algorithm. The researchers Ateniese et al. treated data file f to be n vectors. Every tagged file f could be recognized by using the state information computed in encoding algorithm [30]. The HA technique can enhance using random-masking [38] and ring-based signatures [18] schemes, particularly for public data auditing. The homomorphic authenticator-based ring signatures strategies use to share data among multiple cloud users and propose supporting data privacy and Blockless authentication. Furthermore, random masking provides privacy-preserving data auditing process.

3) RSA-based homomorphic methods: The researchers in [34] introduced a sample-based publicly audit data possession technique that integrates the RSA approach with the HVT method. The succeeding RSA-based methods mostly improved their scheme. In their scheme, some essential elements are produced similar to the RSA signature, where the public and private keys are generated as $\{N, g\}$ and $\{e, d, v\}$. The client split the data file F into n number of data blocks $F = \{x_1, x_2, \dots, x_n\}$, where $x_i \in \mathbb{Z}_q^*$. For every data block, the client creates a block tag $\sigma_i = (h.u^{x_i})(y_i)^d modulo\ N$, wherein $h: \{0,1\}^* \to R_N$ is a hash method that homogeneously maps to R_N, u is a creator of R_N, x_i denotes the i-th data block, and the value of y_i is computed by concatenating the index i with the secret value.

The value of y_i is distinct and unidentifiable for every tag. Then, the cloud storage servers store data files and their corresponding tags. Afterward, the user can confirm that the cloud server holds the data by creating a requested message for arbitrarily chosen data blocks. The storage server creates the proofs of data possession based on requested data blocks and related tags. Consequently, the user could ensure data integrity without retrieving entire data blocks. The replica storage, Curtmola et al. [39] also created a tag for data blocks similarly $\sigma_{ij} = (h.u^{x_{ij}})\left(y_{ij}\right)^d modulo\ N$, wherein x_{ij} denotes the j-th data block of i-th copy. Currently several solutions that adapted RSA method just change the hash function, such as $h(filename)$ [40] and $h(filename \parallel n \parallel i \parallel j \parallel g)$ [41].

4) BLS-based homomorphic method: This method generates a shorter signature than the RSA-based homomorphic method at the same security level; thus, most existing data auditing schemes use the BLS-based technique. The first publicly data integrity auditing technique with data dynamics features based on this method was proposed in [42]. The bilinear pairing utilized to construct the BLS technique for confirmation and signature is computed by elliptic-curve cryptography. It is an undisputable technique that verifies parties that the signature is reliable.

Moreover, the BLS could integrate with any other approach in group Diffie-Hellman assumption (GDH) $\mathbb{G}$ [43]. This procedure needs a hash-based method resulting in data space on $\mathbb{G}$. This technique could also be used in data audit schemes. Suppose $\mathbb{G} = \langle g \rangle$ prime number $\mathcal{P}$ set of the GDH, by using hash method $\mathbb{H}: \{0,1\}^* \longrightarrow \mathbb{G}$ be measured in the random oracle model. Each data block can encrypt by utilizing subsequent algorithms [43]:

- Key creation algorithm run by the cloud user by selecting an arbitrary variable, $x \overset{R}{\leftarrow} \mathbb{Z}_{\mathbb{p}}$ and generates $v \leftarrow g^x$. The public $\rho\kappa$ and secrete $s\kappa$ keys are $v \in \mathbb{G}$ and $x \in \mathbb{Z}_{\mathbb{p}}$ correspondingly.
- The tag generation algorithm $\sigma_i = (h.u^{x_i})(m_i)^x$ for each data block. The exclusion of index i supports the technique to provide data dynamics features.
- The signing algorithm utilizes a secret key and message $\mathbb{M} \in \{0,1\}^*$ computed has with $h \leftarrow H(M)$, wherein $h \in \mathbb{G}$ and $\sigma \leftarrow h^x$.
- Verify function generates $h \leftarrow H(M)$ by using a signature σ, public key $\rho\kappa$, and a data block. Therefore (g, v, h, σ) is confirmed as a legal tuple.

These techniques can further enhance supporting public data auditing and data update operations. The Merkle-binary hash-tree (MHT) is a technique to meet these objectives. Qian Wang et al. described that the MHT-based scheme hashes leave to authenticate data blocks [42]. Furthermore, to support dynamic data audits, their work extends the techniques [34, 44] to measure signatures with relative file indexes. Consequently, the previously stored data file needs to be re-computed in the data file modification process. Hence to minimize the file indexes storage overhead, the study [42] discarded the file indexes and generated tags for every data block to support dynamic data operations.

Several BLS-base techniques only change hash functions such as $h(w_i)$ [45, 46], $h(id)$ [47], $h(i)$ [48], and $h(V_i \parallel T_i)$ [49]. To provide the optimum solution, the study [31] presented a common protocol development mechanism for cloud data auditing. They divide the data file F into n number of data blocks and divide these data blocks into sectors s. Then data owner computes the tag of every block of data as $\sigma_i = \left(h.\prod_{j=1}^{s} v^{m_{ij}}\right)(m, fid \parallel i)^x$, wherein fid denotes identifier of the data block, and m_{ij} identifies the j-th sectors of relative i-th data blocks and $\{v_1, v_2, \dots, v_s\}$ are arbitrarily selected by the client. A similar technique $\sigma_i = \left(h.\prod_{j=1}^{s} v^{m_{ij}}\right)(m_i)^x$ presented by Liu et al. [50]. Later this technique was enhanced by [51] for the multi-replicas file system that also supports data update operations by generating $\sigma_i = (h.v^{m_{ij}})(m_i)^x$ block tags for cloud storage, wherein m_{ij} denotes the j-th data blocks of i-th copy. The use of partition mechanism and distinctive hash function design led to developing the different BLS-based techniques for outsourcing data auditing such as for data replication $\sigma_{ij} = (h.v^{m_{ij}})(filename \parallel n \parallel m \parallel v)^x$ [52] and $\sigma_{ij} = \left(h(m_{ij}).\prod_{j=1}^{s} v^{m_{ij}}\right)^x$ [53].

5) ID-based homomorphic methods: This technique does not support certificate features compared with RSA-based and BLS-based signatures. Wang et al. [54] used ID-based cryptography to design a PDP solution; they adapted identity aggregation signatures to develop a proof of data possession technique and demonstrated the system and security models.

The Private Key Generator (PKG) chooses the secrete key as $x \in \mathbb{Z}_p$ and generates the public key as $y = g^x \in \mathbb{G}$ in initialization process. After getting user ID, PKG generates $R = g^r$ and $\sigma = r + xh(ID, R)$ and responds to the user with the private key (R, σ), wherein $r \in \mathbb{Z}_p$ is arbitrarily chosen integer. The user computes the tag $\sigma_i = (h.v^{m_i})(i)^{\sigma}$ for a data block m_i.

The signature construction procedure is similar to BLS-based solution [48]; the only change is that the secrete key is computed by PKG. Hence, study in [55] suggested another ID signature-based PDP public data auditing technique for multi-clouds. In this method, secrete key creation is similar to the study mentioned above [54]; however, the signature structure is different because of the partitioning mechanism and cooperation among different servers. The client generates a tag as $\sigma_{ij} = \left(h.\prod_{j=1}^{s} v^{m_i j}\right)\left(N_i, GS_{l_i}, i\right)^{\sigma}$ for tuple $\left(N_i, GS_{l_i}, i\right)$ can verify the every data blocks different from each other. Nonetheless, in this technique the data security is not sufficient. It does not provide requested blocks for tagGen queries; in other words, the attacker cannot retrieve any tags of these data blocks, which is conflicting with the real capacity of the cloud storage server.

The researchers in [56] proposed an ID-based publicly provable privacy-preserving data auditing solution. Using asymmetric group key agreement suggests a substantial ID-based data auditing technique. The PKG produces the secrete key as $\sigma = (ID)^x$ and send it to the user. Then the user generates the tag $\sigma_i = \sigma^{m_i}.h(filename \parallel i)^{\eta}$ for a data block m_i, wherein $\eta \in \mathbb{Z}_p$ is arbitrarily selected by the user. The serial number integrated with the tag makes data dynamics operations impossible inconceivable.

6) Certificateless-based homomorphic methods: The Boneh–Lynn–Shacham-based technique consistently needs a reliable party to compute the user's private key; hence, data signatures can easily tamper once the party is compromised. The certificate-less cryptography settles this issue. The authors in [57] suggested the first certificate-less publicly provable data auditing scheme to validate the outsourced integrity of cloud storage. A homomorphic verifiable CL signature is constructed for the user/auditor to validate the data integrity without retrieving the entire data file, which is impossible in a conventional CL signature.

In the initial phase, the Key Generation Center (KGC) chooses to secrete the key as $X \in \mathbb{Z}_p$ and generates the public key $y = g^x \in \mathbb{G}$. The PKG receives the user's ID and generates partial-key $D = h(ID)^x$ send it to the user. Then the user chooses another partial key $X \in \mathbb{Z}_p$ to make the secrete key complete and generates public-key $y = g^x \in \mathbb{G}$. The user generates $\sigma_{ij} = (h_2.v^{m_i})(ID \parallel y \parallel id)^x.D$ tag with complete private key for a data block m_i with identifier id. Even though this method provides the solution for the private-key escrow problem with the help of KGC to generate a partial key instead of the complete key, it fails to avoid the public-key replacement attack. He et al. [58] proposed another CL technique for outsourced data integrity verification. The KGC produces the partial key in a generally unpredictable manner as follows:

- KGC sends arbitrary integer $\eta \in \mathbb{Z}_p$ and generates $\mathrm{T} = \eta.p,\ S = \eta + X.h(ID, T)\ modolus\ P$, where P denotes the multiplicative group $\mathbb{G}$.
- The KGC responds with computed partial-key (T, S), after that, the user creates a tag for the data block m_i along with id by generating $\sigma_i = (S + h_2(ID \parallel y \parallel Y).x).\left(h(id) + m_i.h(Y)\right)$ which is secure against public-key replacement and master-key retrieval attack.

The auditor can get the user's data inappropriately by solving the linear equation; this method does not ensure data privacy. Consequently, the study in [59] was introduced the CL privacy-preserving PDP technique by generating the public key with two private-key parts instead of using one part [57, 58]. The security evaluation shows that the proposed technique is verifiable and secure.

III. State-of-the-Art Data Integrity Auditng Techniques

This section presents a detailed comparative analysis of remote data integrity auditing protocols. Several security mechanisms have been projected for ensuring data integrity and overcoming privacy leakage in the literature. These schemes can be categorized according to data states: static, dynamic, privacy-preserving, single-cloud, multi-cloud, multi-owner, etc.

In study [34], the researchers proposed the first PDP protocol to address the issues of public data auditing for outsourcing the user's data on remote cloud storage servers and the authentication of data possession. They have presented two schemes: (1) the sampling-PDP method ensures strong authentication of data possession, and (2) the efficient-PDP approach supports improving proficiency with weak data possession. They used RAS-based homomorphic tags to achieve a public data auditing scheme. However, their methods only support static data, so direct data modification might raise significant security, privacy, and system design issues. The authors [60] improved their scheme and presented a dynamic version of the PDP protocol. However, their technique restricted unlimited challenge queries and supported only limited dynamic data operations, such as unable to provide block insertion.

Bowers et al. [61] introduced the HAIL protocol to provide high availability and ensure data integrity. Their protocol used the erasure codes on both single-server and multi-server layers correspondingly. It also supports the assurance for proof of data retrievability that is outsourced to remote cloud storage. Nevertheless, their protocol does not offer dynamic data and needs to store one segment of each data file locally. Moreover, it is restricted to the number of challenge queries. The authors [62] introduced the SW approach to improving the private data auditing technique presented by Shacham and Waters [63]. The server response size concerning the challenge request of the TPA is directed by the 't' set of elements along with the size of each group element in α bits, where α represented the group size in bit. They considered and improve the size of proof from

$\mathrm{O}(\mathcal{S}\alpha)$ to $\mathrm{O}(\alpha)$ in their scheme by splitting the 't' group components into two group components. It generates a longer public key compared to the technique designed by [34]. Furthermore, their approach is limited to the static nature of data and cannot ensure privacy leakage against TPA during the data auditing phase.

Stefanov et al. [64] considered the static data issue and introduced the first cloud-based PoR protocol along with a dynamic data operation named Iris. They used the MHT data structure to store and ensure outsourced data integrity. However, regardless of proficient read and write data procedure, it requires substantial bandwidth usage, server computation cost, local data space, and server input/output to verify data integrity. Like the protocol [64], Shi et al. [65] have introduced a standard MHT data structure-based publically provable technique.

Qian Wang et al. [42] improved the proof of the data possession scheme for dynamic data operations by using the MHT data structure to authenticate the block tag. They provide the solution for data dynamics and Blockless authentication. The previous studies [34, 44] describe that if the cloud server keeps a tempered data file, then the cloud server can identify this misconduct during the data authentication phase by using a data auditing algorithm with a probability of $\mathrm{O}(1)$. Moreover, this scheme cannot detect and verify minor data modifications [42]. Similarly, in [30], the researchers introduced an extended version of the data auditing protocol using ranked-based MHT, as illustrated in Fig. 5.

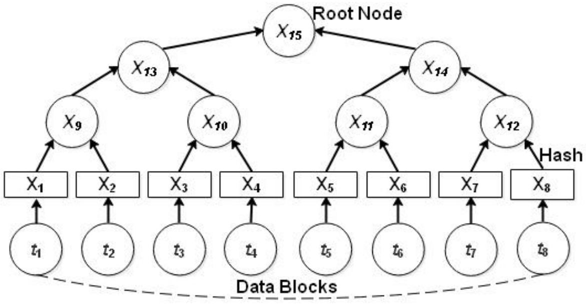

Fig. 5. The basic idea behind the MHT-based solution.

Their protocol used a signature-based approach [66] and supported authorized data auditing to avoid malicious third-party auditors. In their scheme, every node $\mathcal{N}$ should not be more than two child nodes. Every node can be denoted as $\{\mathcal{H}, r\mathcal{N}\}$, wherein $r\mathcal{N}$ representing the rank of the current node and $\mathcal{H}$ indicated hash value. Data blocks or messages m_i belongs to leaf nodes $\mathcal{LN}$, it computes hash value by $\mathcal{H}(m_i), r\mathcal{N}$, and generates the tag σ using following equation:

$$\sigma = \left(\mathcal{H}(m_a) \prod_{b=1}^{s_a} u_b m_{ab} \right)$$

where, $u_b \in \mathcal{U}, \mathcal{U} = \{\mathcal{U}_k \in \mathbb{Z}_{\mathbb{p}}\}, \mathcal{K} \in [1, s_{max}]$ the sector of data blocks s, the data file f is divided as $\{m_{ab}\}$, wherein m is the message or data block, a is the length of the current block, and b is the set of s sectors. One of the significant properties of this protocol is that an unauthorized user cannot generate a challenge for TPA without having this verification tag. Several proposed protocols cannot ensure data privacy against third-party auditors [32, 34, 42, 44]. The researchers already reported that the auditor could learn the data content by data block retrieval in the proof of possession step during the data audit procedure [67].

Several studies [68-71] introduced privacy protection protocols to determine the privacy leakage issues. In [69], the researchers designed a zero-knowledge proof-based privacy-preserving scheme with publicly provable data. Their method saves the computational and communication overhead compared to [72] and ensures data integrity without exposing the content of the user's data to the third-party auditor. However, it does not offer dynamic data operations and is limited to static data only. The above literature shows that the currently proposed data auditing schemes use the public key cryptography approach. So, the cloud needs to identify the user before hosting the data on remote storage servers for spam prevention.

Wang et al. [73] addressed this problem and suggested an ID-based outsourced data verification technique (ID-RDPC) to overcome this problem. It is the first scheme that considers being secured under Diffie-Hellman supposition. Their strategy is more optimized for communication overhead by comparing with [74]. However, their scheme cannot support public audit, generating an extra burden of computational and communication costs at the user-side during the data verification step. Thus, the ID-RDPC scheme is not suitable for resource-constrained devices.

Similarly, Zhang et al. [75] presented another user's identity-based remote data verification protocol using homomorphic tags. In their technique, the computational overhead remains consistent for the third-party auditor for the number of challenge queries. Moreover, their scheme is more proficient for computational and communicational overheads than [47, 76].

Jiang et al. [77] introduced a publically verifiable data integrity auditing technique with client revocation. They utilized a public-key cryptography database and aggregate signature to overcome collusion issues between the cloud and revoked users. It allows users to host data to the storage server and generates authentication codes to verify users from the revocation list. They also enhanced their technique with a batch auditing mechanism, which is challenging to implement in public auditing schemes. Besides, it incorporates other security features, for example, confidentiality, accountability, and traceability, to secure group user updates. The third-party auditor cannot authenticate the impersonation attack if the user does not exist in the revoked list.

Similarly, Fu et al. [78] were motivated to design a new external auditing approach to share data with group managers in CSP. They used standard MHT to maintain verifiable data blocks. This technique guarantees the users to trace the changes through an assigned hash-based binary tree and recover the most recent block of data when any existing data block corrupts. However, it is susceptible to numerous assaults, such as tag forgery, replace, replay, pollution, and data leakage attacks. Later, an identity-based cloud storage technique for the clients to remotely store their data was securely presented by Wang et al. [79]. Their approach does not need to manage certificates and enables inclusive data auditing. They also permit the proxy server to process and host the data file on the user's behalf for efficiency. However, their technique does not support data privacy and recovery, treating all system parties as trusted entities.

A scheme to secure outsourced data in the cloud uses the re-computing codes suggested by Liu et al. [80]. A semi-authorized proxy server is accessible on the user’s behalf. The proxy server keeps the compensation of the hashed data blocks and homomorphic verifiers dependent on BLS-based signatures. Furthermore, the proxy-server resolves unapproved validator issues generated by specific keys in the absence of a user who is not consistently accessible online. Consequently, this technique could nearly release the burden of data owners to become available online permanently. They used the coefficients encoding and a pseudorandom method to accomplish the privacy of the user’s data. Nonetheless, their strategy is unable to support external data auditing.

Yuan and Yu [81] presented a new public data auditing PoR mechanism based on homomorphic linear authentication commitment with constant communication costs for the cloud and TPA. It provides proficiency for storage, communication, and computational costs and releases the user's burden from being always online for data auditing. Though, it cannot support dynamic data update procedures, batch auditing, preserving data privacy, and Blockless verification.

Later, Fan et al. [82] introduced an ID-based data verification technique using aggregate signatures named (SIBAS) to overcome the vulnerability of user’s data to an adversary CSP. They introduce a trusted auditor (TEE) to verify the remotely stored data on the local side. Moreover, the scheme also accomplishes the management of security keys in the TEE environment by using Shamir’s (t, n) mechanism. It used group Diffie-Hellman supposition under the random oracle model (ROM) to resist the adversary attacks that might select messages and target identities for security verification. It is also optimized for computation and communication costs compared to [38, 76]. However, it does not support privacy-preserving, Blockless validation, and dynamic data operation.

In study [83], the researchers presented a secure data deduplication and integrity verification protocol, which can decrease the data volume hosted on cloud storage by removing identical copies of the data file. It also allows users to delegate the computational procedures to the trusted third-party auditor to authenticate data integrity proficiently. Several research works have been directed toward these issues, while this study designs a new scheme by combining the features like deduplication and publicly provable data integrity. This study supports the third-party auditor in releasing the user-side burden, particularly for resource-constrained mobile devices. Moreover, it used the linear-homomorphic authenticators and BLS signature to perform challenge-response mechanisms. However, it generates high computational and communication costs in the data deduplication step on the user side. It does not provide data update operations and batch auditing.

A multi-agent and multi-copy-based data integrity authentication technique for big data files in single cloud storage servers with low audit efficiency was introduced by Chunbo Wang and Xiaoqiang Di [84]. It utilizes a bilinear mapping technique to build a key creation procedure and multi-branch confirmation tree for performing multi-copy data signature to deploy multi-copy validation, signature, and confirmation. Moreover, it addresses task association in the work process, task assignment, and asset allotment dependent on QoS request inclination settings to plan various tasks using a directed acyclic graph (DAG). Moreover, it reduces the communication cost and storage overhead and improves audit proficiency by 20% compared to [63, 85]. However, it cannot perform dynamic data updates, batch auditing to increase efficiency, and privacy-preserving against TPA.

Yang et al. [86] introduced a certificate-less signature-based scheme for multi-user privacy-preserving with traceability and confirmation for cloud data auditing. They addressed denial-of-service (DoS) attacks, single-supervisor misconduct, and identity revelation problems. In contrast to the conventional data integrity techniques, it preserves the secrecy of the user’s identity without using a group and ring signature, which ensures the tag is minimal. Besides, it supports collaborative traceability of malevolent users with at least d managers, evading single-supervisor power maltreatment. It overcomes the DoS attack between TPA and cloud server providers by using identity verification measures. Any user can send a challenge to CSP to resolve the network congestion and waste of cloud resources. It also supports proficient user revocation and releases the burden of certificate management and key-escrow problems using certificate-less cryptography. However, TPA cannot prevent impersonation attacks if the user does not exist in the revocation list, imposing high communication and computation costs due to static data.

Later, a study [87] presented an efficient PDP scheme under the Diffie-Hellman assumption to verify data integrity in storage servers by preserving users' anonymity against TPA. Therefore, the auditor cannot get the user’s identity in the data audit process. It avoids certificate management by using an identity-based cryptographic approach. It ensures the connection between data and the owner in the proof creation step, not the integrity audit phase. Hence, TPA is unable to know liaison to find challenged data usage. Simultaneously, the CSP creates a relation for the proofs in the initialize phase to diminish TPA's computational overhead significantly. Moreover, use arbitrary requested data blocks in the proofs step to strengthen the security of the technique. Though, it is unable to support dynamic data updates and batch auditing.

Neela et al. [88] introduced a technique by improving Rivest-Shamir-Adleman (RSA) algorithm with Cuckoo Filter for secure cloud storage in semi-trusted CSPs. They eliminate the third-party auditor to overcome privacy issues and reduce communication overhead. However, they impose high computation costs on the user side and cannot support public data auditing. Later, Chaudhari et al. [89] suggested the data auditing technique based on modern Indistinguishability Obfuscation, a modern encryption construct that used one-way hash functions. The main goal of their study is to address public verification, dynamic data, collusion resistance, and privacy-preserving. Though, it cannot support batch auditing to reduce computation overhead at TPA, including high verification time, especially for mobile devices.

IV. Comparison of Data Integrity Auditing Techniques

This section offers a comprehensive comparative analysis of the techniques discussed in Section III, focusing on the strengths, weaknesses, and key attributes of remote data integrity audit protocols. The analysis is systematically presented in Table I and Table II. Table I details various data integrity schemes, examining their advantages and disadvantages. Meanwhile, Table II outlines the essential characteristics of state-of-the-art data integrity auditing protocols. These characteristics encompass Public Auditing, Dynamic Data Support, Privacy Preservation, Blockless Verification, Support for Unlimited Queries, Batch Verification, and Data Sharing capabilities.

TABLE I. Merits and Demerits of Data Integrity Schemes

Schemes	Merits	Demerits
Ateniese et al. [34]	Used RSA-based homomorphic encryption to provide public data auditing. Their S-PDP shame ensures data possession, and E-PDP improved proficiency with weak data possession.	This work does not address dynamic data operation. Hence, direct extension raises security, privacy, and system design issues.
Ateniese et al. [60]	Improve the PDP protocol proposed by [34] and provide some dynamic data operations.	It is limited to the number of challenges during the audit phase and supports only limited dynamic data operations; for instance, unable to support block insertion operations.
Bowers et al. [61]	Improves proficiency and security of the existing techniques and efficiency against the active mobile adversary.	Restricted to static data and required to store one segment of each file locally, limited to the number of challenge queries.
Zhu et al., [90]	It used the same construction of a message authentication code proposed in [61] by combining universal hashing with PRFs.	It is unappropriated for the system that requires substantial data read operations. It minimized the storage cost by increasing the communication overhead.
Xu et al. [62]	They considered the private data auditing and efficiency issues of the scheme designed by [63] and provided an efficient public data auditing protocol.	Their protocol is restricted to static data only; it does not consider the privacy leakage to the TPA
Stefanov et al. [64]	Iris supports publicly verifiable dynamic data auditing by using the MHT. It provides a proficient read and writes data operation.	It requires substantial bandwidth, server computation time, local data space, and server input/output to verify the data integrity.
Shi et al. [65]	It supports efficient reading and writing operations and provides a publicly provable dynamic nature of data using standard MHT.	Validate the integrity requires the high computational power of the cloud server, bandwidth, and local storage space.
Zhang et al. [70]	It provides privacy-preserving public data auditing PoR-based scheme with aggregate verification.	It is not suitable for dynamic data environments and is only limited to static files.
Yu et al. [69]	It provides a zero-knowledge proof-based method to prevent data privacy leakage in the audit process.	The proposed scheme is limited to static data only.
Tan and Jia [76]	Identity-based cumulative signature is used to generate homomorphic tags. Eliminates data auditing burden on cloud users and is proficient to computational and communicational overheads compared with [47, 76].	It cannot perform dynamic data operations; the TPA can expose data content during the audit phase, which raises privacy issues.
Wang et al. [73]	It generates homomorphic aggregate tags using the user identity; it is optimized in terms of communication and computation cost compared with [34, 74].	Not suitable for resource constraints devices because it supports private audit, which generates computation and communication overheads on user-side in the audit phase.
Jiang et al. [77]	Used public-key cryptography and group signature to overcome collusion issues between the cloud and revoked users, generating the authentication code to verify the user from the revocation list.	It is unable to provide data recovery, imposes high computation and communication overhead, and the auditor is not capable of verifying impersonation attacks.
Yuan and Yu [81]	Used homomorphic authenticators with constant communication for cloud and TPA. Proficient in computation cost and reduced the storage overhead.	It is unable to provide dynamic data procedures.
Liu et al. [80]	Proxy resolves the user’s absence issue by generating specific keys, using the coefficients encoding and a pseudorandom method to accomplish the privacy of the user’s data.	Their approach is unable to support public data audits.
Fu et al. [78]	Use MHT to preserve verifiable data blocks. Ensures users trace the changes and recover the most recent block of data when an existing data block corrupts.	It is vulnerable to tag forgery, replace, replay, pollution, data leakage attacks, etc.
Wang et al. [79]	It does not need to manage certificates and enables inclusive data auditing, more proficient by incorporating a proxy server for processing and hosting the data file on the user’s behalf.	It does not provide data privacy or recovery, and all the involved entities in the system are treated as trusted.
Fan et al. [82]	Using aggregate signatures to overcome vulnerability against untrusted CSP resists adversary attacks that select its data and target identities, optimizing computation and communication costs more than [38, 76].	Restricted to the static nature of data, privacy-preserving, Blockless verification, dynamic data operation, replay, replace, tag-forgery attacks, etc.
Youn et al. [83]	It performs secure deduplication and data integrity verification, reduces the storage overhead by removing duplicated copies, and uses linear-homomorphic authenticators with BLS signature to perform challenge-response mechanisms.	Generating high communication and computation costs on the user-side during the data deduplication phase is unsuitable for mobile device resource constraints. It does not support dynamic data updates and batch auditing.
Wang and Di [84]	it reduces the communication cost and storage overhead and improves audit proficiency by 20% compared to [63, 85].	It is unable to perform dynamic data updates, batch auditing to increase efficiency, and privacy-preserving against TPA.

Yang et al. [86]	Provides collaborative traceability of malevolent users to minimize the network congestion and waste of cloud resources, preserves identity revelation and DoS attack, and uses certificate-less cryptography.	The auditor cannot authenticate impersonation attacks if the user does not exist in the revoke list, imposing high communication and computation costs due to the static data.
Yan and Gui [87]	The auditor is unable to get the user's identity in the data audit process; it avoids the certificate management and cloud setting up a connection in the proofs creation phase to minimize the computation cost of TPA.	It is unable to provide data-dynamic and batch auditing.
Neela et al. [88]	Improve RSA algorithm with Cuckoo Filter for secure storage in semi-trusted CSPs.	Impose high computation costs on the user side and cannot support public data auditing.
Chaudhari et al. [89]	The auditor cannot get the user's identity in the data audit process; it avoids the certificate management and cloud setting up a connection in the proofs creation phase to minimize the computation cost of TPA.	It does not support batch auditing and imposes high computation and communication costs, which is unsuitable for energy-constrained mobile devices.

V. PERFORMANCE-BASED COMPARISON TECHNIQUES

A performance comparison to evaluate different protocols and data structure involved in these schemes are presented in this section. The following section will explain several open research issues to design a proficient data auditing protocol.

The cloud data storage is not indisputable and is constantly modified according to the user's request, for example, insertion, deletion, modification, and append procedures. For example, when the user's first-time outsourced data may not be complete, the user needs to update and complete it after uploading it to CSP. Alternatively, the client may want to delete obsolete or useless data from cloud storage servers, which is unavoidable for utilizing cloud services. In short, data update operations are necessary to protect cloud data storage, and several techniques have been developed for this perspective. Generally, the subsequent data techniques are commonly utilized to develop data update verification techniques for outsourcing users' data.

A. *Merkle Hash Tree (MHT)*

It is a famous binary hash tree data structure introduced by [42]. It can proficiently ensure and verify whether a series of data blocks is compromised or not. The tree nodes hold the hash value of relating sibling data blocks. The MHT is designed by computing the has value in pair from bottom to up and obtaining the root node's distinct hash value. The MHT is a provable and broadly explored data structure supporting data dynamics operations. The MHT-based secure cloud data verification technique was suggested in [42].

Nevertheless, the curious storage servers may pass the audit process without appropriate authentication of the block indices by generating proof with other authentic data blocks when the assaulted data blocks are compromised. In [50], researchers proposed a fine-grained data dynamics technique for remotely storing user's data. However, they assume that the cloud storage server remains honest in responding to the challenging queries over outsourced data. Later, in [53], researchers utilized the MHT in data duplication auditing; it develops an MHT for every copy of the data file and uses the root node to construct the two-level data structure. However, in this way, the usage of MHT cannot support sequence number authentication issues.

To overcome these issues, the study [51] proposed a multi-replica technique that integrates the other parameters, including node level and node number accessible from the node. Boolean value denotes the node either on left or right node location to its parent node in auxiliary authentication path. In this manner, multiple-replica MHT can design to validate data update operations and authenticate the block indices proficiently.

B. Ranked-Based Skip List (RASL)

It is an authentication model that verifies the integrity of data blocks and provides data dynamics operations. It is a hierarchical key-value pair storage data structure like a tree, where nodes are arranged concerning their corresponding keys. By using this technique, every node v stores two parameters $right(v)$ and $down(v)$ with the goal that a particular data node can position in searching procedure. The study [91] introduced the RSAL-based first PDP technique. In their proposed structure, every node stores $right(v)$, $down(v)$, and produced $f(v)$ by iteratively using hash method to $f\left(right(v)\right)$ and $f\left(down(v)\right)$. The root value use to validate server's response in challenge-proof phase. The primary disadvantage of this technique is the absence of checking the single block integrity. In [41], the researchers enhanced the RSAL to multi-replica data dynamics. The enhancement integrates all data blocks of all data copies in an identical structure, supporting the proficient data auditing mechanism for copies. Moreover, using M-RASL can minimize the communication cost for updating authentication of outsourced data with multi-replicas.

C. Index Hash Table (IHT)

IHT stores the data block modification and supports to creation hash value of every data block during authentication. The IHT design is identical to an array, which involves indices sequence i_{no}, block sequence b_{no}, block version sequence v_{no} and arbitrary value r_{no}. It was first proposed in [85] for cloud storage, decreasing computational and communicational costs by keeping the index hash table on the auditor rather than the storage server. Insertion and deletion procedures reason for the change of b_{no}, thus suffering re-generation of compromised data blocks.

A subsequent procedure is to change the arrangement of specific components, such as $(i_{no}, b_{no}, v_{no}, r_{no})$ [31]. In [47], researchers modified the components to (i_{no}, V_i, R_i, S_i), where V_i denotes the virtual index, S_i represents the signer identity of the data block. In particular, guarantees that every data block is in the proper order, and V_i of the inserted data block m_i' use the smallest number of $m_i' = (V_i + V_{i-1})/2$. Thus, the user can adequately run the data insert procedure for shared data.

Additionally, there are two more distinctive data structures, like Dynamic Hash Table (DHT) [92] and Novel Data Structure (NDS), introduced by [49], respectively. Endeavoring enhanced data update operations proficiency, a DHT-based publicly provable data auditing technique was introduced to ensure files and block-level modification. The DHT is innovative two-dimensional information stored by the auditor, minimizing communicational costs during data auditing and modification authentication.

Even though it provides better results than the existing auditing techniques, it still has a few deficiencies. First, the cloud storage server may suffer a collision attack between user and auditor because the user creates a time-stamp for validation. The auditor has just approved the user. Furthermore, it does not integrate the indices and position sequence of the data blocks. To address these problems, NDS was intended to support data dynamics operations comprising doubly-link information and position array.

The user with a novel data structure can perform insertion and deletion procedures without affecting other data blocks. Likewise, NDS effectively controls the connection between the given blocks of data and their particular position can also be appropriate for multi-copies. The user may change auditor inappropriately due to geographic location or price effect. NDS should be re-structured for every change, leading to extra overhead compared to implementing the developed data structure stored by the cloud server.

VI. Open Research Issues and Challenges

Several RDA schemes are currently proposed to ensure outsourced users' data in cloud environments. However, some problems that require attention as an open research direction are described below:

A. Dynamic Data Update

In the static data auditing approach, to change the location or update a single data bit, the user needs to modify more than half bits of files after downloading the entire data and again hosted on the cloud storage server. It creates high computation, communication, and storage overheads for the user, cloud, and the auditor. Consequently, dynamic data operation is a fundamental property of the outsourced data integrity audit techniques, for example, electronic records and log files in cloud computing and mobile cloud computing. Nonetheless, the main restriction of PoR and POW-based schemes is the data updates procedure [91].

Even though the study [93] introduced a PoR-based scheme for avoiding data update issues in cloud infrastructure, private data auditing makes this technique unusable for mobile cloud computing. Furthermore, existing dynamic data update strategies also suffer computation costs on the user side, particularly for resource constraints devices. Accordingly, allowing mobile clients to update their data effectively requires future research and improvements.

B. Shared Data Access Control

Currently, several CSPs offer services, including online blogs, web services, and web applications required to store their data on remote cloud storage servers. These clients must gain access to their data anytime, anywhere, and simultaneously execute data update operations. For example, most hosted websites support their users to update data freely. Nonetheless, most existing techniques guaranteeing data integrity cannot fully achieve these requirements or impose high computation and storage overhead on the user side.

C. Data Privacy Issue

Supporting data privacy has been essential to meeting the SLA for cloud storage services. A public data auditing approach must not expose data privacy to third-party auditors. An auditor must be proficient in securely conducting the audit process regardless of any security risk of exposing the data content. For privacy-preserving, a MAC-based solution can use for users' data. The TPA generates cloud storage challenges for data integrity by arbitrarily selecting data blocks and respective MAC. The cloud storage replies with data blocks and MAC, and then the TPA verifies it using the secret key. However, as the server responds, a linear data blocks sequence to TPA, so the auditor can breach the SLA between the user and TPA. Moreover, it supports static data and restricts the number of challenges. The user must retrieve the complete data, generate the new keys, and host it on the storage servers, imposing significant computation and communication costs. Homomorphic authenticators with arbitrary masking can use to overcome these issues [38].

D. Blockless Data Auditing

An audit strategy that does not utilize accumulation signature and verification tag need the cloud server to respond to the requested data blocks for integrity assurance. This approach imposes a high communication cost on the cloud server and affects audit proficiency. The study Wang et al. [42] introduced a Blockless auditing approach that verifies tags rather than validating actual data blocks in the auditing phase. Even though this approach can improve the proficiency of the data auditing strategy and highly minimizes the communication cost, it might allow the CSP to cheat. Assume the user wants to achieve the data update procedure, which is possible because the storage server possesses old data and signatures. As the signatures and data are legitimate, the auditor might not recognize whether they are appropriately updated or not.

E. Deletion Assurance

It is required to assure the data delete operation; else, it might result in a data breach for the cloud storage [94]. Another significant perspective in guaranteed data deletion is that different versions of data files with similar data contents of the deleted identical copies or files must be kept secure. Rahumed et al. [95] introduced a fine-grained version control backup system named "FADE" to ensure deletion operation. The deleted versions of files are guaranteed to be forever unavailable. In [96], the researchers describe mechanisms for securely assuring data deletion, the classification of adversaries, and capacities for exploiting the cloud servers without secured deletion. This term can also be named self-destruction in [97],[98],[99] and [100].

VII. Future Research Work

Cloud computing has a rapidly growing business model and evolving new features to facilitate users. The researchers can take advantage to improve the data auditing schemes. The future research direction concerning data auditing with cloud computing is following.

A. Geolocation Assurance

The CSPs are restricted by Service Level Arrangement (SLA) to outsource users' data in a specific geographic area with a particular time zone, political border, state, or city level. For administration reasons and law variance, some cloud clients needed to guarantee data geolocation [101], [102], [103] and [104]. The CSP may transfer users' data to abroad servers for less expensive IT costs, disregarding the SLA agreement. Such activities of the CSP may disclose the client's data to foreign governments, who can assess it via court orders or any lawful approach. In this situation, timely recognition proof of purposeful deceitfulness or breach of SLA with CSPs is a fundamental need for cloud clients. The data integrity verification technique must incorporate geolocation confirmation for future research work.

B. Big Data Auditing

Big data auditing of RDA schemes is challenging because storage, communication, and computation costs may exponentially increase when data size increases. The cloud providers may also delete rarely used data to save storage costs without intimating the user and try to hide data loss info for the sack of their repute [105], [106], [107] and [108]. Consequently, it needs to develop an RDA scheme for supporting big-data auditing to minimize storage overhead, computation complexity, and communication cost.

C. Support for Collaborative Auditing

To audit the user's data in a multi-cloud environment is named collaborative auditing. Several data auditing schemes [34], [38], [42], [44], [60], [63], and [91] proposed for a single cloud cannot support a multi-cloud environment. Distributed File Systems were introduced to cloud storage systems for local independence and low cost for owner's data. However, collaborative auditing is challenging for job assignments, security assurance, and communication costs. Furthermore, reducing the computation overhead, storage cost, and system usability should also be considered when designing data auditing protocols.

D. Data Auditing with Deduplication

The cloud server store duplicates data, especially in multi-replica that generates different copies of the same data file, creating storage overhead for identical copies. It is significant to resolve this problem by improving the RDA schemes. Currently, [109], [110], and [111] were suggested data auditing techniques with PoW to overcome this issue considering only single data files. However, how to improve the multi-replica RDA scheme with PoW mechanism to ensure data security still seems a vital research contribution in the future.

E. Blockchain-Based Data Auditng

The blockchain is an undisputable distributed accounting, consensus approach, and intelligent contract technology with asymmetric cryptography, ensuring data security and privacy. The researchers can take advantage of decentralizing features that could generally use in data integrity auditing schemes [112], [113] and [114] for single and distributed infrastructures. However, improving the security framework of data auditing techniques for single and multiple copies scenario could be an auspicious future research direction.

F. Data Auditing in Fog Computing

Fog computing is an extension of cloud computing to facilitate the edge network for easy access and fast corresponding services for end-users. Users can use multiple devices as fog nodes to support cloud servers and reduce CSP charges. Recently, Wang et al. [115] suggested a fog-based secure and anonymous data auditing scheme. Even though the scheme is efficient and secure; however, they consider the cloud a fully trusted entity. Therefore, secure fog-based data auditing is still an open research direction for cloud computing.

G. Data Auditing in Edge Computing

Edge computing is a distributed computing paradigm that provides computational and storage facilities closer to the end-user for fast response times (low latency) and reducing bandwidth utilization. It is an ongoing business model that requires improving data auditing techniques to incorporate cloud computing changes. However, duplicated data may lead to storage problems for single and shared clouds; auditing techniques must include deduplication [116] and [117] and ensure data security and privacy in edge computing. Furthermore, the researchers can explore the edge computing model for data auditing with blockchain technology in future research. Cloud computing saves time and monitoring costs for any organization and turns technological solutions for large-scale systems into server-to-service frameworks [118].

VIII. Conclusion

The paper has highlighted the significance of remote data auditing techniques, involved entities, and the concerns related to public and private data auditing. We thoroughly reviewed existing data integrity techniques by exploring their merits and demerits. Also, we introduced the qualitative comparison of auditing techniques and compared their performance regarding communication and computational overhead. Lastly, we highlighted the desirable features of different schemes, open issues, and future research directions for designing efficient and secure data auditing schemes for the cloud environment.

***Abstract*—Security is a major issue in the IT world, and its aim is to maintain user confidence and the coherence of the entire information system. Various international and European research projects, as well as IT manufacturers, have proposed new solutions and mechanisms to solve the problem of security in the IoT environment. Software-Defined Networking (SDN) and Blockchain are advanced technologies utilized globally for establishing secure network communication and constructing resilient network infrastructures. They serve as a robust and dependable foundation for addressing various challenges, including security, privacy, scalability, and access control. Indeed, SDN and Blockchain technologies have demonstrated their ability to efficiently manage resource utilization and facilitate secure network communication within the Internet of Things (IoT) ecosystem. Nonetheless, there exists a research gap concerning the creation of a comprehensive framework that can fulfill the unique requirements of the IoT environment. Consequently, this paper presents a recent investigation into the integration of SDN and Blockchain with IoT. The objective is to analyze their primary contributions and identify the challenges involved. Subsequently, we offer relevant recommendations to address these challenges and enhance the security and privacy of the IoT landscape.**

***Keywords*—Internet of things; SDN; blockchain**

I. Introduction

The Internet of Things (IoT) paradigm is shaping the future of computing, rapidly integrating into our daily lives to enhance our quality of life by connecting various smart devices, technologies, services, and applications [1]. Nonetheless, managing IoT networks poses several challenges that demand innovative solutions. These challenges primarily revolve around the inherent vulnerabilities of IoT devices, including susceptibility to outages, failures under heavy traffic loads, security vulnerabilities, limited energy efficiency, and scalability issues. Given the heterogeneity and resource constraints of IoT devices, they require specialized network behaviors and services, such as security protocols, efficient power management, and load balancing modules.

Software-Defined Networking (SDN), with its novel network management approaches and recent advancements in the IoT domain, offers promising solutions. It grants global visibility into network status and enables logically centralized resource control, which can be physically distributed as needed via programmable APIs from a central point [2]. Consequently, SDN facilitates the implementation of innovative network management techniques. Consequently, considerable research efforts are dedicated to developing SDN-based IoT management frameworks [3]. While SDN lays the groundwork for robust management solutions, the integration of intelligent decision-making in uncertain scenarios is still lacking, necessitating the incorporation of AI-based approaches alongside SDN.

Blockchain and IoT are both innovations that can bring significant advantages to IoT networks, such as improved security, transparency, immutability, privacy, and automated business processes. However, when combined within an SDN framework for IoT network management, the potential benefits of these technologies are further amplified. Looking ahead, we envision the introduction of adaptive resource management frameworks for IoT networks with the assistance of AI, which will also incorporate blockchain-based SDN frameworks. Furthermore, as IoT is expected to undergo large-scale deployment in the future, practical challenges that go beyond controlled laboratory settings or theoretical assessments will emerge. The current state of research in this field suggests that the dynamic capabilities offered by SDN can be leveraged to reconfigure, update, and enhance IoT networks in real-time to address emerging challenges.

Despite the many advantages mentioned above, the integration of new emerging technologies into the security of information and communication systems can give rise to a number of problems. Critical situations, in particular, raise further questions. Since the integration of Blockchain and SDN into the Internet of Things (IoT) is a dynamic process influenced by several interdependent factors, the addition of Blockchain to the IoT ecosystem intensifies technological and organizational requirements. As such, this paper aims to present an in-depth study of the challenges associated with IoT integration. Consequently, attention is specifically focused on the following research questions:

RQ1: What current challenges hinder the integration of Blockchain and SDN technologies into the IoT?

RQ2: What guidance does the literature provide to surmount these challenges?

This paper offers several significant contributions. Firstly, despite the use of Blockchain in recent years, there is a lack of in-depth research into the challenges of the Internet of Things (IoT). This study proposes a comparative study of IoT security solutions, based on existing literature relating to its integration. The paper explores the current problems of decentralizing the IoT with Blockchain, as well as future challenges in this field.

The paper's structure is outlined as follows: In Section II, we delve into related work that is pertinent to our paper. Following that, in Section III, we present a comprehensive comparative analysis of technological solutions aimed at enhancing IoT security. Section IV is dedicated to the discussion of our findings and the presentation of results. Ultimately, the paper wraps up with a conclusion in Section V.

II. Related Work

A. Internet of Things with SDN

The authors in [4] examined the Manufacturer's Use Description (MUD) model, which encompasses network access control, data privacy, as well as policies for channel and authorization protection. They employed an SDN platform to efficiently access device data and resources and utilized Blockchain technology, specifically Hyperledger, for sharing data among IoT devices. Additionally, Molina and colleagues in [5] introduced a security framework for the continuous, on-demand management of virtual authentication, authorization, and accounting (AAA) in SDN-enabled IoT networks. Their work achieved scalable bootstrapping of IoT devices and fine-grained management of network access control.

Moreover, the authors in [6] introduced a novel combination of cloud computing, IoT, and SDN, resulting in the CENSOR framework. This framework was designed to establish a secure gateway within the IoT environment, featuring a reliable and secure IoT network architecture powered by cloud computing and based on SDN technology. The authors also highlighted several challenges and potential threats that need to be addressed, including advanced security measures to counter Distributed Denial of Ser-vice (DDoS) attacks, appropriate routing algorithms, and network scalability.

The authors in [7] proposed the use of a distributed controller cluster to address is-sues related to reliability, scalability, fault tolerance, and interoperability in an SDN network. Their method was found to maintain reasonable CPU utilization, thus optimizing controller performance, with a particular focus on enhancing the security of IoT applications.

Lastly, the authors in [8] introduced Middlebox-Guard (M-G), an SDN-based model for enhancing data transfer security in response to various attacks and to improve network stability. They first addressed the placement of middleboxes, which are associated with predefined security policies, using a placement selection algorithm. Subsequently, two SDN resource control algorithms were employed to fulfill coverage requirements within switching volume constraints. Simulation results demonstrated that the M-G model they designed could effectively enhance the security and stability of IoT networks.

B. Internet of Things with Blockchain

Cryptocurrency and financial transactions initially introduced blockchain technology, wherein all nodes within the blockchain execute and store all transactions. Blockchain, with its versatility, finds application in various domains, one of the most prominent being the Internet of Things (IoT) [9]. The IoT consists of networks of intelligent devices like Raspberry Pi, ESP, etc., which interconnect seamlessly to form a network used for sensing, processing, and communication. These smart IoT devices operate autonomously, consuming minimal energy and possessing lightweight characteristics. According to Statista Com [10], the estimated number of IoT devices in 2020 stood at 31 billion globally, and this number is projected to reach 75 billion devices by the end of 2025 [11].

In the IoT context, smart devices are primarily dedicated to energy-intensive tasks related to vital applications, making the implementation of privacy and security measures challenging. Malicious attacks can disrupt IoT services and pose threats to user privacy, data security, and overall network confidentiality [12]. These attacks in IoT-based systems fall into four main categories: physical attack, network attack, soft-ware attack, and data attack [13].

Physical Attack: In this category, attackers are physically close to the network and attempt to carry out malicious activities through various means, such as manipulating IoT devices, blocking RF signals, injecting malicious code, and conducting side-channel attacks. One countermeasure involves the use of physical non-clonable functions (PUF) to authenticate IoT devices, as it prevents physical attacks [14]. PUFs have a unique feature that makes it impossible to replicate the precise microstructure of an IoT device.

Network Attack: Attackers in this category seek to manipulate the IoT network through methods like RFID spoofing, man-in-the-middle attacks, traffic analysis, and Sybil attacks. Preventative measures include authentication techniques and secure hash functions [15].

Software Attack: Attackers exploit vulnerabilities in the current software of IoT systems.

Data Attack: This category involves unauthorized data access and data inconsistency. To thwart such attacks, blockchain technology can be used to provide effective privacy-preserving mechanisms [16].

Furthermore, several studies have proposed solutions to enhance IoT security:

In study [17], an algorithm secures the externalizations of bilinear pairings of IoT devices, significantly improving performance compared to standard bilinear matching.

The authors in [18] presents a framework based on a hybrid blockchain approach to secure multinational-level Industrial Internet of Things (IIoT) deployments across multiple countries.

In research [19], a patient-centric blockchain framework addresses data protection, authentication, and immutability concerns, built on the Hyperledger platform.

In study [20] proposes an Ethereum-based smart contract platform for a blockchain-driven healthcare infrastructure, offering potential efficiency improvements in hospital settings.

Lastly, in study [21] introduces an approach utilizing an open-source blockchain (Ethereum) to secure the outsourcing of bilinear pairs in IoT systems, addressing limitations of centralization and validating its effectiveness in securing IoT applications.

C. *Blockchain and SDN for the Internet of Things*

This section addresses the two research questions (RQ1: What current challenges hinder the integration of Blockchain and SDN technologies into the IoT? RQ2: What guidance does the literature provide to surmount these challenges?) We consulted the relevant literature for answers to the research questions. The search strategy encompassed the use of all well-known databases, including ACM digital library, Elsevier, IEEE and MDPI.

In their study [22], the authors introduced an innovative IoT architecture that effectively merges cutting-edge SDN and Blockchain technologies. The primary objective of this architecture is to integrate SDN controllers into IoT networks, utilizing a clustered structure along with a novel routing protocol to tackle various network challenges including security, privacy, access control, and availability. Their particular focus lies in devising energy-efficient mechanisms for data transfer among IoT devices within the SDN framework. This architecture harnesses both public and private blockchains to facilitate peer-to-peer communication between IoT devices and SDN controllers, incorporating a distributed trust authentication method.

Similarly, Chaudhary and colleagues [23] harnessed blockchain and SDN technologies to enhance the quality of service in an intelligent transportation system. They designed BEST, a blockchain-based secure energy exchange system for electric vehicles. BEST employs blockchain for decentralized validation of vehicle requests, thus eliminating single points of failure. Simulation results demonstrated the successful integration of blockchain into the SDN architecture, resulting in improved network QoS and more efficient energy usage, although it did not consider various energy sources.

The authors in [24] introduced Cochain-SC, a blockchain-based architecture that enables secure collaboration and decentralized attack information transfer among multiple SDN domains. This architecture combines intra-domain and inter-domain DDoS mitigation. The authors evaluated Cochain-SC's performance in terms of efficiency, security, cost-effectiveness, and the accuracy of detecting illegitimate flows.

Ferrag et al. [25] provided an extensive overview of Blockchain technology applications across various IoT domains, such as the Internet of Vehicles, the Internet of Energy, virtual web, cloud computing, and edge computing. Their study also addressed the five most common attacks in IoT networks, namely identity-based, cryptanalysis-based, reputation-based, manipulation-based, and service-based attacks. They established taxonomy of recent methods for achieving secure, privacy-preserving Blockchain technologies, comparing them based on specific models, security objectives, performance, computational complexity, limitations, and communication costs.

In study [26], the authors introduced the "DistBlockNet" framework, designed for a secure distributed SDN architecture for IoT through the use of Blockchain technology. They presented a scheme for updating and validating rule tables using Blockchain, with experimental evaluation demonstrating the effectiveness of DistBlockNet in terms of accuracy, scalability, defense capabilities, and performance overhead.

Blockchain technology, despite relying on a group of nodes that may not all be fully trustworthy, offers a dependable data structure thanks to its appropriate consensus algorithm. This makes it a valuable solution to address security challenges in IoT and SDN. In [27], decentralized security architecture based on SDN and block-chain for the IoT ecosystem was proposed, aiming to enhance attack detection and mitigation. Blockchain was employed for dynamic attack detection model updates and Fog node rewards based on proof-of-work.

Additionally, the authors in [28] introduced a blockchain-based controller designed to combat the injection of fake flow rules, primarily focusing on SDN controller authentication. The authors in [29] presented a novel blockchain-based authentication handover for an SDN-based 5G network, aiming to eliminate unnecessary reauthentication during repeated handovers between heterogeneous cells in 5G net-works.

Lastly, Qiu et al. [30] explored the Industrial Internet of Things scenario involving multiple SDN controllers. They proposed a blockchain-based consensus protocol for collecting and synchronizing network-wide views between different SDN controllers, employing the Q-learning method to optimize view switching, access selection, and computational resources.

In summary, various studies have proposed diverse solutions to integrate block-chain within an SDN-based IoT ecosystem. However, comprehensive scenarios that encompass all aspects of these works are yet to be fully developed.

III. Comparative Study of IoT Security Technology Solutions

The significance of combining blockchain and SDN with IoT has found application across a diverse range of domains. Table I highlights prevalent areas and recent research endeavors where the integration of blockchain and SDN with IoT applications plays a pivotal role. The majority of these studies are dedicated to enhancing security and privacy within the IoT landscape through the utilization of these two technologies. Notably, Table I reveals that these articles contend with specific challenges, notably in the realms of privacy and scalability.

IV. Discussion

After examining 80 articles, it became evident that 80% of them were centered on enhancing the security of the Internet of Things (IoT). Additionally, 37% of these articles concentrated on matters pertaining to IoT privacy, while 30% delved into the evolution of IoT security. Consequently, blockchain has emerged as a potent and actively utilized tool for delivering the proposed security services for IoT applications.

Our initial approach involved categorizing diverse IoT applications by identifying their specific security requirements and the challenges they inherently face. Subsequently, we explored IoT solutions that addressed aspects of confidentiality, privacy, and availability, drawing upon conventional methods. Furthermore, we introduced emerging technologies such as Software Defined Networking (SDN) and Blockchain, both recognized for their effectiveness in mitigating scalability issues within the IoT ecosystem.

Moreover, we dedicated attention to security solutions that take into account the contextual aspects inherent to IoT applications, as delineated in Table II. We also considered the varying impacts of security concerns on system safety, alongside the corresponding countermeasures. Throughout our exploration, we provided an extensive comparative analysis of the different approaches, grounded in specific criteria. We also conducted an examination of techniques suitable for different types of IoT applications.

Despite ongoing efforts to confront the myriad challenges confronting the Internet of Things, numerous issues remain unresolved, notably those related to scalability and dynamism. This is particularly pertinent as the IoT continues its evolution into an "Internet of Everything," where humans, data, processes, and objects coalesce within a highly dynamic and intricately interconnected system.

TABLE II. NUMBER OF RELATED ARTICLES RANKED BY SCOPE OF CONTRIBUTION

Scope of the literature	Number of articles
IoT security	62
IoT privacy	29
Scalability	24
SDN-IoT	16
Blockchain	63
IoT security with Blockchain	48
IoT privacy with Blockchain	25
IoT security with SDN and Blockchain	9

V. CONCLUSION

The Internet of Things (IoT) confronts an array of security issues that surpass the complexities encountered in other domains, primarily owing to its intricate ecosystem and the inherent limitations of resource-constrained IoT devices. In recent years, an extensive body of research has been dedicated to addressing the diverse security challenges intimately linked with the IoT landscape. These challenges encompass intricate aspects such as authentication, confidentiality, integrity, access control, and policy enforcement, among a multitude of others.

Predominantly, prior works in the literature have strived to adapt security solutions initially devised for wireless and Internet sensor networks to suit the specific demands of the IoT framework. Nonetheless, it is imperative to underscore that IoT challenges present a novel dimension that proves considerably arduous to surmount using conventional remedies. Furthermore, it is crucial to emphasize that a significant proportion of prevailing security methodologies are rooted in centralized architectures, rendering their application within the IoT context notably more intricate due to the sheer abundance of interconnected entities. Consequently, a shift towards distributed approaches is imperative to effectively address the multifaceted security challenges that the IoT inherently presents.

Departamento Académico de Ciencias Básicas, Universidad Nacional Micaela Bastidas de Apurímac, Abancay, Perú[3]

Abstract—**Learning Disorders, which affect approximately 10% of the school population, represent a significant challenge in the educational field. The lack of proper diagnosis and treatment can have profound consequences, triggering psychological problems in those affected by disorders that impact reading, writing, numeracy and attention, among others. Notable among them are Attention Deficit Hyperactivity Disorder (ADHD) and dyslexia. In this context, a literature review focusing on Machine Learning applications to address these educational problems is addressed. The methodology proposed by Barbara Kitchenham guides this analysis, using the online tool Parsifal for the review, generation of search strings, formulation of research questions and management of information sources. The first findings of this research highlight a growing trend in the application of Machine Learning techniques in learning problems and disorders, especially in the last five years, as of 2019. Among the primary sources, the IEEE Digital Library emerges as a key source of information in this rapidly developing field. This innovative approach has the potential to significantly improve early detection, accurate diagnosis and implementation of personalized interventions, thus offering new perspectives in understanding and addressing the educational challenges associated with Learning Disorders.**

Keywords—Machine learning; learning disorder; deep learning; ADHD; dyslexia; learning impairment

I. Introduction

Learning Disorders (LD) are the most prevalent neurodevelopmental disorders in the population, affecting about 10% of the population at school age. AT cause that children with an adequate schooling and normal intelligence with difficulties of neurobiological origin, due to the lack of a proper diagnosis and treatment, suffer this problem of learning disorders causing psychological problems to those affected. These disorders affect reading, writing, calculation and/or attention, among others [1]. Some of the best known disorders are ADHD and dyslexia.

ADHD attention [2] deficit and hyperactivity disorder, considered as a specific learning disorder, as well as a behavioral disorder, has been one of the main reasons for consultation in pediatric neurology, although the clinical criteria are well established, probably the clinical history is not rigorously reviewed and the most determinant symptoms are not adequately noted.

Dyslexia is a brain condition that makes reading, spelling, writing and sometimes speaking difficult. The brains of people with dyslexia have difficulty recognizing or processing certain types of information. It occurs in people who do not have any physical, motor, visual or other disabilities. [3] Likewise, people with dyslexia have normal cognitive development.

Learning disorders are not considered problems, although they were for many years, but thanks to advances in neuroscience, it is now defined as a learning disorder, and the causes are neurobiological in origin. [3] The child is born and the cause is generally of genetic origin, although several institutions still maintain the name of learning disabilities, it must be clear that they are not problems but learning disorders.

It is therefore important to recognize the importance of approaching Learning Disorders from a holistic perspective. While science has advanced in understanding their neurobiological origin, it is essential to emphasize the need for early detection and a multidisciplinary approach to ensure accurate diagnosis and appropriate treatment. Lack of awareness and understanding of these disorders can lead to children facing unnecessary difficulties in their academic and emotional development. Therefore, advocating for greater awareness, education and support for those affected is key to building an inclusive society that recognizes and values diversity in learning abilities.

Machine Learning techniques can help in investigating and addressing learning disorders, such as Attention Deficit Hyperactivity Disorder (ADHD) and dyslexia, due to their unique ability to analyze vast amounts of heterogeneous data and extract complex patterns that may go unnoticed by conventional methods. These disorders, characterized by a diversity of clinical manifestations and associated factors, present significant challenges for accurate diagnosis and a thorough understanding of their underlying mechanisms. The application of these algorithms allows the integration of information from various sources, such as reading tests, magnetic resonance imaging and electroencephalography, thus facilitating a multidimensional approach. In addition, the classification and predictive capabilities of these techniques can be crucial to improve early detection, personalize intervention strategies and move towards the development of automated diagnostic systems.

The aim of this article is to make a systematic review on the contributions of Machine Learning and Deep learning in learning disabilities and learning disorders detection. For which a methodology inspired by Barbara Kitchenham's proposal was used, then in the results section the information extracted from the selected articles is analyzed and finally the conclusions obtained are specified, the information collected is intended to serve as a basis for other studies related to the application of Machine Learning in the problems of learning disorders. It is also intended to motivate readers to delve deeper into this area of research.

II. Methodology

For the development of this article, Barbara Kitchenham's methodology was applied as an inspiration, it is important to highlight that it helps significantly in works related to the systematic review of the literature, the phases that helped to develop this study are described below.

Plan the systematic literature review using the Parsifal tool.

- Determine research questions.
- Establish search process.
- Define inclusion and exclusion criteria for articles.
- Select query sources.
- Create search strings.

Develop the systematic literature review with the defined planning.

- Search for articles.
- Selection of definitive articles for information analysis.
- Analysis and classification of information.

Document and interpret the results of the review.

- Develop the report of the research questions of the review.

The tools used for the development of this research are as follows:

- Mendeley: It is a tool that allows the management and administration of bibliographic sources. It allowed the management of the references mentioned in this research work.
- Parsifal: It is a web tool that helped with the creation of search strings, keywords and research questions.

III. Development

A. Plan the Systematic Literature Review

Each of the tasks performed during the planning stage of the systematic literature review are detailed below:

1) Determine the research questions: Based on the purpose of this article, the following research questions are raised.

- In which repositories have most of the articles on the topic of study been published?
- In what year were most articles published, and how are they interpreted?
- How does Machine Learning help in the detection of learning problems and disorders?

2) Establish the search process: Base terms were identified by applying the PICOC method [4] to define the scope of the systematic review. Its components are population, intervention, comparison, results and contexts. This method made it possible to define the expressions that make up the search strings. They are detailed below:

- Population (P): “Learning disorder” OR “Learning Impairment” OR “ADHD” OR “Learning Deficit”.
- Intervention (I): “Machine learning” OR “Deep Learning”.
- Comparison (C): Not applicable.
- Outcomes (O): “Algorithms” OR “Classification” OR “Detection” OR “Methods” OR “Techniques”
- Context (C): “Artificial Intelligence”.

3) Define the inclusion and exclusion criteria for the articles: According to the objectives and scope of this article, it is necessary to establish four inclusion criteria (IC) and four exclusion criteria (EC), which are described as follows:

Inclusion criteria (IC):

- IC1: Articles containing information on Machine Learning or Deep Learning techniques.
- IC2: Articles written in English or Spanish.
- IC3: Articles published from 2019 onwards.
- IC4: Articles that have been published in scientific journals, scientific articles, and scientific articles.

Inclusion criteria (EC):

- EC1: Duplicate articles.
- EC2: Articles whose title is not related to the object of study.
- EC3: Articles that do not belong to the area of Science and Computing
- EC4: Book chapters, manuals, gray literature.

4) Select sources of consultation: Four search sources indicated in Table I were selected due to their accessibility and advanced query support.

TABLE I. Scientific Databases

Database	URL
IEEE	https://ieeexplore.ieee.org
ScienceDirect	https://www.sciencedirect.com
Scopus	https://www.scopus.com
Doaj	https://doaj.org/

5) Search Strings: The keywords were considered on the basis of what was applied in the PICOC method, and the logical operators "AND/OR" were used to generate the search strings.

The Parsifal tool generated the general search string, which was modified according to each database, and all the keywords were defined in English, as shown in Table II.

TABLE II. SEARCH STRING

Database	Search Strings
Parsifal	("Learning disorder" OR "ADHD" OR "Learning Deficit" OR "Learning Impairment" OR "TDAH") AND ("Machine Learning" OR "Deep Learning") AND ("Algorithms" OR "Classification" OR "Detection" OR "Methods" OR "Techniques")
IEEE	(("Learning disorder" OR "ADHD" OR "Learning Deficit" OR "Learning Impairment" OR "TDAH") AND ("Machine Learning" OR "Deep Learning") AND ("Algorithms" OR "Classification" OR "Detection" OR "Methods" OR "Techniques"))
ScienceDirect	(("Learning disorder" OR "ADHD") AND ("Machine Learning" AND "Deep Learning") AND ("Algorithms" AND "Classification" OR "Detection" AND ("Methods" OR "Techniques"))
Scopus	TITLE-ABS-KEY(("Learning disorder" OR "Learning Deficit" OR "Learning Impairment" OR "ADHD" OR "TDAH") AND ("Machine Learning" OR "Deep Learning") AND ("Algorithms" AND ("Classification" OR "Detection") AND ("Methods" OR "Techniques"))) AND (LIMIT-TO (DOCTYPE,"ar") OR LIMIT-TO (DOCTYPE,"cp")) AND (LIMIT-TO (SUBJAREA,"COMP")) AND (LIMIT-TO (PUBYEAR,2023) OR LIMIT-TO (PUBYEAR,2022) LIMIT-TO (PUBYEAR,2021) OR LIMIT-TO (PUBYEAR,2020) OR LIMIT-TO (PUBYEAR,2019))
Doaj	"Learning disorder" AND "machine learning"

B. Develop the Systematic Literature Review

1) Search for articles: The search string was implemented in each of the selected databases (IEEE, ScienceDirect, Scopus and Doaj), where 413 articles were obtained. Of these, articles that did not meet the inclusion criteria were ignored and duplicate articles or those that had no relevance to the field of study were discarded. Of the 413 articles, 22 were selected for further review as they met the prerequisites.

2) Selection of definitive items for data analysis: The norm in this section, according to the methodology proposed by Barbara Kitchenham, is that the articles go through a series of quality questions in order to select the articles that contribute the most to the research objective. However, since there are only 22 articles and all meet the requirements for inclusion, the 22 definitive articles were considered for the analysis of information.

3) Analysis and classification of information: Sources of information: Thanks to the Parsifal tool, the following figure was created, showing the level of contribution of the sources of information in percentages in Fig. 1.

By observing and analyzing Fig. 1, the following can be determined:

- IEEE Digital Library information source with 45% obtains a higher percentage in the graph, in this group are [5] [6] [7] [8] [9] [10] [11] [12] [13] [14].
- Science@Direct obtains 36.4% of contribution level for the present article. In this group are [15] [16] [17] [18] [19] [20] [21] [22].
- Scopus, which is another of the repositories that made the greatest contribution to the research, contributed 13.6%. This group includes [23] [24] [25].
- Finally, 4.5% belongs to Doaj with the article [26].

Years of publication: Thanks to the Parsifal tool, a graph showing the number of articles per year was generated in Fig. 2.

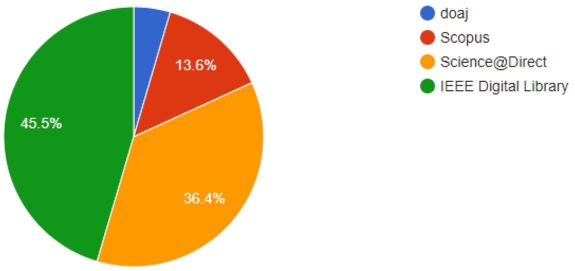

Fig. 1. Information sources.

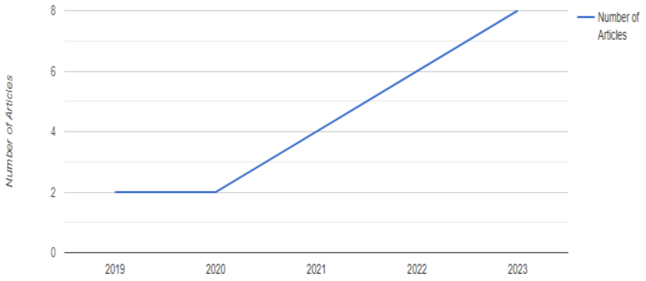

Fig. 2. Articles by year.

C. Document and Interpret the Results of the Review

The following section presents the answers to the research questions.

1) In which repositories have most of the articles on the topic of study been published?: Taking into account the information analysis and classification section, it was observed that the information source with the most articles published was the IEEE Digital Library with 10 articles, followed by Science@Direct with eight articles, these being the repositories with the greatest contribution in the field of Machine Learning in learning problems and disorders.

2) In what year were most of the articles published, and how are they interpreted?: Taking into account the section of analysis and classification of the information, it is possible to identify that the year 2023 was when more articles were published with a total of 8 articles and this was growing since 2019, this could indicate that interest in applying Machine

Learning techniques in areas such as learning disorders is growing.

3) How does Machine Learning help in the detection of learning problems and disorders?: According to the review of the articles, most of them are focused on the early detection of learning disorders, and another large percentage apply Machine Learning techniques for the classification of people with ADHD, followed by another group of articles related to the prediction of the presence of dyslexia in children. And a small percentage focus on optimizing the detection or classification of learning disorders using new and novel Machine Learning techniques, obtaining promising results.

IV. Results

The present review allowed answering the research questions, obtaining that the major source of information is the IEEE Digital Library and the year 2023 is the highest percentage of published articles indicating that more and more emphasis is being placed on the application of Machine Learning in learning problems and disorders. A brief summary of some articles will be given below:

They analyzed in [6] the classification performance of three machine learning algorithms (Naive Bayes, kNN, logistic regression) applied on the dataset of 157 children, of which 77 were ADHD patients and 80 healthy. The closest classifier k is able to predict with a high accuracy of 86% and is much better than Naive Bayes (52%) and logistic regression (66%).

This study in [15] focused on addressing data imbalance in prescreening tests for developmental dyslexia. It proposed an ensemble-based oversampling and machine learning technique to improve the detection of the minority class (dyslexic patients). The researchers used reading and writing tests, online games, magnetic resonance imaging (MRI), electroencephalography (EEG), photography, and video recording as input data. Simulation results showed that the proposed approach improved the detection accuracy of the minority class from 80.61% to 83.52%.

This research in [26] focused on identifying the neurocognitive characteristics of Attention Deficit Hyperactivity Disorder (ADHD), both in its pure presentation and in its comorbidity with other disorders. Using the Machine Learning Decision Tree (MLT) technique in the Rcran 4.2.1 software, probabilistic rules were constructed based on different neurocognitive variables. We found that children with pure ADHD showed poor performance on working memory and perceptual reasoning tasks, independent of IQ deficits. In addition, deficits in working memory were common across all ADHD presentations and comorbidities. The use of DTM allowed us to establish a clinical hierarchy and identify the most important variables in the different populations of children diagnosed with ADHD. This technique proved to be advantageous in differentiating the importance of dependent variables in the study of ADHD.

This project [5] aims to classify attention deficit hyperactivity disorder (ADHD) using machine learning techniques. The WEKA toolkit was used to perform a comparative analysis of the classification of four forms of ADHD using various machine learning algorithms. Different feature sets were experimented with, including those generated using the genetic algorithm from phenotypic data of the ADHD-200 dataset. The classification algorithms used were Logistic, Support Vector Machine (SVM), Decision Tree (DT) implemented using the J48 algorithm, Random Forest (RF), K-nearest neighbor (KNN) implemented using the instance-based learner (IBk) algorithm and multi-layer perceptron (MLP). Eight performance parameters were evaluated: accuracy, precision, recall, F-measure, Kappa statistic, root mean square error (RMSE), Mathew correlation coefficient (MCC) and area under the receiver operating characteristics curve (AUROC). The ultimate goal is to provide valuable information for the establishment of an automated diagnostic system for ADHD.

V. Discussion and Conclusion

The literature review reveals important points of convergence and divergence among the studies analyzed. First, there is a general consensus in the scientific community on the growing relevance and application of machine learning techniques, especially in the context of learning disorders and problems, such as Attention Deficit Hyperactivity Disorder (ADHD) and developmental dyslexia. All studies highlight the importance of using machine learning algorithms to improve the detection, classification and understanding of these disorders, leveraging diverse data sources, from reading and writing tests to magnetic resonance imaging and electroencephalography.

Different methodological approaches are also observed across studies. For example, while some focus on the performance of specific algorithms for ADHD classification, others address specific challenges such as data imbalance in prescreening tests for developmental dyslexia. In addition, the use of different feature sets and the application of specific techniques, such as the Machine Learning Decision Tree, highlight the diversity of strategies implemented in the research.

However, aspects related to the integration and standardization of the proposed methods remain to be addressed, as well as the validation of the results in clinical settings and the consideration of ethical factors in the development of automated diagnostic systems. The variability in the feature sets and algorithms used suggests the need to establish common protocols for the comparison and replication of results. Furthermore, the practical implementation and acceptance of these technologies in clinical and educational settings requires careful consideration of the ethical and social implications. In this sense, future research could focus on addressing these aspects to move towards the effective application of machine learning techniques in the diagnosis and treatment of learning disorders.

***Abstract*—The durian fruit holds a prominent position as a beloved fruit not only in ASEAN countries but also in European nations. Its significant potential for contributing to economic growth in the agricultural sector is undeniable. However, the prevalence of durian leaf diseases in various ASEAN countries, including Malaysia, Indonesia, the Philippines, and Thailand, presents formidable challenges. Traditionally, the identification of these leaf diseases has relied on manual visual inspection, a laborious and time-consuming process. In response to this challenge, an innovative approach is presented for the classification and recognition of durian leaf diseases, delves into cutting-edge disease control strategies using vision transformer. The diseases include the classes of leaf spot, blight sport, algal leaf spot and healthy class. Our methodology incorporates the utilization of well-established deep learning models, specifically vision transformer model, with meticulous fine-tuning of hyperparameters such as epochs, optimizers, and maximum learning rates. Notably, our research demonstrates an outstanding achievement: vision transformer attains an impressive accuracy rate of 94.12% through the hyperparameter of the Adam optimizer with a maximum learning rate of 0.001. This work not only provides a robust solution for durian disease control but also showcases the potential of advanced deep learning techniques in agricultural practices. Our work contributes to the broader field of precision agriculture and underscores the critical role of technology in securing the future of durian farming**.

Keywords—Vision transformer; durian disease; deep learning; disease control

I. Introduction

The durian fruit's popularity has surged in recent years, primarily driven by increased consumer demand, notably from China [1]. Moreover, it has found a substantial export market in Southeast Asian countries, Hong Kong, Australia, and Western nations such as United States. This upswing in the durian market can be attributed in part to the cultivation of premium varieties renowned for their exceptional flavor and consistent pulp quality. Notably, varieties like D24, D197 (Musang King), and D200 (Black Thorn) from Malaysia, as well as traditional Thai cultivars such as Monthong, Chanee, and Kanyau, have garnered significant attention and are in high demand, painting a promising future for the fruit.

Thailand maintains its position as the primary producer and exporter of durians, with other countries like Malaysia, Indonesia, Vietnam, Cambodia, and the Philippines also cultivating this unique fruit [2]. The global durian fruit trade is characterized by a dominant duopoly, with China taking the lead in imports, while Thailand leads in exports. In 2021, Thailand's durian exports reached an impressive value of 3,920 million USD, making up a significant 82.7% of the total global trade. In contrast, Malaysia's contribution ranked fourth, comprising about 0.67% of the trade volume, with a total value of 31.8 million USD. Simultaneously, China asserted its dominance in global durian imports in the same year, with an astonishing 4,240 million USD, constituting a substantial 89.4% of the overall trade. Additionally, notable participants in the market, following China's lead, included Hong Kong, Vietnam, Chinese Taipei, and Singapore, accounting for 89.4%, 5.37%, 2.43%, 0.72%, and 0.36% of the trade, respectively [3]. Fig. 1 and Fig. 2 depict the top importer and exporter of durians, respectively.

The adoption of modern agricultural practices, including drip irrigation, enhanced fertilizer formulations and application techniques, and improved cultural and postharvest methods, has significantly contributed to the increased productivity of durian farms [4]. Nevertheless, growers remain vigilant due to the persistent threat of diseases in the industry. Durian trees are susceptible to a range of diseases, such as spot cancer, base rot, base disease, seedling disease, dead tip disease, fungal infections, leaf spots, leaf blight, and fruit rot. Among these, stem rot disease, primarily caused by P. Palmivora, stands out as a particularly perilous ailment. This disease severely impairs the tree's nutrient transport system within the stem.

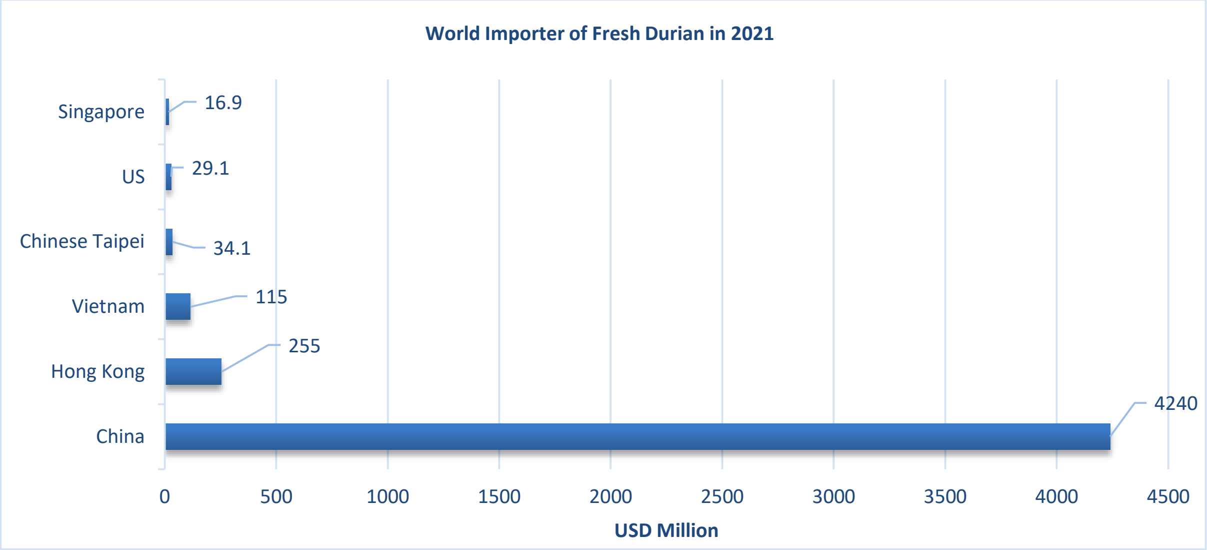

Fig. 1. World importer of fresh durian in 2021.

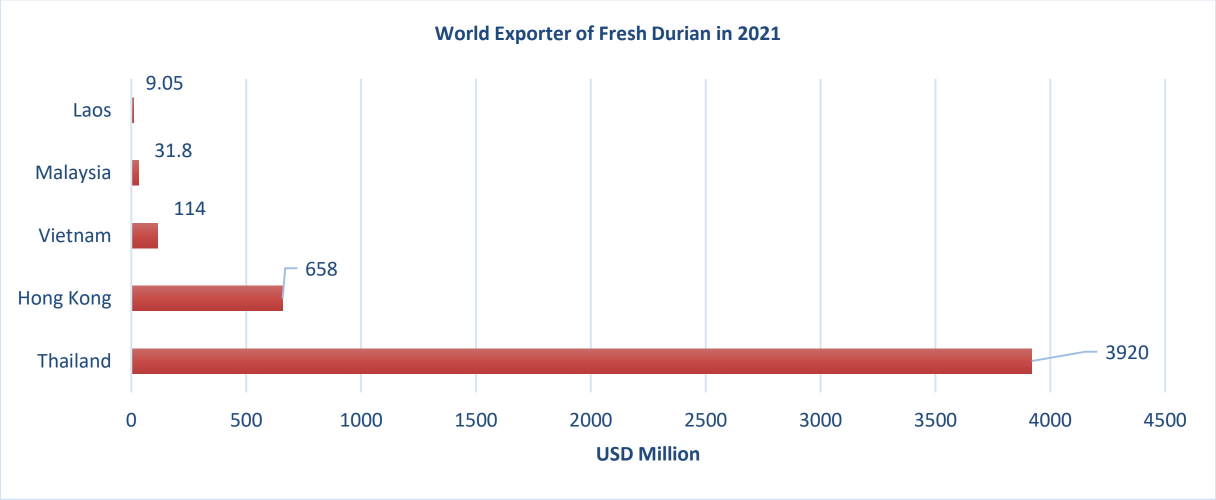

Fig. 2. World exporter of fresh durian in 2021.

Durian trees are susceptible to various diseases, such as algal diseases caused by cephaleuros virescens, characterized by the appearance of orange, rust-colored velutinous spots on the upper surfaces of leaves, twigs, and branches. Another concern is anthracnose, resulting from Colletotrichum gloeosporioides, which manifests as dark lesions on fruit and premature fruit drop. Moreover, Phomopsis leaf spot, induced by diplodia heobromae and C. Gloeosporioides, presents as necrotic, brown circular spots, approximately 1 mm in diameter, featuring dark margins and yellow halos on leaves. The sinister pink disease, attributed to erythricium salmonicolor, is marked by pinkish-white mycelial threads that envelop branches and shoots.

Additionally, postharvest fruit rots caused by Phyllosticta sp. and curvularia eragrostidis result in irregular necrotic patches in varying shades of brown. Rhizoctonia leaf blight, originating from Rhizoctonia solani, leads to water-soaked spots on leaves that coalesce to form larger, irregular, water-soaked patches, eventually drying into light brown necrotic lesions. Lastly, sooty mold and black mildew, caused by Black Mildew fungi, form a hard, lumpy crust on twigs and leaf petioles, and on fruit, they create a spongy crust on the surface. However, a particularly dangerous ailment is stem rot disease, resulting from P. Palmivora, which damages the tree's nutrient transport system in the stem.

A significant aspect of the challenges that arise in agricultural areas can be addressed by computer vision [5]. Traditionally, the detection of plant diseases heavily relied on manual inspections conducted by farmers or laborers, typically with the naked eye (Singh et al., 2017 & Petrellis, 2015). Table I presented traditional disease monitoring procedure for disease management with limitations, such as visual inspection, scouting, weather-based disease forecasting and etcetera. This method can be both laborious and repetitive, especially when dealing with tall Durian trees. However, the advent of artificial intelligence (AI) has revolutionized disease detection in various tree types, including Durian.

TABLE I. TRADITIONAL DISEASE MONITORING PROCEDURE FOR DISEASE MANAGEMENT

Disease Monitoring Procedure	Description	Limitations
Visual Inspection	Regular visual assessment of crops for symptoms of disease.	- Subject to human error and bias. - May miss early or subtle symptoms. - Time-consuming for large fields.
Scouting by Field Observers	Trained personnel systematically inspecting fields for signs of disease.	- Labor-intensive and costly. - Limited coverage and potential variations in observer expertise.
Weather-Based Disease Forecasting	Using weather data to predict disease outbreaks based on favourable conditions for pathogen development.	- Accuracy depends on the quality and availability of weather data. - Doesn't account for all factors affecting disease.
Sampling and Lab Testing	Collecting plant or soil samples for laboratory analysis to identify and confirm disease presence.	- Requires specialized equipment and expertise. - Results may not be available quickly enough for immediate action.
Disease Severity Rating Scales	Assigning numerical scores to rate disease severity, helping quantify disease progression.	- Subjective and dependent on the assessor's judgment. - Can be time-consuming, especially for large areas.
Trap Crops and Indicator Plants	Planting susceptible species near valuable crops to serve as early warning indicators of disease presence.	- May not always provide timely detection. - May require additional land and resources.
Neighbouring Farm Communication	Exchange of information among neighbouring farms about disease outbreaks or observations.	- Relies on the willingness of nearby farmers to share information. - Limited to local awareness.

In agriculture, diseases are a common occurrence across different fruit varieties. When it comes to monitoring fruit diseases, researchers and practitioners often grapple with the challenge of finding a balance between the accuracy of deep learning models and the computational resources necessary for efficient monitoring. To tackle this challenge and enhance both precision and efficiency, various deep learning architectures and techniques have been explored.

Considering there are more pixels in an image than there are words in NLP applications, the use of the attention mechanism in vision applications has been considerably more constrained due to the high computing cost [6]. This means that typical attention models cannot be applied to visuals.

II. RELATED WORKS

Transformer network applications in computer vision were recently reviewed in [7] and vision transformer (ViT) is a major step towards adopting transformer-attention models for computer vision tasks [8]. Compared to CNN-based models that consider picture pixels, using image patches as information units for training is groundbreaking. ViT uses self-attention modules to analyze the relationship between image patches included in a shared region. ViT was demonstrated to outperform CNNs in image classification accuracy given vast quantities of training data and processing resources [8].

State-of-the-art deep learning models can achieve impressive results and are well-suited for drone applications, but they come with a hefty need for computational resources during the training process. In contrast, Vision Transformer (ViT) offers a promising alternative [26]. ViT avoids using Convolutional Neural Networks (CNNs) and performs at a level similar to top-tier CNN models. ViT, a relative of the Transformer model, utilizes a smart technique called self-attention to establish a global reference for each pixel in an image during training. It breaks the image into smaller patches, assigns a position to each patch, and learns from them. In the final layers of the ViT model, the similarity between these patch representations significantly improves. Interestingly, adding more layers to the model doesn't enhance its performance [27]. Nevertheless, ViT does pose a challenge when dealing with high-resolution images due to its four-fold increase in memory requirements, making them more difficult to handle.

Numerous research studies have focused on mitigating the shortcomings of Transformer-based models which tend to fall into two main categories: hybrid models and pure Transformer enhancements. Table II illustrates both hybrid and pure transformer enhancements. Furthermore, by employing the Vision Transformer, researchers achieved a minimum of 1% higher accuracy in classifying cassava leaf diseases than well-known CNN models. They also effectively implemented this model on the Raspberry Pi 4, an edge device, showcasing the substantial potential for its application in the realm of smart agriculture [17]. To the best of our knowledge, only [19] has performed durian disease detection using deep learning approach. The durian disease classification was performed using Resnet-9 and VGG-19 where Resnet-9 was outperformed VGG-19 with accuracy of 100% and 99.11%, respectively. Recent advancements in plant disease detection have seen substantial enhancements using CNN-based models. Nevertheless, these models have limitations such as translation invariance, locality sensitivity, and a lack of comprehensive global image understanding.

TABLE II. HYBRID AND ORIGINAL VISION TRANSFORMER METHOD

Paper	ViT Techniques	Results	Limitations
[9]	Ghost-Enlightened Transformer (GeT)	98.14%	-Relies on large labelled data
[10]	PlantXViT	98.33%	-unable to maintain a lower count of Gega floating operation points.
[11]	Convolution vision Trasnformer (CvT)	87.7%	-higher accuracy will increase training and inference times and memory used.
[12]	Convolution-enhanced image Transformer (CeiT)	99.1%	
[13]	LocalVit	94.2%	
[14]	Swin Transformer	81.3%	-larger resolution needed to increase the accuracy
[15]	k-NN attention (KvT)	73.0%	-need to be paired up as the boosting agent for the vision transformer.
[16]	RegionViT	83.8%	Not stated

To overcome these challenges, this study introduces a novel approach that employs a Vision Transformer-based model for more effective plant disease classification. ViT results will be compared with ResNet-9 and VGG-19 [19] in results and discussion part. This approach combines computer vision and deep learning technologies to revolutionize agricultural production management, utilizing large-scale datasets to address current agricultural issues and improve the overall performance of agricultural automation systems, especially in Durian disease classification, thereby propelling agricultural automation equipment and systems toward a more intelligent future [18].

The paper is organized as follows: Section I presents a brief introduction to the type of durian diseases and current method used to detect the diseases. Section II delves into related works. Section III covers the methodology of ViT and how the experiment conducted. Then, Section IV presents the results and discussion of durian disease detected using ViT and Section V gives the conclusion and future work of the research.

III. Methodology

A. Dataset Preparation

In this experimental study, our primary objective was to develop and train a robust deep learning model specifically Vision Transformer capable of accurately classifying diseases that affect durian plants. Our dataset included a total of 1,344 images, which were distributed across four distinct classes. The diseases aimed to precisely classify were ‘durian_leaf_spot’, ‘durian_leaf_blight’, ‘durian_algal_leaf_spot’, and ‘durian_ healthy’, as presented in Table III [20].

To effectively manage the dataset, the original dataset is divided into two sets: training and validation. This was achieved by applying a validation split ratio of 20%, meaning that 80% of the data was designated for training purposes, while the remaining 20% was reserved for validation.

Additionally, to enhance the model's generalization and diversify the training data, data augmentation techniques was implemented. The 'ImageDataGenerator' class is provided by Keras, which facilitated various augmentations of the training data. These augmentations included random rotations of up to 40 degrees, horizontal and vertical shifts of up to 20% of the image dimensions, shearing transformations up to 20%, random zoom adjustments that could expand or contract by up to 20%, and horizontal flipping to create mirror images. When generating new pixels, the 'nearest' method was utilized. This process resulted in the creation of four augmented versions of each original image, significantly expanding the size of the training dataset.

TABLE III. Durian Disease Dataset Extracted From [20]

Dataset	Description	Total number of images	Sample of images
'durian___leaf_spot'	Images of durian leaves with leaf spot disease.	336	'durian___leaf_blight'	Images of durian leaves with leaf blight disease	336	'durian___algal_leaf_spot'	Images of durian leaves with algal leaf spot disease	336	'durian___healthy'	Images of healthy durian leaves	336	

B. Durian Disease Classification using Vision Transformer (ViT)

The ViT model consists of patch creation, patch encoding, multiple Transformer layers, and a final classification head, as shown in Fig. 3.

- Patch creation: Instead of processing entire images at once, the ViT model divides each image into smaller non-overlapping patches or tiles. This patch-based approach allows the model to process large images efficiently. Each patch is treated as a separate input and processed independently by the model.
- Patch Encoding: After splitting the image into patches, each patch is encoded into a numerical representation that the model can work with. This process typically involves linearly projecting the patch's pixel values into a lower-dimensional vector, allowing the model to learn spatial relationships and features within each patch.
- Multiple Transformer Layers: The heart of the ViT model consists of multiple Transformer layers. These layers process the encoded patches and capture contextual information, enabling the model to understand how different patches relate to one another. The self-attention mechanism in the Transformer architecture is particularly crucial for this step, as it helps the model weigh the importance of different patches when making predictions.
- Final Classification Head: At the end of the ViT model, there is a classification head. This part of the model takes the information from the previous Transformer layers and makes predictions based on the features learned during the earlier stages of processing. For tasks like image classification, this is where the model assigns labels or probabilities to different classes.

The ViT model employs two optimizers, Adam and SGD (Stochastic Gradient Descent), which include a regularization technique called weight decay. Weight decay is a regularization method used to prevent overfitting in deep learning models. It works by adding a penalty term to the loss function during training, encouraging the model to have smaller weight values. Smaller weights can make the model more robust and less prone to overfitting.

To improve training efficiency, a learning rate schedule is defined. In this schedule, the learning rate, which determines how much the model's parameters are updated during training, is reduced by 50% every 10 training epochs. This gradual reduction in learning rate is a common strategy to help the model converge to a good solution without making overly large updates to its weights, which can cause instability.

During training, the ViT model periodically saves its current state as checkpoints. These checkpoints capture the model's parameters, allowing you to resume training from where you left off or use the model for inference. The saving of model checkpoints is typically based on validation accuracy, meaning that the model's performance on a separate validation dataset is used as a criterion to determine when to save a checkpoint. This ensures that the saved models are based on their ability to generalize to unseen data.

Furthermore, the training data is divided into two parts: the main training data (90%) and a validation set (10%). The main training data is used to train the ViT model, while the validation set is used to monitor the model's performance during training. This split is important for assessing how well the model is learning and for tuning hyperparameters like the learning rate. After the model has been trained, it is evaluated on a separate test dataset that the model has never seen during training. This evaluation assesses the model's performance on unseen data and provides an indication of how well it can generalize to real-world scenarios. The evaluation reports two metrics: accuracy, which measures the overall correctness of predictions, and top-5 accuracy, which indicates how often the correct label is among the top five predicted labels.

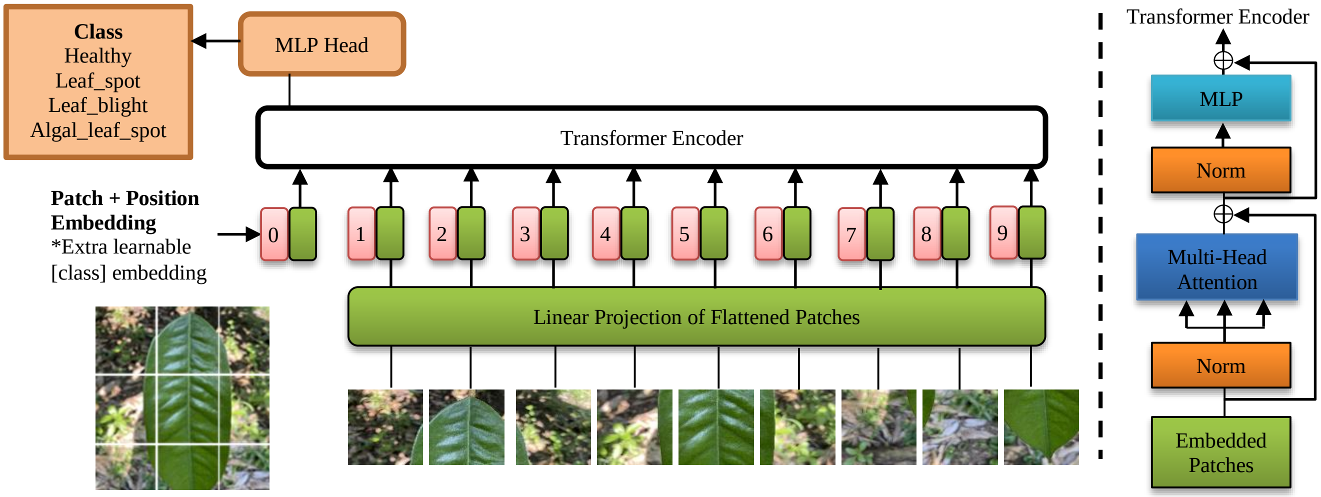

Fig. 3. Vision transformer architecture.

IV. Results and Discussion

In this study, ViT has been deployed and fine-tuned it to perform Durian Disease classification using two well-known optimization algorithms, namely, Stochastic Gradient Descent (SGD) and ADAM optimizer. The experiments encompassed a range of hyperparameters, including different learning rates (0.001, 0.005, and 0.01) and various epoch settings (20, 30, and 40). The outcomes provide valuable insights into how the model's performance varies with alterations in these key hyperparameters, shedding light on the most effective configurations for the task.

As revealed in Table IV, a validation accuracy of 94.12% was attained with the utilization of the ADAM optimizer, a maximum learning rate of 0.01, and an extended training period of 400 epochs. In contrast, Table V displays the outcomes with the SGD optimizer, where a comparable learning rate and epoch setting yielded an accuracy of 85.82%. ADAM's superior performance in this context can be attributed to its adaptability and the fusion of techniques from both momentum and RMSprop optimization. ADAM excels in scenarios involving intricate loss surfaces and fluctuating learning rates. It dynamically tailors the learning rate for each parameter, guided by historical gradient information. This adaptability often results in swifter convergence and enhanced generalization capabilities. In contrast, SGD adheres to a more conventional optimization approach. Achieving parity with ADAM's performance, particularly with complex models like ViT, often necessitates manual fine-tuning of the learning rate and other hyperparameters.

In many cases, the maximum learning rate of 0.01 might lead to faster convergence but might also make the model diverge or not settle into the optimal solution. By reducing the maximum learning rate during training (e.g., from 0.01 to 0.001), the model is allowed to fine-tune and reach a more stable and accurate solution. This phenomenon can be observed where both optimizers are performed well with maximum learning rate of 0.001 compare to 0.01.

Certainly, our training approach involved the incorporation of a learning rate schedule to foster training stability and mitigate overfitting. Simultaneously, data augmentation proved instrumental in enhancing the model's robustness by enabling it to adapt to a broader range of image conditions. Techniques such as resizing, flipping, rotation, and zooming effectively contributed to this augmentation strategy.

However, in Table VI, ResNet-9 is outperformed the other two methods, ViT and VGG-19. When evaluating why ViT might not be as good as the accuracy of ResNet-9 and VGG-19 [19], various factors come into play. First, ResNet-9 and VGG-19, as convolutional neural networks (CNNs), have been explicitly tailored for image classification tasks, boasting a proven track record in this domain. ViT, on the other hand, is a relatively newer architecture that demands substantial fine-tuning for optimal performance.

Additionally, ViT models often require more extended training schedules, specialized initialization methods, and specific architectural considerations, necessitating higher computational resources. Moreover, ViT's capacity to generalize might be challenged when confronted with smaller datasets, as its architecture is not as well-suited to such scenarios. Comparatively, ResNet-9 and VGG-19 [19] models tend to deliver robust performance with limited data, given their established history in this context.

Furthermore, the availability of pretrained weights customized for specific tasks can provide a performance advantage to ResNet-9 and VGG-19 over ViT. It's important to note that ViT is relatively more susceptible to overfitting, especially in cases involving smaller datasets or exceptionally large models. In addition to these considerations, our dataset for durian leaf disease classification is relatively small, posing a challenge for ViT's generalization capabilities. Addressing this issue would necessitate the utilization of larger models, fine-tuning with different hyperparameters, and more extensive tuning.

TABLE IV. VIT WITH ADAM OPTIMIZER

V. CONCLUSION AND FUTURE WORKS

This research represents a significant advancement in the field of durian leaf disease detection and recognition, addressing a critical issue faced by durian farmers in ASEAN countries and beyond. The traditional manual identification of leaf diseases has been a labor-intensive and time-consuming process, posing substantial challenges to the agricultural sector's sustainability. Through the application of cutting-edge deep learning techniques and the utilization of well-established models like ViT, an automated system has been successfully developed and capable of accurately classifying and recognizing durian leaf diseases. Notably, our results demonstrate the remarkable performance, achieving an impressive accuracy rate of 94.12% when utilizing the Adam optimizer. Moreover, this research underscores the broader implications of utilizing cutting-edge machine learning techniques in agriculture. It opens the door to the development of precision agriculture systems that can revolutionize crop management practices. The implementation of ViT-based disease control not only safeguards the economic stability and food security of the Southeast Asian region but also paves the way for further advancements in the field of agriculture. With technology as a key ally, durian farmers and the agricultural sector as a whole are better equipped to overcome the challenges posed by disease and secure a more prosperous future.

The Construction of Campus Network Public Opinion Analysis Model Based on T-GAN Model

Jianan Zhang
School of Education Science, Nantong University, Nantong 226019, China

***Abstract*—The advancement of information technology has made the internet and social media an indispensable part of modern life, but with it comes a flood of false information and rumors. The aim of this study is to develop a technology that can automatically identify campus network public opinion information, in order to protect student groups from the intrusion of erroneous information, maintain their mental health, and promote a clear campus public opinion environment. This study used the Scrapy framework to write web scraping scripts to collect campus public opinion data, and carried out cleaning and preprocessing. Then, a transformer based generative adversarial network (T-GAN) model was designed, combined with a multi-scale convolutional neural network (MCNN) structure, for public opinion analysis on campus networks. The results show that the accuracy of the dataset processed by the T-GAN model has been improved on LGBT, KNN, SVM, and RoBERTa, proving that the campus network public opinion analysis model based on the T-GAN model helps to automatically identify campus network public opinion, protect students' physical and mental health, and promote the healthy development of the campus network environment.**

Keywords—Public opinion analysis; T-GAN; feature extraction; multi-scale convolutional neural network; campus network

I. Introduction

In this era of information explosion on the Internet and social media, research has discovered a new space for people to share, communicate, and influence each other. Despite the continuous innovation of network technology, which promotes communication between people and provides unprecedented convenience in connectivity, there is also the rapid spread of unverified information hidden behind it [1]. Especially in the current era where rumors and false information are rampant, these pieces of information not only disrupt people's daily lives, but also pose a threat to social stability and order [2]. The campus environment, as a special social place, has particularly complex network public opinion management [3]. Students, as important carriers of information dissemination, frequently share insights and emotions related to numerous issues online [4]. However, the convergence of negative information on the Internet may aggravate students' rebellious mood and induce expanding foam of public opinion [5]. The constantly expanding public opinion has increased the complexity of campus management and caused interference with educational activities on campus [6]. In this context, timely monitoring and analysis of campus public opinion data is crucial for adopting effective management strategies and maintaining a harmonious and stable campus environment. In response to this issue, this study proposes a Generative Adversarial Network (GAN) model constructed using deep learning technology, aiming to conduct in-depth analysis of campus public opinion data. In addition, to improve the performance of the model in sentiment classification, this study also designed an innovative generative text data augmentation method. This method can effectively balance the distribution of data and enhance the accuracy of the model's judgment on different emotional categories. Therefore, by mining and analyzing campus public opinion data, it is helpful for schools to timely grasp the growth tendency of campus public opinion, provide important reference basis for taking effective management measures, and maintain a harmonious and stable campus environment. The novelty of this study lies in its innovative combination of Generative Adversarial Network (GAN) structure and Transformer model advantages, and the development of a deep learning model specifically designed for campus network public opinion - T-GAN. Many researchers have conducted research on this issue. Yadav A's research team has designed a deep learning model based on emotion analysis using deep learning and natural language processing techniques. Testing on popular datasets has shown significant effectiveness in solving emotion analysis problems [7]. Researchers such as Nemes L have used recurrent neural networks combined with natural language processing technology to construct an emotion classification model based on recurrent neural networks, which can classify user emotions based on keywords and demonstrate extremely high accuracy [8]. Mehta P and other scholars proposed designing an emotion mining model that utilizes machine learning and Lexicon survey methods for emotion mining. The research results show that the model can effectively match in opinion mining and sensory evaluation [9]. However, the above methods mainly address the issues of sentiment mining and sentiment classification, and research on precise sentiment classification based on campus public opinion data is relatively rare. Therefore, in response to this issue, this study innovatively utilizes deep learning technology to construct a Generate Adversarial Networks (GANs) model for in-depth analysis of campus public opinion data. Meanwhile, to improve the accuracy of the model in sentiment classification in public opinion data, a generative text data augmentation method has been studied and designed, which can expand the corpus with uneven data distribution, thereby achieving a balance in data distribution [10]. Therefore, in order to solve how to automatically identify and filter negative public opinion information in campus networks, and protect the physical and mental health of students, the establish of a campus network public opinion analysis model based on the Transformer-based Generate Adversarial Networks (T-GAN) model is studied to improve the accuracy of the model in sentiment classification and better conduct in-depth analysis of campus public opinion data. Although Yadav A's research team has successfully designed an emotion analysis deep learning model by combining deep learning and natural language processing techniques, and has demonstrated significant effectiveness in solving emotion analysis problems on popular datasets; Researchers such as Nemes L have also used a combination of recursive neural networks and natural language processing techniques to create an emotion classification model. This model classifies user emotions based on keywords and demonstrates extremely high accuracy; Mehta P and other scholars have proposed an emotion mining model that combines machine learning and dictionary research methods, and the research results show that this model is effective in opinion mining and perceptual evaluation. However, these methods mainly focus on the general issues of emotion mining and emotion classification, and there is little research on fine emotion classification based on campus public opinion data. In response to this research gap, our article aims to innovatively use deep learning techniques to establish a Generative Adversarial Networks (GANs) model, deeply analyze campus public opinion data, and explore the underlying factors that affect student emotions. Meanwhile, in order to enhance the accuracy of the model in sentiment classification of public opinion data, this study also designed a generative text data augmentation method. This method achieves data distribution balance by expanding the corpus with uneven data distribution. Through this approach, we hope that the model can more accurately understand and classify emotional tendencies in campus public opinion, provide an effective emotional analysis tool for campus managers, help them identify and respond to emotional dynamics in student groups in a timely manner, and thus maintain a healthy and harmonious campus environment. Overall, the main objective of this article is to construct a generative adversarial network model for analyzing campus public opinion data using deep learning techniques. Design and implement a text data augmentation strategy to balance data distribution and improve the accuracy of sentiment classification. Verify the effectiveness of the model on campus public opinion data and explore its potential positive impact on the campus environment. The overall structure of the entire article is divided into the following parts: Section I is the introduction, which outlines the background, importance, and purpose of the research. Emphasis was placed on the impact of the information age on the mental health and value development of students, as well as the necessity of automatically identifying campus public opinion information. Section II gives details about the design of a T-GAN based campus network. Section III delves into the verification of a campus network and Section IV concludes the paper.

II. Design of a T-GAN-Based Campus Network Public Opinion Analysis Model

The GAN model is the foundation of subsequent research in this paper. This chapter focuses on the collection and enhancement of campus network public opinion data based on the T-GAN model, and embeds a mixed MCNN structure in the network model for public opinion data analysis. The model is validated through experiments.

A. Collection and Enhancement of Campus Network Public Opinion Data Based on T-GAN Model

In the methodology section of this study, the reason for choosing to use a combination of Generative Adversarial Network (GAN) structure and Transformer model is multifaceted. Firstly, this combination fully utilizes the ability of GAN to generate authentic data and the powerful performance of Transformer in processing sequential data, making it particularly suitable for processing text data. Secondly, the current focus of research is on automatically identifying public opinion emotions in campus networks, which typically involve data in the form of text [11]. The Transformer model excels in understanding text sequences. In addition, campus public opinion data often suffers from class imbalance, and the generation ability of GANs can effectively enhance the sample of niche categories to provide richer learning materials, thereby improving the generalization ability and accuracy of the model. The participants are a group of campus network users, especially students in the cognitive development stage. Student groups are usually active in the online space, expressing opinions and feelings related to their personal life and learning experiences, which reflect their true emotions and may have an impact on others. Therefore, collecting data from it is representative and rich in valuable information such as user emotions and attitudes.

The data type to be collected in the study will mainly be public opinion information in text format, such as posts, comments, Weibo, etc. The characteristics of the required data collection include: 1. Text content: specific user statements and comments. 2. Timestamp: The time information of a speech, used to analyze public opinion dynamics. 3. User information: Basic information of the speaker, such as registration time, historical speeches, etc. (subject to privacy and regulatory restrictions).

In order to complete data collection and processing, the following tools will be used in the study: 1. Crawler tools, such as Scrapy, are used to automatically crawl target text data from online platforms and social media. 2. Data preprocessing tools: including text cleaning, denoising, word segmentation, and encoding, to prepare data formats suitable for model input. 3. Deep learning frameworks, such as TensorFlow or PyTorch, are used to construct and train T-GAN and MCNN models. 4. Evaluation and analysis tools: such as Sklearn, used for evaluating model performance and statistical analysis of results. Through this comprehensive method and corresponding tools, this study will be able to accurately capture and analyze emotional public opinion in campus networks, provide a basis for subsequent intervention measures, and thus maintain a healthy online environment.

Currently, the most commonly used social comment platform for students is Weibo, and many schools also set up official accounts on Weibo to post school related information [12]. Therefore, this study will focus on collecting public opinion data from Weibo platforms. Due to the complexity of online comment data, efficient data collection methods are needed. Traditional manual data collection methods are inefficient, so this study utilizes crawler technology to quickly collect data [13]. Through crawler technology, text data can be automatically crawled from Weibo platforms. The specific process of crawling text data is expressed in Fig. 1.

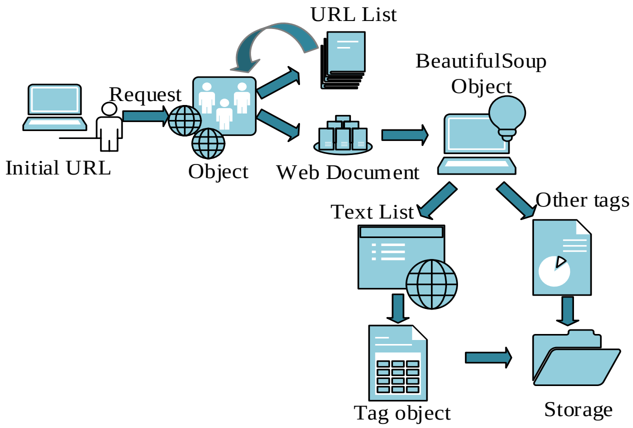

Fig. 1. The specific process of crawling text data.

From Fig. 1, when using crawler technology to crawl campus comment data, the first step is to initialize the Uniform Resource Locator (URL) to send the request. This study uses the Scrapy framework to write crawler scripts, starting from Weibo websites, and automatically accessing URL links after splitting to obtain Hyper Text Markup Language (HTML) resources in comment pages. Next, the Xpath parser is utilzied to quickly locate the target node in the web page text data, and save the HTML text attributes that need to be parsed as BeautifulSoup objects through regularization matching. This step helps to parse and manipulate complex HTML documents, saving the crawled text information in Excel or Csv format for subsequent data analysis [14]. After obtaining the crawled text information, it is necessary to clean and preprocess it for subsequent manual annotation and production of test datasets.

The crawled Weibo comment text data contains meaningless text such as emoticons, images, and punctuation marks, which need to be cleaned and deleted to improve the quality of the text data [15]. Regular matching method is an efficient, convenient, powerful, and flexible matching algorithm with good cross platform performance. Therefore, this study uses regular matching method to batch delete and preprocess the remaining text information, including removing stop words and segmenting Chinese text. During word segmentation, new words that ware not included in the vocabulary may be encountered. Therefore, this study collects 183 new words from online platforms and enters them into the vocabulary library. In addition, this study also utilizes a hidden Markov model to analyze the possible idioms composed of Chinese characters, and calculates the paths through Viterbi. Comment texts on online platforms often appear in the form of short dialogues, which contain non-standard words such as oral language and internet buzzwords. Therefore, it needs to pay attention to these characteristics during the word segmentation process [16]. By analyzing the possible idioms composed of Chinese characters using hidden Markov models, new words and idioms in comment texts can be more accurately identified, improving the accuracy and precision of text segmentation. Preprocessed text data can be transformed into data that computers can recognize and operate on using text representation technology. The Word2Vec model is an associated model that can generate word vectors and can be utilized for training to reconstruct linguistic word texts. By training the Word2Vec model, words can be mapped into vector space for computation and data analysis. The structure of the Word2Vec model is indicated in Fig. 2.

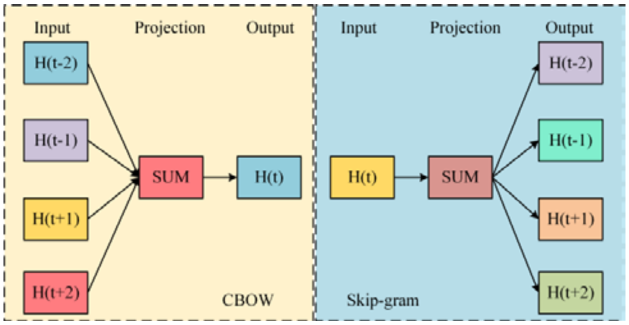

Fig. 2. The structure of the Word2Vec model.

In Fig. 2, the structure of the Word2Vec model includes two parts: Skip gram and CBOW. The Skip gram model can predict the $H(t-1), H(t-2), H(t+1), H(t+2)$ of the preceding and following text with the known head word $H(t)$. This model's goal is to infer the current word through contextual information [17]. In contrast, the CBOW model adopts the opposite approa ch, which can infer the central word from known contextual words. The training of CBOW model can be seen as a language model task, predicting the central word through a large amount of text corpus to preserve important semantic information of the text. The Skip gram and CBOW models together form a bidirectional language model that can help better understand and process natural language. The objective function expression of Skip gram is shown in Eq. (1).

$$O_{Skip} = \frac{1}{T}\sum_{t=1}^{dk}\sum_{-c\le j\le c, j\ne 0}\log P_{Skip}(H_i|H_{i+1}) \tag{1}$$

In Eq. (1), O_{skip} represents the objective function of Skip gram, and T represents time, c means the context window's size during model training. d_k represents the dictionary's size. H_i represents the word vector. $P_{Skip}(H_i|H_{i+1})$ represents the path probability of the word vector in the Skip gram model. The expression is shown in Eq. (2).

$$P_{Skip}(H_i|H_{i+1}) = \frac{\exp(<v_i, v_{i+j}>)}{\sum_{k=1}^{dk}\exp(<v_k, v_i>)} \tag{2}$$

In Eq. (2), $v_{i,}v_k$ represent the output and input vectors, respectively. The objective function expression of the CBOW model is shown in Eq. (3).

$$O_{CBOW} = \frac{1}{T}\sum_{t=1}^{dk}\sum_{-c\le j\le c, j\ne 0}\log P_{CBOW}\left(H_i|H_{i+j}\right) \tag{3}$$

In Eq. (3), O_{CBOW} represents the objective function of the CBOW model, $P_{CBOW}(H_i|H_{i+1})$ represents the path probability of the word vector in the CBOW model, as shown in Eq. (4)

$$P_{CBOW}\left(H_i\middle|H_{i+j}\right)=\frac{\exp\left(<v_i,v_{i+1}>\right)}{\sum_{k=1}^{dk}\exp\left(<v_k,v_{i+j}>\right)} \tag{4}$$

The word vector generated by the Word2Vec model is static, meaning that for the same word, its vector representation remains the same regardless of the context. In contrast, the word vectors generated by the BERT model are dynamic, meaning that the vector representation of the same word may change in different contexts [18]. This is because that the BERT model utilizes a large number of self-attention mechanisms, which can adaptively focus on different words in different contexts, thereby generating different word vectors. In addition, the BERT model differs from traditional temporal networks in that it does not emphasize the order relationship between words. In the BERT model, the vector representation of each word is independent of other words, making it more flexible to handle text data. The mathematical expression of the BERT model is denoted in Eq. (5).

$$\begin{cases} E_{(pos,2i)}=\sin\left(\dfrac{pos}{1000^{\frac{2i}{emb_{\dim}}}}\right) \\ E_{(pos,2i+1)}=\cos\left(\dfrac{pos}{1000^{\frac{2i+1}{emb_{\dim}}}}\right) \end{cases} \tag{5}$$

In Eq. (5), $E_{(pos,2i)}$ and $E_{(pos,2i+1)}$ represent odd and even position matrices, respectively, and $emb_{\dim}$ represents the embedding dimension [19].

The technology used in this article - the T-GAN model that combines Generative Adversarial Networks (GAN) and Transformer models - has the following advantages: 1) Data augmentation ability: GAN's unique data generation ability can expand and balance the dataset by generating realistic text data, which is particularly beneficial for handling imbalanced data distribution and insufficient training data. 2) High text processing performance: The Transformer model has excellent sequential data processing capabilities, making it particularly suitable for analyzing text data. Its self-attention mechanism can capture long-distance dependencies and enhance the model's understanding of context. 3) High model accuracy: Compared to traditional deep learning and machine learning models, T-GAN demonstrates higher accuracy and recall in text sentiment classification tasks, indicating superior classification performance of the model. 4) Strong generalization ability: Due to the combination of two powerful neural network models and extensive testing on multiple datasets, T-GAN exhibits good generalization ability, which means it can adapt to different types of text data analysis tasks. 5) Real time analysis capabilities: T-GAN is suitable for real-time data analysis, helping managers monitor and respond to emotional fluctuations in the network in a timely manner. It is particularly valuable for environments that require quick response, such as campuses. 6) Improving user experience: Automated sentiment classification tools can reduce the burden of manual review, improve information supervision efficiency, and thus improve the user experience on campus network platforms. 7) Contribution to social management: This technology can analyze and identify emotional tendencies in a large amount of online public opinion data, providing strong technical support for social public opinion analysis and crisis prevention.

B. Public Opinion Data Analysis Based on Hybrid Embedded MCNN Structure

GAN is a powerful generation model that can generate new sentences related to a given corpus topic [20]. This newly generated sentence is closer to real data, while ensuring data security while also preserving the smoothness of the original data as much as possible. This characteristic enables GAN to effectively improve the classification performance of the network. However, traditional GAN models mainly rely on the LSTM layer as a generator in structure, which has some limitations, such as high computational costs and a lack of interactivity between information. To address these limitations, a self-attention-based autoencoder Transformer is studied to replace the LSTM layer. Transformer, due to its ability to learn long-term dependencies, can effectively address the aforementioned limitations. The structure of the T-GAN model is expressed in Fig. 3.

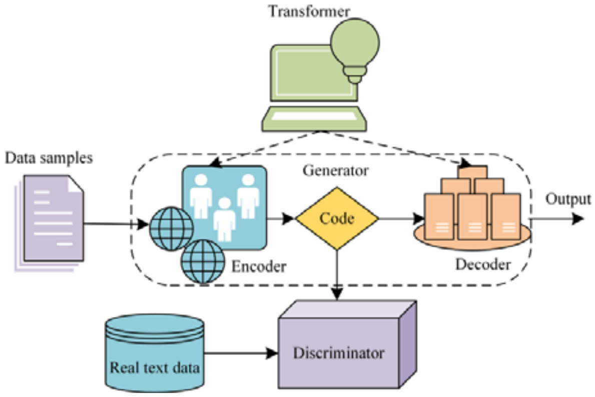

Fig. 3. The structure of T-GAN model.

In Fig. 3, the structure of the T-GAN model includes two main parts: a generator and a discriminator [21]. The generator can randomly generate vectors from space as input, generating pseudo samples with the same dimensions as real samples. The discriminator can use real and pseudo samples for training and predict a binary value to determine whether the input sample is real [22]. The T-GAN model adopts an alternating optimization method during the training process, which trains the generator network and discriminator network alternately to solve the maximum minimum game problem until both networks reach a convergence state. The mathematical expression of the maximum minimum game is expressed in Eq. (6).

$$\underset{G}{Min}\,\underset{D}{Max}\,V(G,D)=F_{x\sim Pdate(x)}\left[\log D(x)\right]+F_{z\sim noise(x)}\left[\log\left(1-D\left(G(z)\right)\right)\right] \tag{6}$$

In Eq. (6), G, D denote the generator and discriminator. x represents the real sample. $D(x)$ expresses the real data. z means the noise vector sample. $G(z)$ refers to the generated sample. $F_{x\sim Pdate(x)}$ indicates the discriminator that follows the real data, and $F_{z\sim noise(x)}$ represents the generator and discriminator that follows the random data [23]. The Transformer architecture is embedded with a VAE module, which consists of two sub modules: encoder and decoder. The mathematical expression of the encoder is denoted in Eq. (7).

$$z \sim Enc(x) = q(z|x) \tag{7}$$

In Eq. (7), $q(z|x)$ represents the encoding space, and $z \sim Enc(x)$ represents encoding the sample x into the sample z. The mathematical expression of the decoder is expressed in Eq. (8).

$$x \sim Dec(z) = p(x|z) \tag{8}$$

In Eq. (8), $p(x|z)$ represents the decoding space, and $x \sim Dec(z)$ represents the decoding of sample z to sample x. The attention mechanism in the Transformer architecture identifies and highlights key values by adjusting weight values, and the process of finding key values is denoted in Eq. (9).

$$O = Attention(Q, K, V) \tag{9}$$

In Eq. (9), O represents the output of the attention mechanism. Q represents the query vector. V represents the key value. K represents the key value. Due to the use of multi head attention mechanism in the Transformer architecture, the three vectors Q, K, V will be projected into different subspaces, as shown in Eq. (10).

$$MH(Q, K, V) = concat(H_1, H_2, ..., H_n)W^0 \tag{10}$$

In Eq. (10), MH represents the multi head attention mechanism. H represents the subspace. n represents the degree. W^0 represents the initial matrix. By calculating the self-attention function in different subspaces, the projection output of each subspace can be obtained. Then, these output results are concatenated and the final output is obtained through projection, as shown in Eq. (11).

$$O_{MH} = Attention(QW_i^Q, KW_i^K, VW_i^V) \tag{11}$$

In Eq. (11), O_{MH} represents the projection output processed by the multi head attention mechanism. W_i^Q, W_i^K, W_i^V represents the linear projection of the corresponding response Q, K, V vector. The generator structure in the T-GAN model enhances the language model by introducing an LSTM layer to improve the attention mechanism of the decoder [24]. The generator structure of the T-GAN model is shown in Fig. 4.

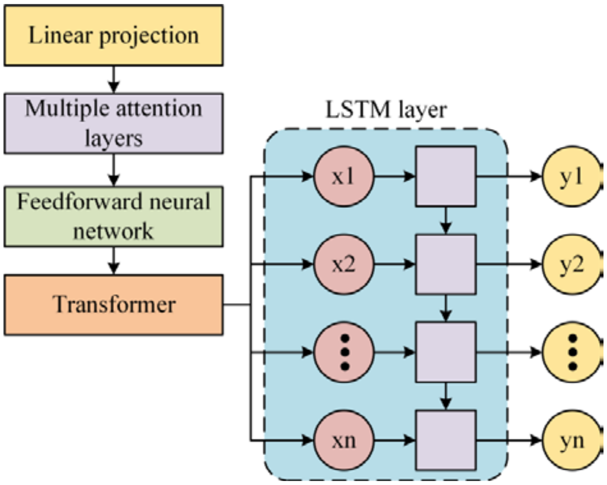

Fig. 4. The generator structure of T-GAN model.

As shown in Fig. 4, in the generator structure of the T-GAN model, the output results generated by the Transformer decoder are input into the LSTM layer for language model enhancement. This design enables the model to better focus on more advanced semantic and stylistic features, thereby generating more realistic and natural samples. The data text enhanced by the T-GAN model requires the use of MCNN for feature extraction [25]. In this process, the data text is mixed and embedded as input to add more forms of representation from the feature extraction level, thereby improving model performance. The structure of mixed embedded MCNN is shown in Fig. 5.

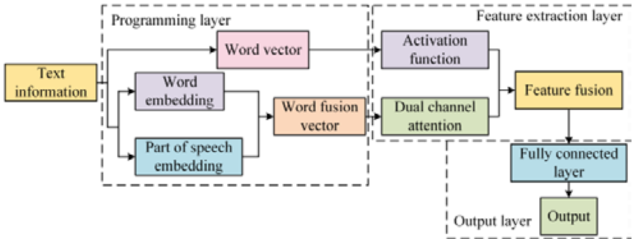

Fig. 5. The structure of mixed embedded MCNN.

As shown in Fig. 5, the structure of hybrid embedded MCNN consists of three parts: encoding layer, feature extraction layer, and output layer [26]. In the encoding layer, multi-channel input is used to improve the representation ability of short dialogue text [27]. And through part of speech embedding and word embedding, the association of parts of speech in the text is strengthened to generate mixed word vectors. The expression of the mixed word vector is shown in Eq. (12).

$$\begin{cases} w_{pi} = w_i \oplus pos_i \\ W_p = [w_{p1}, w_{p2}, ..., w_{pm}]^T \end{cases} \tag{12}$$

In Eq. (12), w_{pi} represents the mixed word vector. W_p represents the mixed word vector channel. m represents the embedding sequence [28]. The feature extraction layer performs feature extraction in the form of dual channels, as shown in Eq. (13).

$$\begin{cases} Vc = Conv(c) \\ vc = GMP(Vc) \end{cases} \tag{13}$$

In Eq. (13), Vc represents the feature vector obtained after convolution operation. c represents the word vector. GMP represents global maximum pooling. vc represents the feature vector obtained after global maximum pooling operation. The feature vectors of words and mixed words obtained through two channels are shown in Eq. (14).

$$\begin{cases} V_\alpha = \sum_{i=1}^{m} \alpha c_i \times Vc \\ V_\beta = \sum_{i=1}^{m} \beta c_i \times Vc \end{cases} \tag{14}$$

In Eq. (14), V_α, V_β represents the feature vectors of the word and the feature vectors of the mixed word, respectively. These two feature vectors are concatenated in the output layer, then input into the fully connected layer for fusion, and then processed using a Softmax classifier to obtain the classification probability as shown in Eq. (15).

$$P = soft\max(\omega\lfloor V_\alpha \oplus V_\beta \rfloor + \mu) \tag{15}$$

In Eq. (15), P represents the classification probability of the output. ω represents the weight transformation matrix. $\oplus$ represents the connection operation. μ represents the bias vector [29].

III. Verification of Campus Network Public Opinion Analysis Model Based on T-GAN Model

To experimentally validate the T-GAN-based campus network public opinion analysis model, this chapter first set the experimental environment and parameters, and analyzed the impact of experimental parameters on the performance of the model [30]. Finally, the performance of the T-GAN model was verified.

A. Experimental Environment and Parameter Settings

All experiments in this article were conducted in the Python 3.6.7 environment. The dataset used was Senti Large, with 20% of the data samples used as the test set and the other 80% used as the training set. The Senti Large dataset is an enhanced dataset generated through T-GAN based on publicly available Sentiment datasets. The Sentiment dataset is mainly used for sentiment analysis, which is a natural language processing technique aimed at identifying and extracting subjective information from text. This type of information may include the author's emotions, emotions, or opinions on a specific topic or product, which can be positive, negative, or neutral. The Sentiment dataset mainly focuses on text data, as the core of sentiment analysis is to understand and analyze emotions or emotions in the text. Therefore, this type of dataset does not contain image data. The main application scenarios of this dataset include product review analysis, social media sentiment tracking, and public opinion research. Overall, the Senti Large dataset is an enhanced text dataset for sentiment analysis, utilizing advanced T-GAN technology to expand the original Sentiment dataset to improve model performance and generalization ability. To evidence the generalization ability of the model, the study also added a manually calibrated Weibo data sample set as a pure test set. The careful setting of experimental parameters will directly affect the training effect of the model and the final classification results. To optimize the effectiveness of the model, the following parameters were set in the experiment based on the characteristics of the T-GAN model. The experimental environment configuration and parameter settings are indicated in Table I. As shown in Table 1, in order to conduct this experiment, corresponding parameters need to be configured in a specific environment. Firstly, the experiment should be conducted on the Windows 10 operating system to ensure sufficient memory capacity. Here, 64GB was chosen as it can effectively handle large datasets and run deep learning models. The graphics processor used in the experiment is NVIDIA's TITAN BLACK GPU, which can accelerate the training and prediction of deep learning models. Meanwhile, the study chose Intel Core i5-4460 as the central processing unit. PyTorch 1.8.1 was chosen as the deep learning framework in terms of software, and the CUDA11.1 platform and API were utilized to fully utilize NVIDIA GPU for computation. In terms of parameter settings, research has set vector spaces with dimensions of 30 and 300 for part of speech vectors and word vectors, respectively. The learning rate is set to 0.002, the number of convolutional kernels is 256, and the batch size is 16. In order to prevent overfitting of the model, the study set the Dropout ratio to 0.5, which means that half of the neurons will be randomly ignored during the training process. These configurations will ensure the smooth progress of the experiment and the accuracy of the results.

TABLE I. EXPERIMENTAL ENVIRONMENT CONFIGURATION AND PARAMETER SETTINGS

Experimental environment	Configuration	Parameter Description	Paramete r value
OS system	Windows10	Part of speech vector dimension	30
Memory	64GB	Word Vector Dimension	300
GPU	NVIDIA TITAN BLACK GPU	Learning rate	0.002
CPU	Intel(R)Core(TM)i 5-4460	Number of convolutional kernels	256
PyTorch framework	PyTorch 1.8.1	Batch size	16
CUDA Framework	CUDA11.1	Dropout rate	0.5

B. The Effect of Experimental Parameters on Model Performance

To delve deeper into the impact of parameter dropout rate on model prediction results, the experiment set the dropout rate range between $[0.1,0.2,0.3,0.4,0.5]$. After training, the impact of different dropout rates on prediction performance is shown in Fig. 6. From Fig. 6 (a), when the discard rates were 0.5 and 0.2, the accuracy reached the highest of 90.1% and the lowest of 81.8%, respectively. From Fig. 6 (b), when the discard rates were 0.1 and 0.2, the recall rates reached the highest of 89.9% and the lowest of 78.8%, respectively. From Fig. 6 (c), when the discard rates were 0.5 and 0.2, the F-value reached the highest of 90% and the lowest of 78.3%, respectively. Overall, when the discard rate was 0.5, all performance indicators of the model reached the optimal state.

The batch size is the amount of data input into the model at once when training the corpus, and the setting of this parameter has a huge impact on the training efficiency of the model. If the batch size is set too large, overfitting may occur, increasing training costs, while if the batch size is set too small, it may reduce training efficiency. Therefore, choosing an appropriate batch size is crucial. The range of batch size parameters selected for the experiment was $[4,8,16,32]$, and the impact of batch size on accuracy obtained through training is shown in Fig. 7. From Fig. 7, when the batch size was 16, the accuracy of the model reached its highest value, at 90%. In contrast, when the batch size was 4, 8, and 32, the accuracy of the model was 84.8%, 89.1%, and 82.3%, respectively, which increased by 5.2%, 0.9%, and 7.7% compared to the accuracy of the batch size of 16, respectively. Overall, the most suitable value for the batch size parameter was 16. This setting could effectively improve the accuracy of the model while ensuring its training efficiency.

In the learning process of neural networks, parameter learning rate plays a crucial role. The learning rate can help update the weight of the model through backpropagation, thereby achieving reasonable adjustment of the weight. To deeply explore the influence of learning rate on the loss function, the experiment plotted the influence of parameter learning rate on the loss function as shown in Fig. 8. From Fig. 8, when the learning rate was less than 0.002, the value of the loss function showed a significant downward trend as the learning rate increased. When the learning rate was 0.002, the decline rate of the loss function was the fastest. This observation indicated that when the learning rate was 0.002, the model could more effectively optimize weights, thereby achieving a better level of loss function.

C. Performance Verification of T-GAN Model

To visually demonstrate the performance of the T-GAN model, the new data generated by the T-GAN model was projected onto the same two-dimensional plane as the real data. The data projection is shown in Fig. 9. From Fig. 9, the new data generated by the model highly overlapped with the real data on the projection plane, which strongly proved the accuracy of the model's prediction. This phenomenon indicated that the model could capture the main features of the data and generate results that are highly similar to real data.

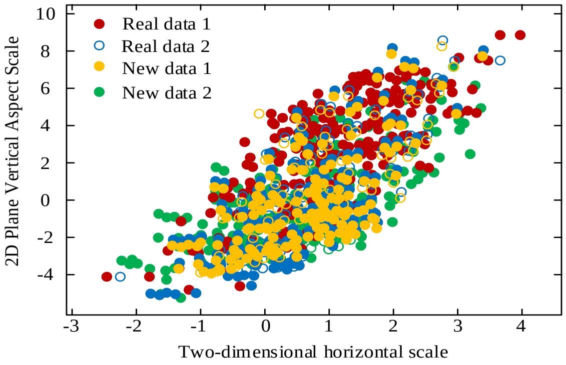

Fig. 9. Data projection map.

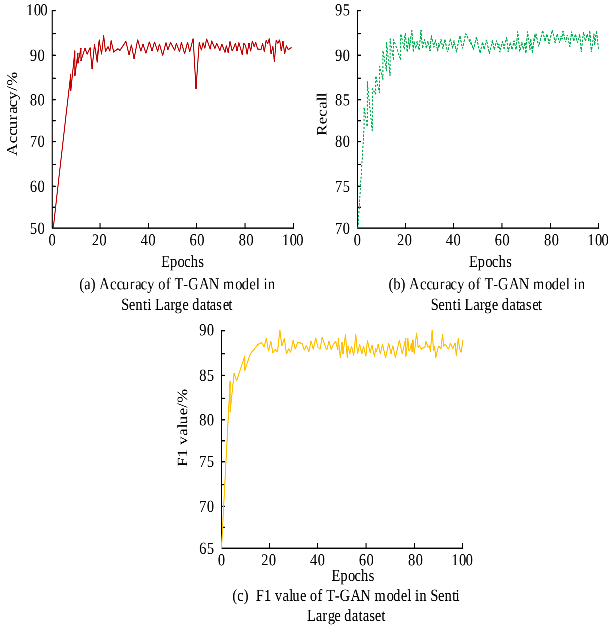
To prove the effectiveness of the T-GAN model, it was trained on the Senti -Large dataset and its predictive performance was evaluated. The predictive performance results of the T-GAN model are shown in Fig. 10. From Fig. 10, the T-GAN model converged rapidly on the training set, approached convergence after nearly 20 iterations, and achieved excellent predictive performance. Specifically, the T-GAN model achieved an accuracy of 92%, a recall rate of 91.8%, and an F1 value of 88.7% on the training set. These indicators all indicated that the T-GAN model performed well in predicting performance on the training set.



(a) Accuracy of T-GAN model in Senti Large dataset

(b) Accuracy of T-GAN model in Senti Large dataset

(c) F1 value of T-GAN model in Senti Large dataset

Fig. 10. Prediction performance results of T-GAN model.

In order to further verify the superior performance of the T-GAN model, state-of-the-art text feature extraction models such as LGBM, KNN, SVM, and RoBERTA [20] were used to conduct comparative experiments on the test set and training set [31]. The accuracy comparison of different models is shown in Table II. From Table II, in the training set, the accuracy of the T-GAN model was 91.56%, which was 8.89%, 6.78%, 15.87%, and 1.18% higher than models such as LGBM, KNN, SVM, and RoBERTA, respectively. In the test set, the accuracy of the T-GAN model was 92.89%, which increased by 8.93%, 8.25%, 19.01%, and 1.57% compared to models such as LGBM, KNN, SVM, and RoBERTA, respectively.

TABLE II. COMPARISON OF ACCURACY BETWEEN DIFFERENT MODELS

Model	Test set accuracy/%	Training set accuracy/%
T-GAN	92.89	91.56
LGBM	83.96	82.67
KNN	84.64	84.78
SVM	73.88	75.69
RoBERTa	91.32	90.38

In order to verify the effectiveness of the T-GAN model in physical argumentation, a series of application examples were conducted to verify its effectiveness. Taking campus cafeteria public opinion as an example, when food safety issues trigger public opinion, public opinion data mainly comes from social platforms such as Weibo, WeChat, and campus forums. The study utilized the T-GAN model to conduct in-depth public opinion analysis on the text data of these platforms, and successfully extracted internet buzzwords closely related to campus cafeteria public opinion. The extraction of campus cafeteria public opinion text using the T-GAN model is shown in Fig. 11. From Fig. 11, it can be seen that the model has successfully extracted five key network buzzwords: food safety, hygiene issues, poisoning incidents, inadequate supervision, and school responses. The frequency of these hot words appearing on social media platforms is 8054, 12567, 11067, 9104, and 11972, respectively. This data fully demonstrates that the T-GAN model performs well in extracting text information closely related to campus cafeteria public opinion. Through comprehensive analysis, it can be found that the text content extracted by the T-GAN model is highly consistent with the actual campus cafeteria public opinion. This further validates the superior performance of the T-GAN model in practical applications, proving that it can effectively extract key information closely related to food safety public opinion from massive text data.

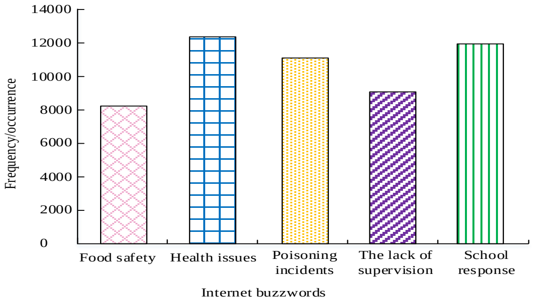


Fig. 11. Extracting public opinion text from campus canteen using T-GAN model.

IV. Conclusion

As the speed growth of network technology, the problem of spreading rumors and false information on social media is becoming increasingly prominent. To effectively and automatically identify and filter negative public opinion information in campus networks to protect students' physical and mental health, this study innovatively constructed a T-GAN model by combining the advantages of GAN network structure and Transformer model. At the same time, a hybrid embedding method using MCNN was used to conduct in-depth research on public opinion data as the analysis object. The results showed that when the discard rate was 0.5, the accuracy of the model reached the highest level of 90.1%, and the recall rate also reached the highest level of 89.9%. In addition, when the batch size was 16, the accuracy of the model also reached its highest value, at 90%. This indicated that the performance of the model was relatively stable for different discard rates and batch sizes. In the Senti-Large dataset, the accuracy of the T-GAN model reached 92%, the recall rate was 91.8%, and the F1 value also reached 88.7%. In the training set, the accuracy of the T-GAN model was 91.56%, which improved by 8.89%, 6.78%, 15.87%, and 1.18% compared to models such as LGBM, KNN, SVM, and RoBERTA, respectively. In the test set, the accuracy of the T-GAN model was 92.89%, which increased by 8.93%, 8.25%, 19.01%, and 1.57% compared to models such as LGBM, KNN, SVM, and RoBERTA, respectively. In summary, the T-GAN model performs best when the discard rate is 0.5 and the batch size is 16. Meanwhile, compared to other models, the T-GAN model has shown certain advantages in accuracy. These results indicate that the T-GAN model studied has good generalization performance and adaptability, and is worthy of further research and application. However, the research only analyzed the Chinese text, and the results are not comprehensive enough. This aspect still needs further improvement. Given the improvement in accuracy of the model compared to other models, we can look forward to further development of this model in future related research and applications. For example, in practical applications, the T-GAN model has the potential to serve as an important tool for campus public opinion supervision, accurately identifying negative public opinion, intervening in a timely manner, and ensuring the health of the campus network environment. In addition, its outstanding performance also provides strong reference value for expanding the model to multilingual public opinion analysis in the future.

***Abstract*—Method for hyperparameter tuning of EfficientNetV2-based image classification by deliberately modifying Optuna tuned result is proposed. An example of the proposed method for textile pattern quality evaluation (good or bad textile pattern fluctuation quality classification) is shown. When using the hyperparameters obtained by Optuna without changing them, the accuracy certainly improved. Furthermore, as a result of learning by changing the hyperparameter with the highest degree of importance, the accuracy changed, so it could be said that the degree of importance was certainly high. However, the accuracy also changes when learning is performed by changing the least important hyperparameter, and sometimes the accuracy is improved compared to when learning is performed using the optimal hyperparameter. From this result, it is found that the optimal hyperparameters obtained with Optuna are not necessarily optimal.**

Keywords—Hyperparameter tuning; EfficientNetV2; Optuna; textile pattern; optimal hyperparameter; learning process; pattern fluctuation

I. Introduction

To optimize these hyperparameters, hyperopt, gpyopt, AutoML, PyCaret, Optuna, etc. have been proposed as black box optimization methods, which automate trial and error regarding hyperparameters and automatically discover optimal solutions. Similarly, as black box optimization methods, white box conversion of DL, binary decision trees, random forests, and mind maps using GNNs has also been proposed [1]. In particular, Optuna uses an algorithm called TPE (Tree-structured Parzen Estimator), which is a new method in Bayesian optimization, and is capable of parallel processing, and can be restarted midway by saving the results to the database.

Depending on the definition of the objective function and the validity of the importance of the parameters, hyperparameters that are not necessarily suitable for comparison with the evaluation criteria may appear. Therefore, in this paper, we introduce such a case and propose a method of intentionally changing the hyperparameters obtained through optimization with Optuna and selecting parameters with greater accuracy through trial and error.

As an application example of this method, we will show an example in which it was applied to the classification of pattern shifts in Kurume Kasuri. This is just one application example, and the proposed method can be widely applied to other classifications.

In Section II, research background and related research works are described followed by the proposed method for hyperparameter tuning by modifying Optuna tuned result in Section III. Then experiment of application of the proposed method given in Section IV followed by remarks in Section V. Conclusion and future research work is given in Section VI and Section VII respectively.

II. Research Background and Related Research Works

A. Research Background

Kurume Kasuri is a traditional cotton fabric handed down in the Chikugo region, and it is completed through over 30 steps, including design, binding, dyeing, and weaving. A major feature of Kurume Kasuri is that the yarn is pre-dyed and the patterned thread is woven while matching the patterns, resulting in subtle deviations and a unique faded pattern.

Regarding the degree of deviation, it is fine if the pattern shift is moderate, but if the deviation is too large, the product will not sell and will have to be sold at a low price. In addition, there is the problem that the evaluation criteria for the degree of deviation differ depending on the manufacturer. Therefore, in this study, we build an image recognition model that classifies whether the pattern shift of Kurume Kasuri is within an acceptable range (good or bad). At that time, Optuna searches for optimal hyperparameters and intentionally changes the most and least important parameters to improve accuracy.

B. Examples of Quality of Kurume Kasuri

Typical patterns of Kurume Kasuri are shown in Fig. 1. This Kurume Kasuri is woven with a rectangular pattern in mind. An example of pattern shift is shown in Fig. 2. Green indicates patterns within the acceptable range, and red indicates patterns outside the acceptable range. The red color has a shape that is almost different from the rectangular pattern, and it can be seen that the pattern is clearly too out of alignment.

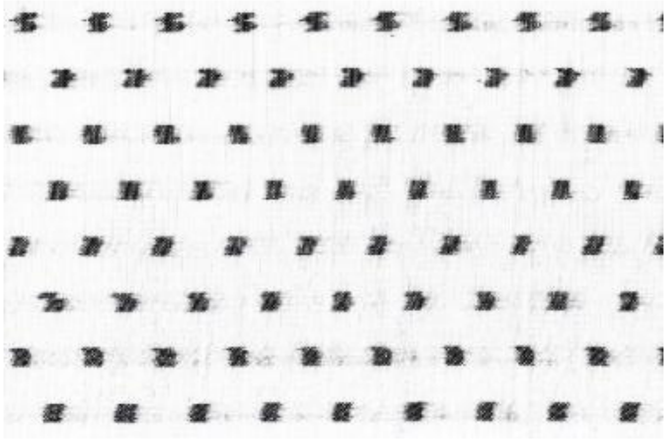

Fig. 1. Typical kurume kasuri image. (sideways)

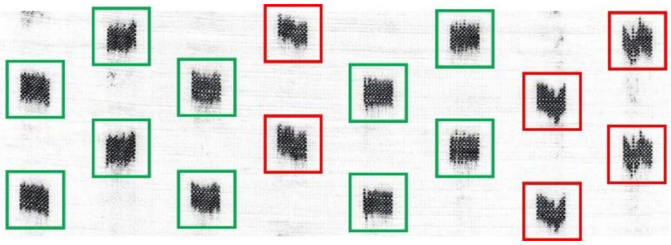

Fig. 2. Example of kurume kasuri pattern shift. (Green: Within the acceptable range, Red: Outside the acceptable range).

C. Related Research Works

It has been proposed a method to evaluate the quality of pattern shifts in Kurume Kasuri by considering them as 1/f fluctuations [2]. Other than this, there are image classification method related research works as follows,

EfficientnetV2: Smaller models and faster training are proposed [3] together with deep neural network configurations of network is network [4].

Classification by re-estimating statistical parameters based on auto-regressive model is proposed [5]. Meanwhile, multi-temporal texture analysis in Landsat Thematic Mapper: TM classification is also proposed [6]. On the other hand, maximum likelihood TM classification taking into account pixel-to-pixel correlation is proposed [7] together with a supervised TM classification with a purification of training samples [8]. Meantime, TM classification using local spectral variability is proposed in [9]. Also, classification method with spatial spectral variability is proposed in [10] together with TM classification using local spectral variability [11].

Application of inversion theory for image analysis and classification methods is proposed [12]. Meanwhile, polarimetric Synthetic Aperture Radar: SAR image classification with maximum curvature of the trajectory in Eigen space domain on the polarization signature is proposed [13].

A hybrid supervised classification method for multi-dimensional images using color and textural features is proposed [14]. On the other hand, polarimetric SAR image classification with high frequency component derived from wavelet Multi Resolution Analysis: MRA is proposed [15].

Comparative study of polarimetric SAR classification methods including proposed method with maximum curvature of trajectory of backscattering cross section in ellipticity and orientation angle space is proposed [16].

Human gait gender classification using 2D discrete wavelet transforms energy is attempted [17] together with human gait gender classification in spatial and temporal reasoning [18]. Meanwhile, comparative study on discrimination methods for identifying dangerous red tide species based on wavelet utilized classification methods is conducted [19].

Multi spectral image classification method with selection of independent spectral features through correlation analysis is proposed [20]. Meanwhile, image retrieval and classification method based on Euclidian distance between normalized features including wavelet descriptor is proposed [21].

Gender classification method based on gait energy motion derived from silhouettes through wavelet analysis of human gait moving pictures is proposed [22] together with human gait skeleton model acquired with single side video camera and its application and implementation for gender classification [23]. Meantime, gender classification method based on gait energy motion derived from silhouette through wavelet analysis of human gait moving pictures is proposed [24] together with human gait gender classification using 3D discrete wavelet transformation feature extraction [25].

Image classification considering probability density function based on Simplified beta distribution is proposed [26]. Maximum likelihood classification based on classified result of boundary mixed pixels for high spatial resolution of satellite images is proposed [27]. On the other hand, context classification based on mixing ratio estimation by means of inversion theory is proposed [28].

Optimum spatial resolution of satellite-based optical sensors for maximizing classification performance is found [29]. Meanwhile, the combined non-parametric and parametric classification method depending on normality of Probability Density Function: PDF of training samples is proposed [30]. In recently, method for hyperparameter tuning of image classification with PyCaret is proposed and well validated [31].

III. Proposed Methods

A. Image Recognition Model

In order to classify whether the pattern shift is within an acceptable range, we used the pre-trained model EfficientNetV2 [3]. EfficientNetV2 is a model that achieves both learning efficiency and high classification accuracy by using NAS (Neural Architecture Search) and model scaling.

Regarding the implementation, using TensorFlow in Python, we added Global Average Pooling [4] and dropout to the final layer of EfficientNetV2, which is a model that has already trained ImageNet, and built a model that changed to binary classification (see Fig. 3). Global Average Pooling is a layer that takes the average value for each feature map obtained in the previous layer. By using this, it is possible to reduce the number of parameters compared to the case of a fully connected layer.

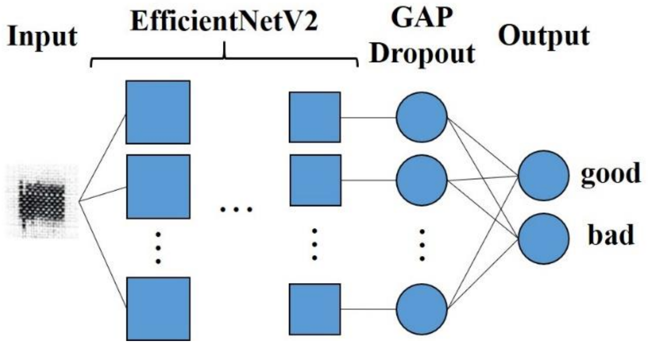

Fig. 3. Model architecture.

With this model, we performed two types of learning: transfer learning only and transfer learning + fine tuning.

B. Hyperparameter Tuning

Hyperparameter tuning was performed using the following three methods, and the accuracy of each method was compared.

1) Manual setting.

2) Optimization using Optuna.

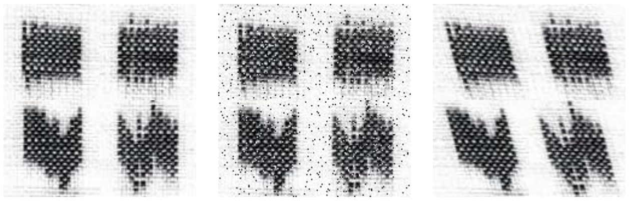
3) Deliberately changing the most important (lowest) hyperparameter among the hyperparameters obtained by Optuna.

In addition, in (2) Optimization using Optuna, specify TPE as the Sampler.

IV. Experiment

A. Data Used

From the scanned Kurume Kasuri images, contour extraction and other operations were performed using OpenCV, and a total of 70 pattern images of 80 × 80 pixels were extracted. Then, based on the results obtained from the pattern evaluation questionnaire to weavers, patterns with pattern shift within the acceptable range were classified as good, and patterns outside the acceptable range were classified as bad [2]. After that, we used a total of 210 image data (training: 180 images, test: 30 images) that was created by applying data augmentation to all of them by adding salt-and-pepper noise and skew (see Fig. 4).



(a) Original (b) Salt and pepper noise (c) Skew

Fig. 4. Sorted Kurume Kasuri pattern image. (upper - good, lower - bad).

B. Transfer Learning

Table I shows the hyperparameters and prediction accuracy for test data when optimizing manually and using Optuna in transfer learning. The two hyperparameters searched were dropout rate and batch size, and the results showed that learning using the optimal hyperparameters obtained by Optuna resulted in better accuracy.

TABLE I. Hyperparameters and Prediction Accuracy for Test Data when Optimized Manually and with Optuna

	Manual	Optuna
Dropout Rate	0.5	0.129 [0 ~ 0.5]
Batch Size	16	32 [16, 32, 64]
Accuracy	76.67%	90%

※The hyperparameter search range is in []

The importance of hyperparameters obtained through optimization using Optuna is shown in Fig. 5. The dropout rate is 0.77 and the batch size is 0.23, indicating that the dropout rate is more important.

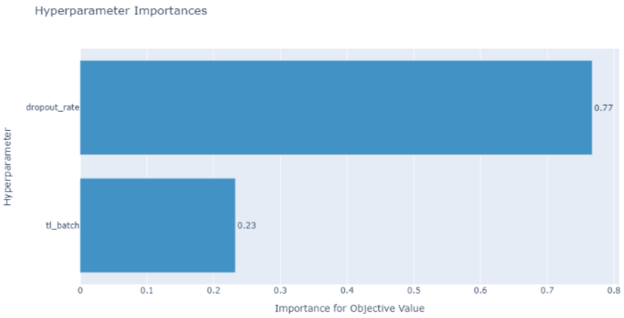


Fig. 5. Importance of hyperparameters when transfer learning was performed.

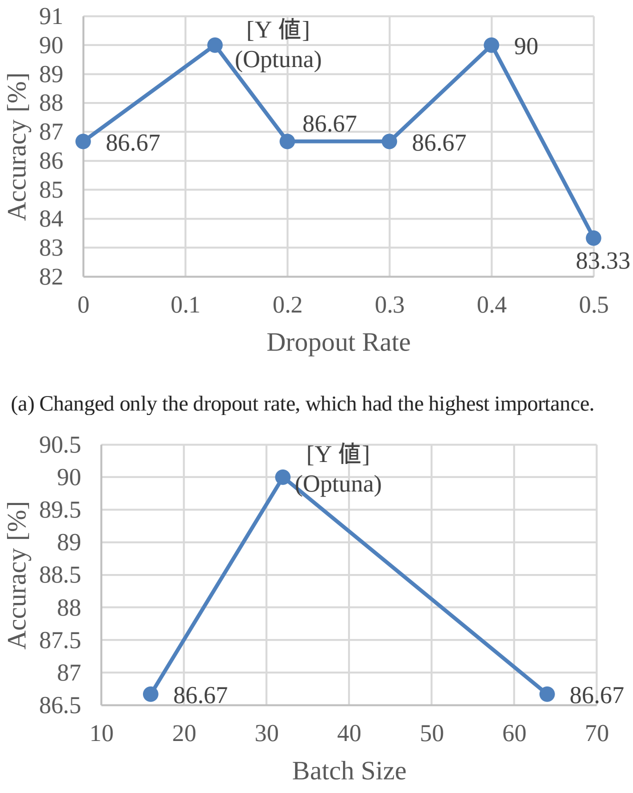

(a) Changed only the dropout rate, which had the highest importance.

(b) Changed only the batch size, which had the lowest importance.

Fig. 6. Change in accuracy when changing hyperparameters of high (low) importance among the hyperparameters obtained by optimization with Optuna.

Fig. 6(a) shows the change in accuracy when only the dropout rate, which was highly important, was changed. Accuracy changed to some extent, but not regularly, and never exceeded the 90% accuracy in Optuna.

Fig. 6(b) shows the change in accuracy when only changing the batch size, which was of low importance. Accuracy changed little and never exceeded the accuracy of Optuna of 90%, as was the case when only the dropout rate was changed.

C. *Transfer Learning and Fine Tuning*

Table II. shows the hyperparameters and prediction accuracy for test data in transfer learning + fine tuning when optimized manually and with Optuna. The searched hyperparameters were the dropout rate, the learning rate, the number of epochs and batch size for transfer learning, and the batch size for fine tuning.

TABLE II. HYPERPARAMETERS AND PREDICTION ACCURACY FOR TEST DATA WHEN OPTIMIZED MANUALLY AND WITH OPTUNA

	Manual	Optuna
Dropout Rate	0.5	0.124 [0 ~ 0.5]
Learning Rate	0.001	0.001 [0.001, 0.0005, 0.0001]
Epoch (Transfer Learning)	10	15 [10, 15, 20]
Batch Size (Transfer Learning)	16	32 [16, 32]
Batch Size (Fine Tuning)	16	32 [16, 32]
Accuracy	50%	80%

※The hyperparameter search range is in []

As with the case where only transfer learning was performed, the optimal hyperparameters obtained by Optuna were used. The result was that the accuracy was better when learning was performed. The importance of hyperparameters obtained through optimization using Optuna is shown in Fig. 7. The dropout rate was the most important at 0.49, and the batch size (transfer learning) was the lowest at 0.05.

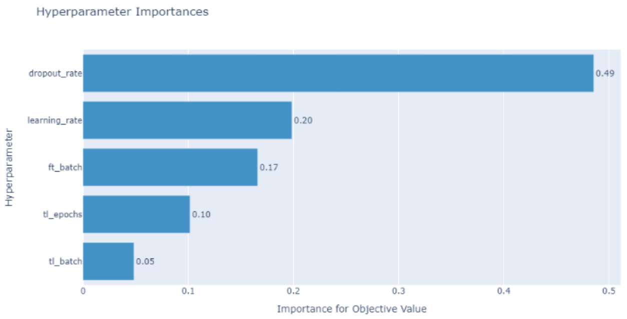

Fig. 7. Importance of hyperparameters when transfer learning and fine tuning were performed.

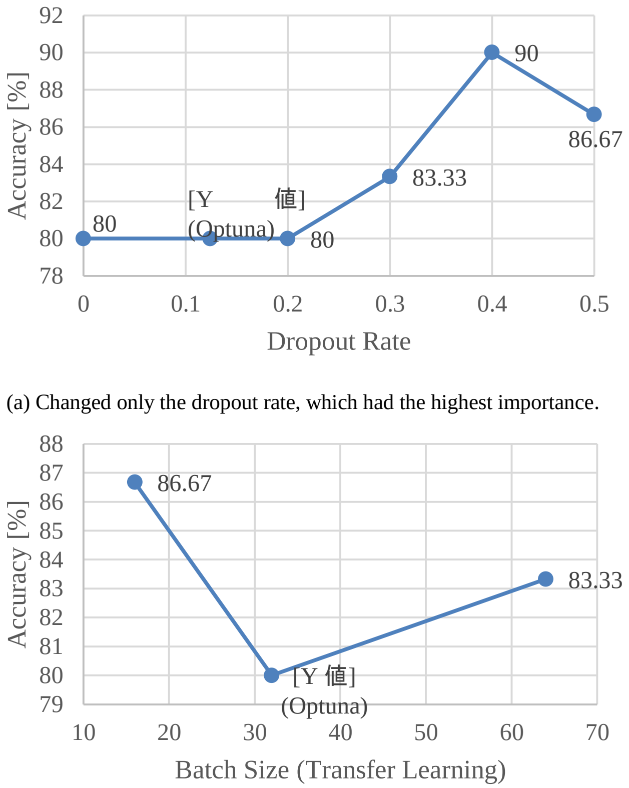
Fig. 8(a) shows the change in accuracy when only the dropout rate, which was highly important, was changed. Unlike the case of only transfer learning, the accuracy changed significantly, and when the dropout rate was 0.4, the accuracy was 90%, which exceeded the accuracy of Optuna of 80%.

Fig. 8(b) shows the change in accuracy when only changing the batch size (transfer learning), which was of low importance. Unlike the case of only transfer learning, the accuracy changed to some extent, and exceeded the accuracy of Optuna of 80%, which is the same as when changing only the dropout rate.



(a) Changed only the dropout rate, which had the highest importance.

(b) Changed only the batch size in the transfer learning, which had the lowest importance.

Fig. 8. Change in accuracy when changing hyperparameters of high (low) importance among the hyperparameters obtained by optimization with optuna.

V. REMARKS

In both the case of transfer learning only and the case of performing fine tuning after transfer learning, the dropout rate was the most important. This is thought to be because only the dropout rate had a continuous search range and the widest search range, while the other hyperparameters had a categorical search range.

The reason why the accuracy change was not regular when only the dropout rate was changed is because the nodes deleted by Dropout are random, so if a node with features that have a large impact on classification is deleted. This is thought to be due to the fact that there were cases where this was not done. In order to measure accuracy more accurately, it is necessary to perform verification using K-fold cross validation.

In transfer learning + fine tuning, by changing the hyperparameters with the highest (lowest) importance, the accuracy was improved compared to the results with Optuna. This is because Optuna's search algorithm used this time, TPE, is based on Bayesian optimization and does not exhaustively search all hyperparameters like grid search, so a locally optimal solution was reached. This is thought to be the cause.

VI. CONCLUSION

We proposed a method of intentionally changing the hyperparameters obtained through optimization using Optuna and selecting parameters with greater accuracy through trial and error. As an application of the proposed method, we classified pattern shifts in Kurume Kasuri.

In both cases, whether it's transfer learning alone or fine-tuning after transfer learning, learning with hyperparameters obtained through optimization with Optuna clearly improved accuracy compared to setting them manually. In transfer learning + fine tuning, by changing the hyperparameters with the highest (lowest) importance, the accuracy was improved compared to the results with Optuna.

From this result, we found that the optimal hyperparameters obtained with Optuna are not necessarily optimal.

VII. FUTURE RESEARCH WORKS

Further study is required for validation of the proposed method for hyperparameter tuning with a variety of examples of image classifications. Also, the other method for optimization of automate hyperparameter search has to be investigated in the near future.

ACKNOWLEDGMENT

The authors would like to thank the team members of Applied AI laboratory of Kurume Institute of Technology for their useful discussions we have had through this study.

In 1994, she became an assistant professor at the department of engineering in Kurume Institute of Technology; in 2001, a lecturer; from 2012 to 2014, an associate professor at the same institute; from 2014, an associate professor at Hagoromo university of International studies; from 2017 to 2020, a professor at the Department of Media studies, Hagoromo university of International studies. In 2020, she was appointed Deputy Director and Professor of the Applied of AI Research Institute at Kurume Institute of Technology. She has been in this position up to the present. She is currently working on applied AI research in the fields of education.

A Novel Framework for Risk Prediction in the Health Insurance Sector using GIS and Machine Learning

Prasanta Baruah, Pankaj Pratap Singh, Sanjiv kumar Ojah
Department of Computer Science & Engineering, Central Institute of Technology Kokrajhar, Kokrajhar, India

***Abstract*—Evaluation of risk is a key component to categorize the customers of the life insurance businesses. The underwriting technique is carried out by the industries to charge the policies appropriately. Due to the availability of data hugely, the automation of underwriting process can be done using data analytics technology. Due to this, the underwriting process becomes faster and therefore quickly processes a large number of applications. This study is carried to enhance risk assessment of the applicants of life insurance industries using predictive analytics. In this research, the Geographical Information Systems (GIS) system is used to collect the data such as Air pollution, Industrial area, Covid-19 and Malaria of various geographic areas of our country, since these factors attribute to the risk of an applicant of life insurance business. Thereafter, the research is carried out using this dataset along with another dataset containing more than 50,000 entries of normal attributes of applicants of a life insurance company. Artificial Neural Network (ANN), Decision Tree (DT), and Random forest (RF) algorithms are applied on both the datasets to predict the risks of the applicants. The results showed that random forest outperformed among all the algorithms, providing the more accurate result.**

***Keywords*—Risk prediction; data analytics; predictive analytics; underwriting; geographical information systems; random forest; artificial neural network; decision tree**

I. Introduction

Assessment of risk plays a significant role in the classification of applicants in any life insurance industry. The life insurance businesses use underwriting procedure to choose applications and set insurance product prices accordingly. For quicker application processing, the underwriting procedure might be automated thanks to the growth of data and developments in data analytics [13]. In order to develop solutions that cater to the demands of various client and market groups, insurance companies are giving emphasis of using machine learning (ML) techniques on big data. The evaluation comprises estimating the company's risk factor and offering potential employees health insurance based on their medical histories.

Developing a scalable risk assessment model for the customer segment of the insurance domain using geospatial technologies alike Global Positioning System (GPS) is very much suitable, particularly for surveillance of areas appearing infectious disease or environmental health hazards such as air pollution, water pollution, etc.,. This research discusses how the insurance companies can use a GIS data model to analyze these type parameters across the globe while addressing their biggest bottleneck. Numerous tools and systems will be developed that enable the visualization of disease/health hazard data in location and time as a result of this ongoing public health burden and technological advancements with spatial data [5]. This geospatial technology will therefore offer insurance businesses and decision maker’s visualization and analytical tools to conduct life insurance programs for clients in afflicted and/or suspected locations as well as analysis and forecasts that were previously technologically impractical.

The research problem addressed in this study is the development of an innovative framework leveraging Geographic Information Systems (GIS) and Machine Learning techniques for enhanced risk prediction in the Health Insurance Sector. The research question comes like as “What specific methodologies and algorithms within GIS and Machine Learning can enhance health insurance risk prediction?” The primary objectives of this study are to design and implement a novel GIS and Machine Learning framework for accurate health insurance risk prediction, assess its performance, and provide recommendations for practical implementation in the health insurance sector. The research holds significance by offering an innovative approach to health insurance risk prediction, potentially improving accuracy and decision-making in the sector through the integration of GIS and Machine Learning technologies. The main research contribution is the development of an advanced and novel framework that integrates GIS and Machine Learning to enhance the accuracy and effectiveness of risk prediction in the Health Insurance Sector.

GIS, GPS, and satellite-based technologies such as Remote Sensing (RS) are all examples of geospatial technology. GIS refers to the collection, input, updating, modification, transformation, analysis, query, modeling, and visualization of geographic data utilizing a collection of computer programs. The next Section II and Section III will discuss about the related research work and methodology respectively. The detailed results related discussion is mentioned in Section IV and finally conclusion given in Section V followed by the references section of this paper.

II. Related Work

A map-based dashboard was proposed for visualizing the COVID19 pandemic in order to deliver information to individuals all around the world who want to safeguard themselves and their communities and how a complete GIS platform may aid in the surveillance, preparedness, and response of infectious diseases [3]. By collecting data from satellites can be made available to users. Satellites are terrain surveillance equipment that provides regional information on climatic parameters and terrain features. Additionally, GPS uses satellite data to provide locating, direction-finding, and timing services. As a result, while GPS and RS provide local and spatial information, GIS offers accurate geospatial analysis and real-time geospatial data integration. This study is conducted and found that machine learning algorithms like DT, RF, and ANN are effective in estimating the risk level of applicants in an insurance industry [4, 7].

In this paper, a potential risk variables was investigated those contribute to the cases of COVID-19 at the various districts of Bangladesh. In this work, three global models and one local model were built based on demographic, economic, built environment along with the factors like health and facilities which affect rates of COVID-19 occurrence cases [10]. It was found that the percentage of urban population of the districts was responsible for the COVID-19 occurrence rates. This is due to the fact that in high-density urban regions, movements of people as well as activities are higher than the non-urban regions. The researchers discovered that the higher the inhabitant's density, there is more possibility that a person will come into contact with an infector. In this paper, a framework is presented which shows the different flood hazards in spatial hotspots areas and also assessed the vulnerability in the districts using MODIS data [16]. A ML approach was used to classify and find risk based on diabetics disease [17].

In the univariate analysis, population density was also revealed to be a significant variable in this study [2]. In this paper, authors found that in the OCHIN (Oregon Community Health Information Network) PBRN (practice-based research network) consist of community health centres. These networks were used to display of EHR (electronic health record) data using GIS web based mapping and thereby serving in detecting societies having higher number of patients without health insurance. The author suggested that this strategy might be adapted for use by PBRNs, primary care providers, public health officials, and others to recognize a wide range of practice and community needs and to correctly implement targeted interventions using additional EHR data pieces [5]. This paper work added current COVID-19 assessments by providing a geographical viewpoint. It's a collection that recognizes the themes and analyses that GIS and spatial-statistical tools are being used for [1]. The detailed comparative studies are mentioned below in the Table I which is done by the several researchers.

The main objective of this research work is to develop a software model that makes use of web GIS technology to calculate risk in a specific location using information for the health insurance industry. As a result, the insurance company might carry out a more thorough examination and come to better judgments that will benefit both their clients and the business. The insurance company may compare data from the previous year to help it make better decisions. Additionally, with the use of various hazard data, such as information on air pollution, malaria, COVID-19, industrial regions, etc., the companies may analyze the geographic area and make better decisions in order to provide consumers a variety of life insurance plans.

TABLE I. COMPARATIVE STUDY OF THE ALGORITHMS USED IN THE RELATED WORKS

Authors	Year	Objective	Methods used	Method giving the best performance
Rahman et al. [2]	2021	To identify the risk factors of Covid-19	GIS based spatial model	GIS model
Saran et al. [6]	2020	Reviewing of Geospatial Technology	GIS approach and dynamic modelling algorithms	GIS approach
Boulos et al. [3]	2020	Tracing and mapping of Covid-19 patients	GIS system	GIS system
Pardo et al. [1]	2020	Covid-19 analysis	GIS and spatial analysis	GIS method
Angier et al. [5]	2014	Identification of communities in need of health insurance	GIS web based	GIS web based
Boodhun et al. [4]	2018	Implementation of ML algorithms to classify the applicants risk levels	Multiple Linear Regression (MLR), ANN, RF, REPTree algorithms	REPTree performed better with Correlation Based Feature Selection (CFS) whereas MLR showed the best performance using Principal Components Analysis (PCA) method
Hutagaol et al. (2020) [11]		Examined risk level of customers using ML in life insurance companies	RF, Support Vector Machine (SVM) and Naive Bayesian algorithms	RF have highest precision in comparison to the SVM and Naive Bayesian (N.B.) algorithm
Mustika et al. [14]	2019	Applied a ML models to predict the risk level of applicants in life insurance	Extreme Gradient tree boosting (XGBoost), DT, RF and Bayesian ridge models	XGBoost model is provided more accurate result
Jain et al. [12]	2019	An ensemble learning method for assessing risk associated with a policy applicant	ANN and gradient boosting algorithm XGBoost	XGBoost provided the best result.
Biddle et al. [13]	2018	To automate the underwriting process	Logistic Regression, XGBoost and Recursive Feature Elimination	XGBoost is the most ideal one giving better accurac.
Dwivedi et. al. [15]	2020	ML algorithms are used to predict the risk levels of applicants	ANN, MLR, RT and RF	RF came out to be most efficient one.

III. Methodology

As part of the research methodology, data is acquired from online databases. The research paradigm adopts a positivist stance because the study is largely predictive and uses machine learning and some geospatial approaches to assist this research work goals. The major task of the gathered data is to use Quantum-GIS (QGIS) to turn all of the non-spatial data into spatial data. The process flow of the model which utilizes different techniques is shown in the Fig. 1. The details of the data, format, source and description are mentioned in the given below Table II.

A. Data Collection and Preparation

The 59,381 applications that make up the life insurance data collection each have 128 attributes that describe the traits of applicants for life insurance. The data set contains anonymised nominal, continuous, and discrete variables. Customer related sample dataset of the applicants is shown in the Table III. The data pre-processing, commonly referred to as data cleaning, which comprises removing erratic data or outliers from the target dataset. This step also includes developing any methods necessary to deal with the target data's inconsistencies. To facilitate analysis and interpretation in the event of disputes, certain variables will be changed. In this phase, the data will be cleaned to get rid of any missing values and make sure it can be used for the analysis. To determine the optimal imputation procedure for the dataset, it will be necessary to look into the structure and methodology of missing data.

B. Geospatial Technology

Geospatial technologies and services can help with the representation of spatio-temporal data and the analysis of dynamic spread when illnesses or hazards are present [8]. A "spatial health information infrastructure" must be built using geospatial technology and real time services. In order to better comprehend analysis the spread and outbreak of the phenomenon, a review of several geospatial technologies with enabled IT services will be conducted in this section using a case study on the COVID-19 pandemic, malaria illness, air pollution, and industrial region.

Fig. 2. COVID-19 sample data in JSON format.

Fig. 2 shows the sample data of covid-19 for the districts of Assam in JSON format. Fig. 3 shows the sample data of malaria-PV (Plasmodium Vivax) virus and Fig. 4 shows the sample data of malaria-PF (Plasmodium Falciparum) virus in GEOJSON format of all the districts of India [9]. The red marks are shown in the Fig. 5 which denotes the industrial areas of NER for the 3rd Land Use Land Cover (LULC) cycle (2015-2016). Fig. 6 shows the MODIS data of NER air pollution for 15 January 2021.

C. Model Development

The optimal model is chosen using a combination of decision tree and ensemble techniques because risk level is a multi-class variable. Combining data from a number of different models to increase accuracy and stability is referred to as an "ensemble." The many algorithms that were used to create the predictive models using the data set were covered in this section. Several machine learning methods, including DT, RF, and ANN have been applied on the dataset after pre-processing the data.

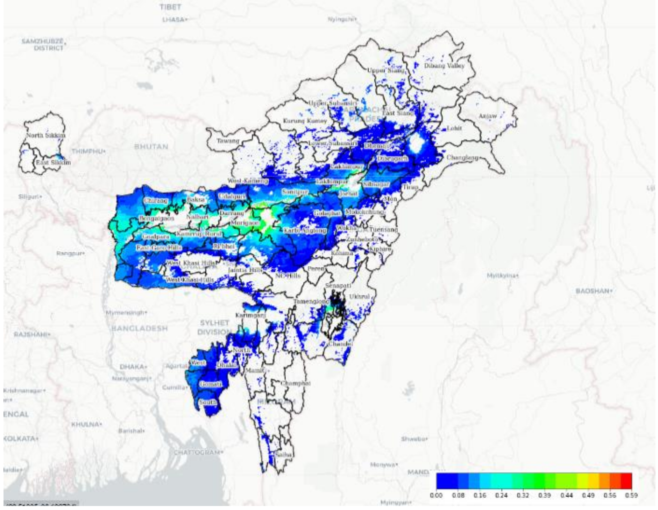

Fig. 6. MODIS data of NER air pollution.

1) Decision Tree: The SKlearn module in Python is used to build the DT as shown in Fig. 7 and also the information gain is calculated with the help of sample estimation which are shown below in Eq. (1), (2) and (3). The accuracy of this algorithm is coming 80%.

$$\mathrm{E(s)} = \sum_{i=1}^{c}(-p_i \log_2 p_i) \qquad (1)$$

$$\mathrm{E(T, X)} = \sum_{c\in X} P(c)E(c) \qquad (2)$$

$$\mathrm{InforGain\ (T, X) = E(T) - E(T, X)} \qquad (3)$$

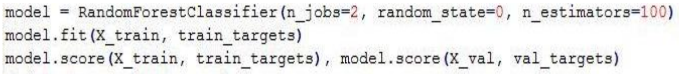
```
from sklearn.tree import DecisionTreeClassifier
model = DecisionTreeClassifier(random_state=42)
```

Fig. 7. Decision tree code snippet.

2) *Random Forest (RF):* The SKlearn module in Python is used to build the Random Forest technique as shown in Fig. 8, and 100 decision trees are employed to provide the final output for classification. The feature importance value for RF is calculated with the help of normalized importance of feature which are shown below in Eq. (4) and Eq. (5). The accuracy of the algorithm is coming 95%.

$$\mathrm{normfi}_i = fi_i / \sum_{j\in all\ features} fi_j \qquad (4)$$

$$\mathrm{RFfi}_i = \sum_j normfi_{ij} / \sum_{j\in all\ features, k\in all\ trees} normfi_{jk} \qquad (5)$$

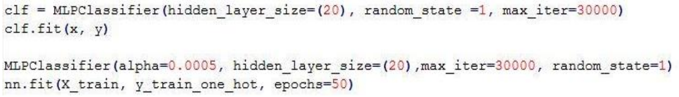


```
model = RandomForestClassifier(n_jobs=2, random_state=0, n_estimators=100)
model.fit(X_train, train_targets)
model.score(X_train, train_targets), model.score(X_val, val_targets)
```

Fig. 8. Random forest code snippet.

3) *Artificial Neural Network (ANN):* The input, hidden, and output layers of neurons are the three that are chosen in this procedure. There are 20 units in the hidden layer and a 0.1 starting random weight, for a total of 30000 iterations. The ANN code snippet is mentioned in the below Fig. 9. The accuracy of the algorithm is 90%. Eq. (6) shows the output layer calculation. Fig. 10 shows the following diagram illustrates the neural network used in this application. The neural network is too large to be plotted.

$$\mathrm{f(x)} = \sum_{i=1}^{m}(w_{ij}x_i) + bias \qquad (6)$$



```
clf = MLPClassifier(hidden_layer_size=(20), random_state =1, max_iter=30000)
clf.fit(x, y)

MLPClassifier(alpha=0.0005, hidden_layer_size=(20),max_iter=30000, random_state=1)
nn.fit(X_train, y_train_one_hot, epochs=50)
```

Fig. 9. ANN code snippet.

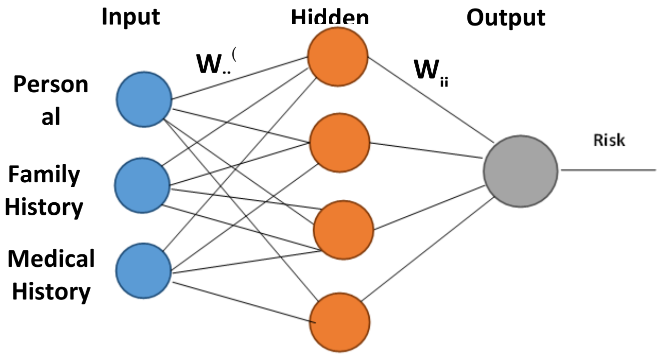


Fig. 10. A diagram of neural network for risk related application.

4) *Heat Map:* A heat map is a representation of two-dimensional data which shows the values having different intensities of colors. A simple heat map provides an immediate visual summary of information which is shown below in the Fig. 11. The heat map helps the viewer to understand and interpret the complex data sets. The color variation based on the different intensities provides understandable visual indications and also signifies the phenomenon of cluster or non-cluster over space.

IV. Results and Analysis

Here I have developed a web GIS-Dashboard using scripting languages like HTML, CSS, JavaScript as front end and PHP, python as back end. Geoserver is used here to publish different layers for displaying in this portal. Different base maps like Google map, Cartodb, Bhuvan map and Open street map were used here. In addition to its state boundary and district boundary of North East India were used here as overlay layers. Moreover, census data and three cycles of LULC data viz., LULC 1st cycle (2005-06), LULC 2nd cycle (2011-12) and LULC 3rd cycle (2015-16) are provided for analyzing and comparing trends over time. Different hazards like malaria (2019), covid-19 (2020-2021), MODIS air pollution data (2021) and industrial area (LULC 3rd cycle) were shown on this dashboard. Fig. 12 shows the UI of the dashboard. The default map that appears here is the Bhuvan map and NER district boundary on top of it. Different types of platforms are used for developing the web GIS-Dashboard which is as follows:

- Front End: HTML, CSS, JavaScript
- Back End : PHP, Python
- Web Server : XAMP, Geoserver
- Database : Postgres

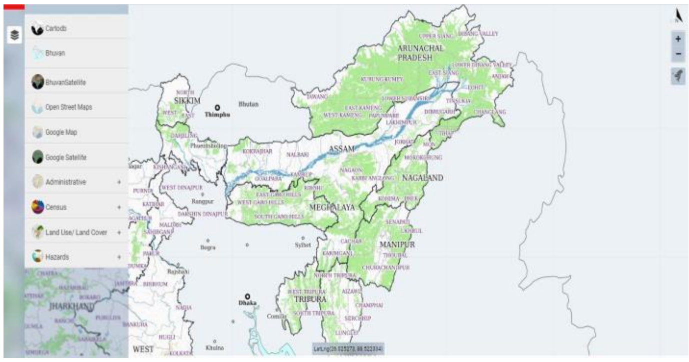

Fig. 12. Web portal designed using script language based environment.

Fig. 13 shows different base maps like Cartodb, Bhuvan, Open Street and Google map. In addition to it different overlay layers like state boundary, district boundary, census, LULC and different hazard layers are shown in this figure. The census data for Barpeta district is shown in Fig. 14, which includes total population, total work population, literacy, and the number of households.

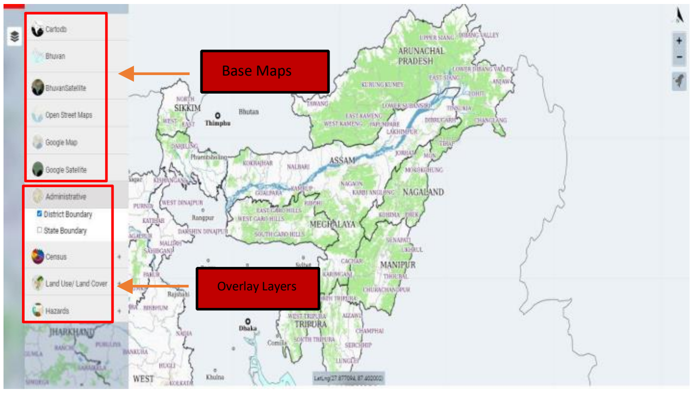

Fig. 13. Different base maps and overlay layers.

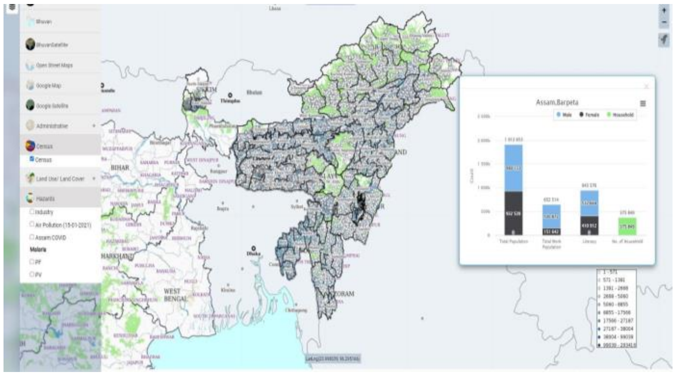

Fig. 14. Representation of census data for barpeta district.

Fig. 15 depicts the various LULC 1st cycle sectors for the Karbi Anglong district, including agriculture, built-up, forest, wasteland, and waterbodies. The analysis and comparison of all three LULC cycles in different sectors viz., agriculture, built up, waterbodies, snow, shifting cultivation, wastelands; forest for the Karbi Anglong area is shown in Fig. 16. In the Fig. 17, the risk level of different districts of Assam is depicted based on the insurance data and industrial data for the LULC 3rd cycle. The industrial area is shown in red marks for the NER region.

Fig. 18 displays the air pollution MODIS data for the NER region on January 15, 2021. Red indicates a high level of pollution, whereas blue indicates a low level of pollution. The figure shows various risk levels for insurance company applicants broken down by district. The following Figure 19 shows the corona virus count for the Assam district from January 2020 to October 2021. The graph shows the varied risk levels for insurance applicants in various districts of Assam.

V. Conclusion

A GIS software model that makes use of online GIS technologies for analysis and visualization purposes which have been developed in this paper. The insurance provider might therefore be in a position to conduct a more thorough investigation and come to better judgments for its customers and business. Additionally, the corporate environment will specifically benefit from this research endeavour. Data visualization and analysis are becoming more and more common among enterprises all around the world. In this paper, several factors are incorporated in QGIS which provides risk analysis in better interpretable form. When compared to conventional methods, predictive modeling using GIS technologies can have a substantial impact on how business is performed in the life insurance market. Previously, lengthy and difficult actuarial calculations were used to evaluate risk for life underwriting. With the use of a web GIS map, the task may now be accomplished more quickly and with better results. As a result, it would benefit the company by enabling quicker customer service, thereby boosting satisfaction and loyalty.

The future research development is being planned in the following ways:

- Calculating premium for the customers in a specific geographic location based on the prediction.
- Collecting data in large quantities in order to increase the accuracy and usability of the model in real life situations.

Enhancing Underwater Object Recognition Through the Synergy of Transformer and Feature Enhancement Techniques

Hoanh Nguyen*, Tuan Anh Nguyen
Faculty of Electrical Engineering Technology, Industrial University of Ho Chi Minh City, Ho Chi Minh City, Vietnam

Abstract—**Underwater object recognition presents a unique set of challenges due to the complex and dynamic characteristics of marine environments. This paper introduces a novel, multi-layered architecture that leverages the capabilities of Swin Transformer modules to process segmented image patches derived from aquatic scenes. A key component of our approach is the integration of the Feature Alignment Module (FAM), which is designed to address the complexities of underwater object recognition by enabling the model to selectively emphasize essential features. It combines multi-level features from various network stages, thereby enhancing the depth and scope of feature representation. Furthermore, this paper incorporates multiple detection heads, each embedded with the innovative ACmix module. This module offers an integrated fusion of convolution and self-attention mechanisms, refining detection precision. With the combined strengths of the Swin Transformer, FAM, and ACmix module, the proposed method achieves significant improvements in underwater object detection. To demonstrate the robustness and effectiveness of the proposed method, we conducted experiments on the UTDAC2020 dataset, highlighting its potential and contributions to the field.**

Keywords*—*Underwater object recognition; swin transformer; self-attention; feature alignment

I. INTRODUCTION

Underwater object recognition is a specialized domain within computer vision and robotics that focuses on identifying and locating objects within aquatic environments. The complexities associated with this field are manifold, given the unique challenges posed by underwater conditions. These include limited visibility due to turbidity, light refraction and attenuation, and the dynamic nature of the aquatic medium with constantly moving particles and organisms. Detecting objects in such environments is crucial for a variety of applications, ranging from marine biology research, underwater archaeology, to defense and surveillance. Advanced techniques and algorithms in this area not only aim to improve the accuracy of detection but also enhance the real-time processing capabilities, making it possible for autonomous underwater vehicles (AUVs) and remotely operated vehicles (ROVs) to perform intricate tasks with minimal human intervention. Traditional underwater object detection is usually based on handcrafted features of images for detecting objects [1], [2], [3]. In these conventional methods, detection was often based on basic image processing techniques. Specifically, thresholding, contour detection, and basic filter operations were commonly employed to differentiate objects from the surrounding environment. While these methods had their merits, especially in low-visibility conditions, they often struggled with false positives and lacked the precision needed for intricate tasks. Furthermore, these approaches were highly dependent on manual calibration and expert interpretation, making them labor-intensive.

In recent years, deep learning has revolutionized the field of object detection, ushering in a new era of accuracy and efficiency. These methods leverage complex neural network architectures, particularly Convolutional Neural Networks (CNNs), to automatically learn hierarchies of features from raw pixel data, eliminating the need for handcrafted feature extraction. Advanced architectures such as Faster R-CNN [4], YOLO [5], [6], SSD [7], R-FCN [8], Mask R-CNN [9] have emerged as frontrunners, offering real-time detection capabilities with impressive precision. These models have been applied in various vision applications such as depth estimation [10], intrusion detection [11], [12], vehicle license detection [13], and face mask detection [14]. With the success of deep learning-based object detection models, researchers have begun to apply deep learning to underwater object detection [15-24]. Although these methods have achieved certain successes, they encounter a number of issues. Firstly, all objects, regardless of their ambiguity, are subjected to the same supervisory signal. As a result, the classification scores obtained using simple cross-entropy loss don't accurately represent the ambiguity of the objects. This leads to misleadingly overconfident predictions. Secondly, these methods struggle with objects that are vague due to blurred boundaries or colors similar to their background. This similarity makes it challenging for the methods to distinguish such objects from their surroundings effectively.

Recognizing these limitations, our study aims to overcome these specific challenges. We propose an innovative approach for underwater object detection leveraging a multi-layered framework powered by the Swin Transformer. In the model, images pass through a patch partitioning process, segmenting them into smaller patches. These patches are then processed through several Swin Transformer layers. After each transformation, techniques like concatenation, upsampling, and convolution are utilized to enrich the feature maps. These enhanced feature maps pass through the FAM to amplify feature representation, ensuring precise object detection in complex underwater scenarios. Following the FAM, the framework integrates multiple detection heads, ensuring reliable localization of objects in underwater imagery. By addressing the core issues of overconfidence in predictions and the struggle with vague object boundaries, our method seeks to provide a more robust and accurate solution for object detection.

The remainder of this paper is organized as follows: Section II provides an in-depth review of related work. Section III details our proposed methodology. In Section IV, we present a thorough analysis of our experiments. Finally, Section V concludes the paper with a summary of our findings and implications for future research.

II. Related Work

Underwater object detection, a crucial technology enabling AUVs to execute various tasks beneath the surface, has garnered significant interest globally among researchers. In [15], the authors introduced a method that utilizes a region proposal network from Faster R-CNN to enhance underwater object detection and recognition speed. This approach achieves quicker detection by employing convolutional networks to produce superior object candidates and integrating these networks with the primary detection systems. Chen et al. [16] proposed the Sample-WeIghted hyPEr Network (SWIPENET) and the Curriculum Multi-Class Adaboost (CMA) training paradigm to address challenges in underwater object detection, specifically blurry images with noise and small object detection. SWIPENET uses Hyper Feature Maps for enhanced resolution and detection of small objects, while its sample-weighted detection loss function emphasizes learning from high weight samples and disregarding low weight ones. Wei et al. [17] addressed challenges in underwater image target detection, particularly blur caused by water particles, by integrating squeeze and excitation modules into the YOLOv3 model after its deep convolution layers, enhancing semantic information. Zeng et al. [18] introduced the Faster R-CNN-AON network by integrating an adversarial occlusion network (AON) with the standard Faster R-CNN detection algorithm. The AON competes with the Faster R-CNN, teaching it to obscure targets, which in turn enhances the robustness of underwater seafood detection and prevents overfitting of the detection network.

In another approach, Lingyu et al. [19] adapted the YOLOv4 neural network for underwater target recognition by substituting its upsampling module with a deconvolution module and integrating depthwise separable convolution. Cao et al. [20] addressed underwater dynamic target tracking by developing a deep learning-based detection algorithm that uses the YOLO v3 network to identify targets in multibeam forward-looking sonar images and determine their positions. Huang et al. [21] introduced three specialized data augmentation techniques to address the scarcity of labeled samples in underwater environments: the inverse process of underwater image restoration for creating varied marine turbulence scenarios, perspective transformation to simulate different camera viewpoints, and illumination synthesis for replicating uneven lighting conditions underwater. In study [22], an innovative underwater salient object detection method that integrates both 2D and 3D visual features was introduced. This approach combines color and intensity (2D features) with 3D depth features, enhanced by a region-specific method that separately extracts these features in artificial and natural light regions, leading to more comprehensive and accurate detection results in three-dimensional underwater environments. Lin et al. [23] focused on augmentation policies designed to simulate overlapping, occluded, and blurred objects, constructing a model that achieves enhanced generalization. They introduce RoIMix, an innovative augmentation method that blends proposals from multiple images, unlike previous methods that operate on single images, thereby creating more complex and varied training data to improve model performance. Recently, Song et al. [24] introduced a two-stage underwater detector called boosting R-CNN, which features a novel region proposal network named RetinaRPN for high-quality proposals and models object prior probability through objectness and IoU prediction.

III. Proposed Model

A. Overview Pipeline

Fig. 1 illustrates the overall structure of our method for underwater object detection. The proposed method employs a multi-layered architecture that exploits the power of Swin Transformer modules. The input underwater image is first processed through a patch partition module, which segments the image into manageable patches. These patches are then sequentially passed through four layers of Swin Transformer modules. Specifically, Layers 1 and 2 involve two repetitions of the Swin Transformer module, Layer 3 contains six repetitions, while Layer 4 processes the patches twice through the Swin Transformer module. After the transformation process in each layer, specific operations including concatenation, upsampling, and convolution are performed to refine the feature maps. These refined feature maps are then passed through the Feature Alignment Module (FAM) to further enhance the feature representation, ensuring accurate object detection in the complex underwater environment. Following the FAM, the architecture incorporates multiple detection heads, which are responsible for the final object detection, ensuring robust identification of objects present in the underwater image. The details of each module are explained in the following subsections.

B. Swin-Transformer Backbone

- Transformers, initially introduced by Vaswani et al. in 2017 [25], are a type of neural network architecture primarily designed for handling sequence-to-sequence tasks in the field of natural language processing (NLP). They make use of attention mechanisms, notably self-attention, to weigh the significance of different parts of the input data. While Transformers have achieved remarkable success in NLP, their direct application to the vision domain presents challenges. One major reason is that unlike textual data which is inherently sequential, images are spatially structured with local patterns and hierarchies. Processing an image as a flat sequence of pixels loses this spatial coherence. Additionally, due to the high-dimensionality of images, Transformers can be computationally expensive and memory-intensive. To address these challenges, various adaptations, such as Vision Transformers (ViTs) [26] which divide images into fixed-size patches and then linearly embed them, have been proposed to better suit the unique characteristics of visual data. However, they sometimes lack fine-grained local feature extraction. Recently, Swin Transformer [27] has emerged as a novel and powerful architecture that brings together the strengths of both classic CNNs and Transformers, and in some contexts, it has outperformed both. While CNNs have traditionally been strong at capturing local features through their hierarchical design of convolutional layers, they often struggle with long-range dependencies and global context. Swin Transformer tackles the issues of both CNNs and Transformers by hierarchically partitioning the image into non-overlapping windows and applying shifted windows across layers. This approach allows it to capture both local features within each window and global context across the entire image. The combination of local window-based processing with the global contextual understanding provided by the Transformer structure makes Swin Transformer particularly effective at feature extraction, offering advantages over traditional CNNs and basic Transformers. Underwater images often exhibit a range of complexities, including varying light conditions, attenuation, backscatter, and color distortions. Traditional architectures, like CNNs, can sometimes struggle with these irregularities, especially when it comes to recognizing objects that may be obscured or distorted due to water turbidity. Swin Transformer, with its hierarchical partitioning and shifted windows, can capture both local details and global contexts effectively. The local window-based processing ensures fine-grained feature extraction, which is crucial for identifying subtle characteristics of underwater objects. Meanwhile, the global contextual understanding inherent in the Transformer structure helps in identifying objects even when they are partially obscured or when the surrounding environment is cluttered. Additionally, the self-attention mechanism of the Swin Transformer can focus on long-range dependencies, which is beneficial for analyzing the spatial relationships between various underwater elements. Based on the features analyzed above, we chose Swin Transformer as the backbone network to perform feature extraction.

- The architecture of Swin Transformer is depicted in Fig. 2. It takes an image of dimensions *w*×*h*×*c* (where *c* denotes channels, *h* is height, and *w* is width) and partitions it into non-overlapping patches. These patches pass through a linear embedding transformation and patch merging operations, converting them into token representations suitable for processing by transformer blocks. As the image progresses through the layers of the architecture (Layer 1 to Layer 4), the spatial resolution decreases, while the embedding dimensions increase. Specifically, the resolutions get adjusted by a downsampling factor (*w*/4×*h*/4) to (*w*/32×*h*/32) from Layer 1 to Layer 4. Each stage contains a specific number of Swin Transformer blocks, denoted by multipliers (i.e., ×2, ×2, ×6, ×2).

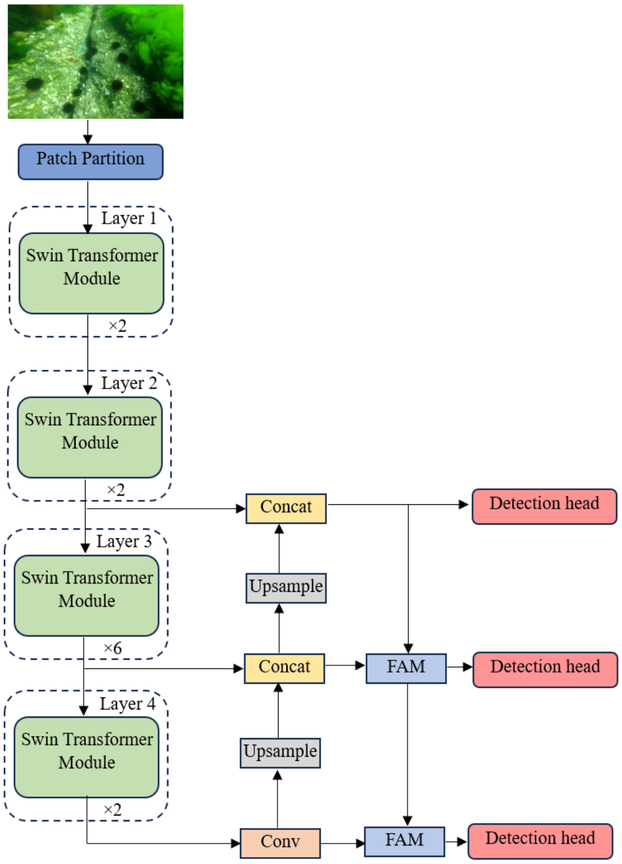

Fig. 1. Overview of the proposed model.

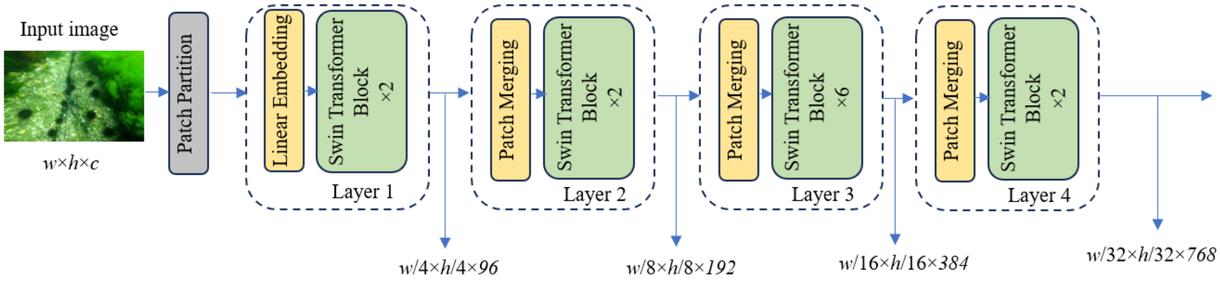

Fig. 2. Swin transformer architecture.

1) Patch partition block: Given an input image $I \in R^{w \times h \times c}$, the patch partition block divides this image into non-overlapping patches of size $p \times p \times c$. The total number of patches, N, produced by this partitioning is given by:

$$N = \left(\frac{w}{p}\right) \times \left(\frac{h}{p}\right) \qquad (1)$$

Each patch is then flattened to produce a vector of dimension $p^2 \times c$. Thus, after the patch partition block, the image representation transforms from I to a matrix P of dimensions $N \times (p^2 \times c)$. In essence:

$$I \in R^{W \times H \times C} \rightarrow P \in R^{N \times (p^2 \times c)} \qquad (2)$$

where, $P[i]$ represents the flattened vector for the i^{th} patch.

2) Linear embedding block: The linear embedding block applies a linear transformation to each of these flattened patches to project them into a specified embedding dimension D. This transformation can be represented by a matrix E of dimensions $(p^2 \times c) \times D$. Thus, the output L of the linear embedding block for each patch can be computed as:

$$L[i] = P[i] \times E \qquad (3)$$

where, $L[i]$ represents the embedded vector for the i^{th} patch.

Given this, the entire input-output relationship for the linear embedding block can be represented as:

$$P \in R^{N \times (p^2 \times c)} \rightarrow L \in R^{N \times D} \qquad (4)$$

where, P is the matrix of flattened patches, L is the embedding matrix.

3) Swin transformer block: The structure of two successive Swin Transformer blocks is depicted in Fig. 3. Each block consists of a sequence of operations: Layer Normalization (LN), Window-based Multi-head Self Attention (W-MSA) or Shifted Window-based Multi-head Self Attention (SW-MSA), and a Multi-Layer Perceptron (MLP) head. The LN standardizes the activations by calculating the mean and variance of the input image patch, thus stabilizing the training process. The W-MSA operates on a set of query (Q), key (K), and value (V) vectors. It matches the query to a set of key-value pairs to produce an output. This matching is achieved by computing the dot product between the query vector and every key vector. Subsequently, a softmax function is employed to scale these dot products, transforming them into weights denoted as k. The process is calculated as follows:

$$Attention(Q, K, V) = Softmax\left(\frac{QK^T}{\sqrt{d_k}}\right)V \qquad (5)$$

where, Q represents the Query matrix, K represents the Key matrix, V stands for the Value matrix, and d_k is the dimension of the keys. The divisions by $\sqrt{d_k}$ functions as a scaling factor, ensuring stability in the gradients during the training phase.

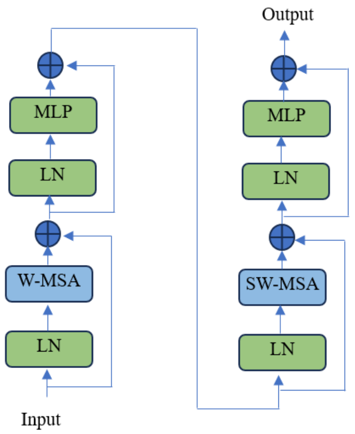

Fig. 3. The structure of two successive swin transformer blocks.

The locality of W-MSA might raise concerns about its ability to capture global context. To mitigate this, Swin Transformer employs multiple blocks of W-MSA and integrates a "shifting" strategy in subsequent blocks (SW-MSA), ensuring that tokens in one window in a certain block can interact with tokens in neighboring windows in the next block.

4) Patch merging block: This block is used to reduce the spatial dimensions of the input while augmenting the feature dimensions. Conceptually, this block aggregates neighboring patches from the previous layer and fuses them to form a larger patch. For instance, four adjacent patches of size p × p are merged to create a single patch of size 2p × 2p. This merging process typically employs a simple linear transformation. As a result, the spatial resolution of the feature map is halved in both height and width dimensions, but the depth or the number of channels is doubled. The purpose of this operation is twofold: firstly, it progressively reduces the computational requirements for subsequent layers, and secondly, it increases the receptive field, enabling the model to capture more global and abstract features as information flows deeper into the transformer.

C. *Feature Attention Mechanism*

In hierarchical models such as Swin Transformers and CNNs, lower-level features often capture fine-grained details, textures, and simple patterns. Meanwhile, higher-level features encompass more abstract, complex, and semantically rich information about objects, enabling the model to recognize more intricate and high-level attributes. By combining features from different layers, the model is equipped with a comprehensive and multi-scale representation of the input image. In addition, the underwater visuals are typically characterized by low-light conditions, varied light absorption and scattering, and blurry images due to particulate matter suspended in the water, which can result in a significant degradation of image quality and object distinguishability. This paper proposes a feature attention mechanism (FAM) to precisely address these challenges by enabling the model to selectively focus on important features and effectively integrate multi-level features from different stages of the network, enhancing the representative power of deep features, especially in the challenging context of underwater object detection. The architecture of the FAM is illustrated in Fig. 4, which consists of two branches: the first branch directly processes the lower-level feature (F_1) through a batch normalization layer, ensuring the features are normalized and thereby enhancing the model's stability and convergence during training. Simultaneously, the second branch takes the higher-level feature (F_2) through a sophisticated pathway comprising a coordinate attention (CA) block, followed by a convolution layer, a max-pooling layer, and a batch normalization layer. The CA block [28] is notable for its capacity to encode both channel relationships and long-range dependencies with precise positional information, implemented through two crucial steps: coordinate information embedding and coordinate attention generation. Once the individual pathways of the two branches have processed the features, their outputs are aggregated by summation and then fed to a ReLU activation layer, which ensures the generation of a robust and hierarchically rich feature representation, designed to significantly enhance the underwater object detection capabilities of the system. The output of the FAM mechanism can be calculated as follows:

$$F_1' = BN(F_1) \tag{6}$$

$$F_2' = BN(MAXPOOL(CONV(CA(F_2)))) \tag{7}$$

$$F_{output} = ReLU(F_1' + F_2') \tag{8}$$

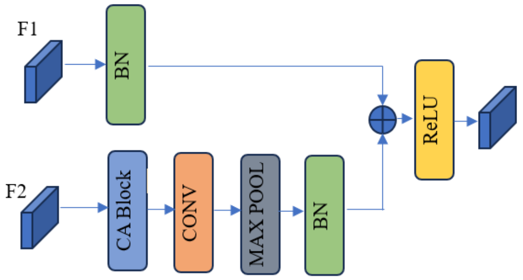

Fig. 4. Feature attention mechanism.

D. Detection Head with Combination of Convolution and Self- Attention

Pan et al. [29] highlighted the connection between convolution and self-attention mechanisms by highlighting computational similarities in both methods. Consequently, they designed a hybrid model, ACmix, which adeptly integrates the advantages of both self-attention and convolution, while maintaining minimal computational overhead relative to pure convolution or self-attention models. Given the potentially robust link between convolution and self-attention, the ACmix module is utilized in this paper to integrate the convolution and self-attention mechanisms. Fig. 5 illustrates the structure of the ACmix module. The module channels the data through a series of three 1×1 convolutional layers. These layers serve to capture local features and correlations in the data. Concurrently, the input is also processed through a self-attention mechanism equipped with a position encoder. This mechanism ensures the model can recognize and weigh global dependencies in the data effectively. Subsequent to their independent processing, the outputs from the convolutional and self-attention pathways pass through a 'Shift Operation' and are concatenated. This combined representation exploits the strengths of both paradigms, ensuring a comprehensive understanding of the data's local and global patterns. Finally, the concatenated output is summed to produce the final output. The output of each ACmix module is input into a YOLO detector head for location and classification.

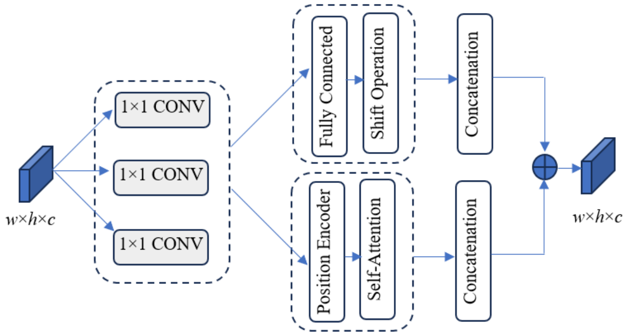

Fig. 5. The structure of ACmix.

IV. Experiments and Results

A. Dataset

The experiments utilize the UTDAC2020 dataset, which originates from the Underwater Target Detection Algorithm Competition in 2020 [18]. This comprehensive dataset comprises 5,168 training images and 1,293 validation images, focusing primarily on four specific marine species: echinus, holothurian, starfish, and scallop. The unique attribute of this dataset lies in its variety of resolutions, with images spanning four distinct sizes: 3840×2160, 1920×1080, 720×405, and 586×480. This dataset serves as an important resource for understanding and advancing underwater image analysis and target detection. For evaluation and comparison purposes, the standard COCO-style evaluation metric is employed.

B. Experimental Settings

The proposed model was implemented using the PyTorch deep learning framework and programmed in Python. All experiments were carried out on machines equipped with an NVIDIA RTX 4080 GPU. The backbone of our architecture is the base version of the Swin Transformer, which was pre-trained on the ImageNet-1K dataset and has an embedding dimension of C = 128. We chose this version because of its balance between computational efficiency, model size, and accuracy. The model was fine-tuned for 15 epochs, using a batch size of 2. For optimization, the AdamW optimizer [30] was employed, starting with a learning rate of 0.0002. This rate was adaptively adjusted based on the training progress, and a weight decay of 0.05 was implemented. Our data augmentation strategies included a variety of techniques such as random resizing, combined random resizing and cropping, as well as horizontal and vertical random flipping. For a comprehensive overview of the hyperparameters employed in the comparative models, (see Table I).

TABLE I. HYPERPARAMETERS OF ALL MODELS

Model	Initial learning rate	Regularizer	Optimizer	Batch size	Number of Epochs
Our model	0.0002	Weight decay of 0.05	AdamW	2	15
Deformable DETR [28]	0.00001	Weight decay of 0.0001	AdamW	2	40
RetinaNet [29]	0.01	L2	SGD with Momentum	10	20
Faster R-CNN with FPN [30]	0.02	Weight decay of 0.0001	SGD with Momentum	2	12
DetectoRS [31]	0.02	Weight decay of 0.0001	SGD with Momentum	2	20
FCOS [32]	0.01	Weight decay of 0.0001	SGD with Momentum	16	20
CenterNet [33]	0.0002	Weight decay of 0.0001	Adam	6	25

C. Comparison with Other Methods

The comparison results on the UTDAC2020 dataset are shown in Table II. Our underwater object detection model based on the Swin Transformer architecture obtains a significant improvement in performance when compared to other state-of-the-art models on the UTDAC2020 dataset. In terms of Average Precision (AP), the proposed model achieved a score of 51.6, which is notably higher than other models utilizing the ResNet50 backbone, such as Deformable DETR [31], RetinaNet [32], and Faster R-CNN with FPN [33], DetectoRS [34], FCOS [35], and especially CenterNet [36] which used ResNet18. Additionally, in the specific AP metrics (AP_{50}, AP_{75}), our Swin Transformer-based model also outperforms the competition, indicating a robustness in detecting objects at different Intersection over Union (IoU) thresholds. Remarkably, there is a significant jump in AP_{75} to 57.5, suggesting that the model is efficient at achieving a tighter fit around the detected objects. When analyzing the performance based on object size (AP_S, AP_M, AP_L), the proposed model consistently delivers superior results. The model's weakest performance is in AP_S at 23.2, which, while comparable to some models like Deformable DETR and DetectoRS, demonstrates that there might be challenges in detecting smaller underwater objects. Nonetheless, the model's AP_M and AP_L scores of 44.6 and 57.9, respectively, emphasize its efficiency in medium to large object detection. In summary, leveraging the Swin Transformer architecture and feature attention mechanisms has enhanced the efficacy of the proposed model in the challenging domain of underwater object detection.

Fig. 6 shows qualitative results of our model on the UTDAC2020 dataset. We can see a notable performance of the proposed model across diverse underwater scenarios. The detection results are evident across a range of images, from those where marine life is interspersed among a sea of green to those with rocky terrains. Even in images with dense clusters of organisms or potential overlapping instances, the model is efficient in differentiating between individual entities, avoiding much of the occlusion-related errors that often plague underwater detection tasks. Furthermore, the model's performance is evident in various lighting conditions and water turbidities, emphasizing its robustness.

D. Importance of Feature Attention Mechanism

We also conducted experiments to evaluate the impact of the FAM. Fig. 7 shows comparing the performance of the model with and without the FAM. When FAM is implemented, there is a noticeable improvement in all metrics. Specifically, the AP increases from 50.1% to 51.6%, indicating a more accurate model overall. This improvement is more pronounced in AP_{50} (from 82.2% to 85.1%), which measures precision at 50% IoU threshold, suggesting that FAM particularly enhances the model's ability to detect objects with a moderate overlap with the ground truth. The increase in AP_{75}, from 54.2% to 57.5%, also highlights better performance at a stricter IoU threshold, implying enhanced precision for more accurately localized predictions. The improvements in AP_S, AP_M, and AP_L are also noteworthy. The model with FAM achieves better results across these size-based categories, with the most significant jump observed in the medium-sized object category, from 40.3% to 44.6%. This suggests that FAM effectively enhances the model's capability to recognize and detect objects of various sizes, especially in challenging underwater environments where visibility and image quality are often compromised. Overall, the integration of FAM into the model clearly leads to better performance in object detection, making it a valuable addition to the model's architecture, particularly for tasks in complex and visually challenging environments like underwater object detection.

TABLE II. COMPARISON RESULTS ON THE UTDAC2020 DATASET

Model	Backbone	AP	AP_{50}	AP_{75}	AP_S	AP_M	AP_L
Deformable DETR [31]	ResNet50	46.6	84.1	47.0	24.1	42.4	51.9
RetinaNet [32]	ResNet50	43.9	80.4	42.9	18.1	38.2	50.1
Faster R-CNN with FPN [33]	ResNet50	44.5	80.9	44.1	20.0	39.0	50.8
DetectoRS [34]	ResNet50	47.6	82.8	49.9	23.1	41.8	54.2
FCOS [35]	ResNet50	43.9	81.1	43.0	19.9	38.2	50.4
CenterNet [36]	ResNet18	31.3	61.1	27.6	11.9	32.5	33.4
Our model	Swin Transformer	51.6	85.1	57.5	23.2	44.6	57.9

V. Conclusions

In this research, we addressed the challenges associated with underwater object detection by introducing a novel multi-layered architectural approach that effectively exploits the capabilities of Swin Transformer. Our method provides a structured approach to process segmented image patches derived from underwater scenes, ensuring accurate and efficient object detection. A significant contribution of our research is the Feature Alignment Module (FAM), specifically designed to address the complexities of marine environments. By focusing on essential features and integrating multi-level features across various network stages, the FAM substantially elevates the depth and precision of feature representation. Moreover, the incorporation of several detection heads, coupled with the ACmix module, represents a transformative approach to enhancing detection accuracy. The results on the UTDAC2020 dataset emphasize not only the efficacy of our proposed method but also its potential as a benchmark solution in the field of underwater object detection. In future, we envision further refining our model by integrating more advanced attention mechanisms and exploring its applicability in other complex environmental scenarios.

A Computational Prediction Model of Blood-Brain Barrier Penetration Based on Machine Learning Approaches

Deep Himmatbhai Ajabani
Application Developer, Lead, Source InfoTech Inc., Atlanta, Georgia, United States

***Abstract*—Within the field of medical sciences, addressing brain illnesses such as Alzheimer's disease, Parkinson's disease, and brain tumors poses significant difficulties. Despite thorough investigation, the search for truly successful neurotherapies continues to be challenging to achieve. The blood-brain barrier (BBB), which is currently a major area of research, restricts the passage of medicinal substances into the central nervous system (CNS). It is crucial in the field of neuroscience to create drugs that can effectively cross the blood-brain barrier (BBB) and treat cognitive disorders. The objective of this study is to improve the accuracy of machine learning models in predicting BBB permeability, which is a critical factor in medication development. In recent times, a range of machine learning models such as Support Vector Machines (SVM), K-Nearest Neighbors (KNN), Logistic Regression (LR), Artificial Neural Networks (ANN), and Random Forests (RF) have been utilized for BBB. By employing descriptors of varying dimensions (1D, 2D, or 3D), these models demonstrate the potential to make precise predictions. However, the majority of these studies are biased to the nature of datasets. To accomplish our objective, we utilized three BBB datasets for training and testing our model. The Random Forest (RF) model has shown exceptional performance when used on larger datasets and extensive feature sets. The RF model attained an overall accuracy of 90.36% with 10-fold cross-validation. Additionally, it earned an AUC of 0.96, a sensitivity of 77.73%, and a specificity of 94.74%. The assessment of an external dataset resulted in an accuracy rate of 91.89%, an AUC value of 0.94, a sensitivity rate of 91.43%, and a specificity rate of 92.31%.**

Keywords*—Central Nervous System (CNS); Blood-Brain Barrier (BBB); Machine Learning (ML); Simplified Molecular Input Line Entry System (SMILES); Support Vector Machine (SVM); K-Nearest Neighbor (KNN); Logistic Regression (LR); Multi-Layer Perceptron (MLP); Light Gradient Boosting Machine (LightGBM); Random Forest (RF)

I. Introduction

In the last few decades, human brain diseases like tumors in the brain, dementia, Alzheimer, and other brain disorders are the most common fastest-growing issue nowadays that causes disability in humans and received the most attention from the research community in medical sciences. As there are no effective treatments have been made by neurotherapist to treat these kinds of serious diseases. Almost all macro and small molecule drugs are blocked by a barrier named the BBB [1]. The BBB is the most important key point in the treatment of brain diseases as it forcibly prevents the drugs from crossing this barrier and enters the CNS [2]. Many ML and Deep learning techniques have been made in the past and till now most researchers have been working on this problem of BBB permeability but still, the question arises on the performance of models and their precise results for drug formation in pharmaceutics [3], [4].

As the name indicates BBB, it is the barrier between blood and the brain. The barrier is made of endothelium cells [5] which can prevent large and even small molecules from entering the CNS [6]. It only allows some specific molecules like water molecules and some lipid-soluble to cross the barrier [7]. The BBB is divided into two classes labeled BBB+ and BBB-. The BBB+ shows the higher permeability and the BBB- shows the lower permeability respectively [8]. Developing a classification model requires a piece of detailed information and a complete understanding of issues or problems regarding BBB permeability. These issues are mainly caused by the selection of algorithms and the dataset on which these computations are performed. The problems faced in algorithms include their lower coverage, overfitting w.r.t dataset, and lower accuracy scores while predicting the molecular compounds i.e., (BBB-). The problems raised regarding datasets are duplication of compounds or improper class label distribution in the BBB dataset, which is a serious cause of inaccurate results [9].

In BBB there are molecular descriptors used as features in the dataset. The definition of molecular descriptor states that the transformation of chemical compounds by applying mathematical procedure converts these compounds into standardized numeric information that can be used for further experiments [10]. Molecular descriptors encompass various characteristics of molecules, such as their weight, amount of carbon atoms, and hydrogen bonds. The literature review primarily focused on the discussion of various classes of molecular descriptors, namely one dimension, two dimensions, and three dimensions. The representation of molecular descriptors is categorized into several kinds. Numerous classes have been discussed in the existing body of scholarly literature. The classes were categorized into three distinct groups, namely 1D, 2D, and 3D.

One-dimensional molecular descriptors, such as the number of certain atoms and molecular weights, are utilized to express the attributes of molecules [11]. The presentation of structural information is accomplished by the utilization of 2D molecular descriptors. It is computed from the 2D molecular structure like the number of donors in the H bond, the number of C6H6 rings, etc. [11]. The structural information is represented by 3D molecular descriptors like a positive partial charge structure of solvent-accessible surface area [11].

In this study, the main focus is given to the diversity of datasets in terms of size and nature of datasets, further applying a variety of machine learning algorithms. The novelty of the work is the generation of chemical features from SMILES and testing them as unseen data for the best model. Further, we have tested machine learning algorithms with different hyperparameters and chosen the best hyperparameter for each algorithm that was missing in the previous literature. In previous studies, experiments were conducted with default hyperparameters [7], [12-15]. Also, the model is evaluated on several different evaluation metrics to validate the performance of the best-chosen model.

II. Related Work

BBB is an up-and-coming research area that is widely used in the formation of drug discovery. In the last decades, several approaches to the BBB have been proposed. These approaches are based on ML algorithms and have followed their method of technique. Permitting the literature study, there were several approaches have been proposed which have their methods and techniques. These techniques vary with the number of compounds used and the selection of important features related to these chemical compounds. So, the proposed system will give outcomes in terms of results of model accuracy, sensitivity, specificity, and the robustness of testing scores.

Dai et al. 2021 [1] proposed a feature representation in sequential-based prediction for BBB peptides. In this study, 16 classes of peptide sequence feature descriptors have been used. For finding the best solution three-step method was used. In the three-step model, features were selected based on the F1 score, and Spearman's rank-order correlation and a sequential forward selection strategy were implemented. In this study, many ML models were compared i.e., ERT, XGB, LR, MLP, RF, and SVM. While comparing the results of each model the LR has the best prediction ability to gain an overall AUC and AUPR score of 0.87 with 10-fold cross-validation. But dataset contains only 119 BBPs compound datasets having only seven features for classification and mainly focusing on peptide-based molecular compounds. On the contrary, Zou 2022 [2] uses the physicochemical properties of amino acids and through these amino properties, the author identifies blood-brain barrier peptides (BBPs) and also applies the features fusion method. In this research, SVM was implemented on a dataset that represents peptide sequences based on 100 samples from BBPs, and 100 samples from non-BBPs were used, together with 10 physicochemical characteristics descriptors. For the selection of discriminative features, the Fisher algorithm was used. The highest accuracy, specificity, and sensitivity achieved by the model on the training dataset is 100%, while MCC and AUC are also 1.00, while on the independent dataset, it was 89.47%. The limitation of this work is limited samples were used and they just employed the correlation information between two different types of physicochemical properties. Also, there is a lack of biological experiments to validate the predicted results.

Similarly, Shaker et al. 2021 [7] proposed a LightGBM algorithm that was implemented on a 7162 compounds dataset with BBB permeability in which 5453 BBB+ and 1709 BBB- class with 1119 molecular descriptors of SMILES format. 10-fold cross-validation was implemented after splitting the dataset into 10% testing and 90% training and the results show an accuracy score of 0.89, specificity of 0.77, sensitivity of 0.93, and area under the curve of 0.94 respectively. However, the accuracy can be improved in the future by testing other ML models as it is critical to decide which molecular compound can penetrate from CNS through BBB. However, the use of these many features increases the complexity of the models. Therefore, Alsenan et al. 2021 [9] proposed a model that used the Kernel Principal Component Analysis (KPCA) method for finding descriptors. The author also compares the deep learning (DL) models with ML models and comes with the result that deep learning models show more accurate results than ML models. The FFDNN and CNN achieve accuracy of 100%, specificity of 98.11 and 99.87, and sensitivity of 96.78 and 98.76 respectively. The AUC was also calculated which was 97.7 and 99.71 and Matthew's correlation coefficient was 95.55 and 92.85 respectively. However, the dataset was composed of 2500 molecular compounds with 6,394 molecular descriptors which are small datasets as a large dataset has a direct impact on accuracy and only focuses on the KPCA feature extraction technique.

Furthermore, various variants of ML models are tested by Kumar et al. 2021 [12]. The author proposed an RF-based method for the prediction of the BBB by using chemical peptides. Different algorithms were implemented i.e., DT, RF, LR, KNN, GNB, XGB, and SVC. Three datasets were used in this study i.e., dataset-1 had 269 B3PPs and CPPs respectively. Dataset-2 was having 269 B3PPs and non-B3PPs respectively, while dataset-3 was having 269 B3PPs and 2690 non-B3PPs. The highest accuracy, specificity, and sensitivity were achieved by RF, which is 85.08, 85.08, and 86.97 respectively. Matthew correlation and AUC are also calculated which are 0.51 and 0.93. But the author collected only 465 peptides from the B3Pdb database which is a small dataset of cell-penetrating peptides with 80 selected features.

Also, Liu et al. 2021 [13] proposed the SMOTE technique on 1757 chemical compounds, and the feature descriptors were produced by PaDEL-Descriptor software for nine molecular fingerprints and 2D and 3D descriptors on five-fold cross-validation with 100 iterations. Three algorithms were implemented i.e., SVM, RF, and XGBoost from which RF shows the higher scores in terms of accuracy of 0.910, specificity of 0.867, sensitivity of 0.927, and AUC of 0.957 respectively. But there are a smaller number of descriptors used and this model is not a quantitative approach to identifying which BBB chemical compound can penetrate or not. In comparison, Shi et al. 2021 [14] in this approach, 2354 drug molecules of SMILES format were used with 33 molecular features. 10-fold cross-validation was used and six types of methods were used for training of imbalance dataset i.e., Upsampling, RUS, Weight parameter, SMOTE, SMOTECENN, and ADASYN. The results clearly show that XGBoost outperforms other approaches in terms of precision 0.92, recall 0.96, F1-score 0.94, Accuracy 0.95, specificity

0.93, sensitivity 0.98, and AUC 0.98 respectively. It is worth mentioning that, using too many resampling methods can lead to overfitting and inaccuracy. So, it may harm the model's outcomes.

Saber et al. 2020 [15] proposed a comparative approach to ML algorithms. The algorithms that are implemented in this research study are SVM with linear, polynomial, radial basis function kernels, LDA and QDA, and KNN. The author concludes that a genetic algorithm with SVM outperforms other approaches. It shows an accuracy of 96.23, a specificity of 86.67, and a sensitivity of 98.45. All algorithms compiled on 1593 drug compounds and eight molecular descriptors were generated by sequential feature selection and genetic algorithm. There is a lack of a greater number of features and training the model on fewer features has a great impact on the outcomes. Similar dataset dimension biases also happened in the study proposed by Ciura et al. 2020 [16]. The authors suggested a technique that focuses on micellar electrokinetic chromatography and has 50 2D and 3D molecular descriptors from a collection of market available 45 chemical drugs. MLR and SVM were implemented on a given dataset and showed the same results for prediction, by showing the same results of RMSE and cross-validation of 0.310 and 0.314 respectively. But if a large dataset and a greater number of features were applied this will affect the results as model accuracy directly depends on the size of the dataset.

Moreover, a study proposed by Singh et al. 2020 [17] comprised a novel validation approach of QSAR. In this approach, RF has been implemented on a 605 compounds dataset with 1444 molecular descriptors of 1D and 2D generated by PaDEL software 2.21. In the proposed methodology 10-fold cross-validation QSAR approach was used. Two types of thresholds were employed to divide the dataset. Specifically, threshold-1 was defined as (B/P>=0.6 classified as BBB+ and B/P<0.6 classified as BBB-), while threshold-2 was defined as (B/P>0.6 classified as BBB+ and B/P<0.3 classified as BBB-). Threshold-1 and threshold-2 attained precision of 86% and 87% accordingly. However, this study defined a specific range of thresholds to specify the classes of BBB and only focused on the QSAR approach may other techniques improved the results of the proposed model.

A few other researchers such as Radchenko et al. 2020 [18] implemented an artificial neural network on 529 molecular compounds datasets based on their LogBB values and 100 to 1000 descriptors were generated by using substructures of molecular compounds. The silico LogBB-based model used fragmental substructural descriptors representing the occurrence number of the various substructures. The results show that Q2 has a value of 0.815 and an RMSE of 0.318. However, this research work only concentrates on LogBB values of compounds with a small dataset of compounds. Saxena et al. 2019 [19] presented an ML model for permeability prediction of the BBB. In this study, SVM, KNN, RF, and NB were implemented in 1978 molecular compounds. Physicochemical characteristics, MACCS fingerprints, and substructure fingerprints were included in 1917 feature vectors. With an accuracy score of 96.77 percent, SVM with RBF kernel performs better as compared to other proposed ML techniques. However, the dataset used in this research study has a smaller number of chemical compounds which can affect the results. Roy et al. 2019 [20] proposed an approach SVM, KNN, gradient boost machine, and the statistical importance analysis method used to select 37 descriptors, and a generalized linear model was implemented on it. The results show that SVM surpasses other approaches with an accuracy of 96%, a sensitivity of 99%, a specificity of 87%, a precision of 96%, and an F1 score of 97% respectively. The dataset contains 1800 molecules and was divided into 75% training data and 25% testing data. Rui Miao et al. 2019 [21] proposed three clinical phenotypes data of 1000 molecular compounds were used. DL method, SVM with sigmoid, polynomial, radial basis kernel functions, KNN, and DT were implemented. The dataset was utilized for both training and testing with five-fold cross-validation. As 70 percent is used for training and 30 percent is used for testing. The author concludes that the deep learning method outperforms other ML algorithms in terms of area under curve, accuracy, and F1-score i.e., 98%, 97%, and 92% respectively. Saber et al. 2019 [22] implement SVM, ANN, and KNN models with 1593 drug compounds. For the selection of molecular features, a genetic algorithm was used which generated 8 descriptors. The highest overall accuracy was obtained with both Quadratic Discriminant Analysis and SVM classifiers at 96.23%. But this research study only focuses on ADMET characteristics of compounds, and it is not clear how well the system detects permeable compounds because of the small dataset.

By Analyzing the related work, it is observed that the above research have some drawbacks. First, most of the researchers target datasets having a smaller number of molecular compounds. Second, the number of features used in the research is too small, and vice versa.

III. Methods and Methodology

A. Algorithm for Proposed Study

The algorithm for the proposed study was given below which inputs the dataset and applies preprocessing techniques to the given dataset. After preprocessing the dataset is divided into 90% training and 10% testing purposes and for each molecular compound feature values were generated. By applying the ML models on preprocessed datasets if the molecular compound belongs to class BBB+ it would be updated to the permeable list and else the molecular compound belongs to class BBB- it would be updated to the non-permeable list. For validation of our model, we test it on a test dataset and evaluate these results by using an evaluation matrix.

    End If
```

B. Results of Flow Charts

The flow chart of the proposed methodology is discussed in Fig. 1. The dataset contains molecular compounds loaded for the filtration process. After filtration, the dataset was divided into 90% training and 10% testing. After the division of the dataset feature extraction process was applied in which 1D and 2D features were extracted for each compound. The most well-known ML models i.e., SVM, KNN, LR, ANN, and RF were applied to each chemical compound. ML models classify the dataset into two class labels i.e., BBB- (0) non-penetrating list and BBB+ (1) penetrating list. For evaluation and validation of results accuracy, specificity, sensitivity, precision, and recall, the F1-score is applied.

C. Data Collection

The datasets used in the proposed study were collected from the online repository of the LightBBB [23] web server which was in SMILES format [24]. In these datasets, the compounds were grouped as BBB+ which belongs to class 1, and BBB- which belongs to class 0. There are numerous descriptors available for expressing the BBB permeability chemicals. It's crucial to pick efficient descriptors for model training to prevent overfitting and poor performance. The training dataset included chemical compounds with 1D and 2D descriptors for each compound after dataset pre-processing.

D. Data Preprocessing

Preprocessing is an essential task for each ML model. To obtain effective results preprocessing is to be done on the dataset. The accuracy of the model is directly impacted by the size of the dataset. In this research study, molecular compounds were compiled with the experimental BBB permeability which leads to compounds belonging to the class of BBB+ and BBB-. A SMILES format was used to prepare each molecule. The BBB+ belonged to class 1 and BBB- belongs to class 0. The dataset was preprocessed to remove duplicates inconsistent compounds and missing structural information data were also removed. The dataset was split into 90% training and 10% testing using ten-fold cross-validation, with each iteration of validation being repeated ten times. For testing purposes, the external dataset contains molecular compounds of which some compounds belong to BBB+ and BBB- classes.

E. Feature Set

The physical and chemical characteristics of substances were described using molecular descriptors as features. As a result, these aspects provide more information to create a reliable BBB model [7].

F. Machine Learning Models

In recent decades, there has been a numerous growth in ML models and most of all have been used in the prediction of the BBB. Some BBB prediction models show good performance with a high accuracy score. Therefore, it was a challenging task to develop an ML model for the prediction of BBB permeability as the dataset of BBB available in biological science gives the impression of being limited [19]. ML approaches are classified as supervised, unsupervised, or reinforced. There are many supervised learning techniques some of them are; SVM, KNN, LR, ANN, and RF are mainly used for classification or regression problems and some deep learning-based algorithms are used for the prediction of BBB. Scikit-learn, a Python-based toolkit, were used in the implementation of the model.

1) Support Vector Machine (SVM): The support vector machine (SVM) is a widely recognized approach in supervised learning, commonly employed for solving classification and regression problems. The proposal was initially forth during the decade of the 1990s and has since been effectively utilized within the fields of bioinformatics and computer-aided diagnosis. Therefore, the SVM classification model was utilized in this research work to analyze the BBB dataset. The support vector classifier (SVC) is implemented using the support vector machines toolkit. The algorithm typically accommodates the supplied attributes' points of information and identifies the optimal hyperplane for classifying the data into two distinct categories [12]. The SVM model's effectiveness over traditional methods can be attributed to its inherent structure and the risk management philosophy it employs. Multiple kernel functions, such as polynomial, linear, radial basis function, and sigmoid, are utilized in Support Vector Machines (SVM) to facilitate the transformation of data into a higher-dimensional space where a distinct separation between classes can be achieved [20]. This research paper examines the performance of the Support Vector Machine (SVM) algorithm, specifically utilizing a linear kernel function, in the context of classification problems.

2) K-Nearest Neighbors (KNN): The k-nearest neighbor (KNN) approach is an example of supervised machine learning that may be applied to both classification and regression tasks. The technique, which was introduced in 1951, has gained significant popularity over the years as a reliable method for predicting drug penetration and blood-brain barrier (BBB) permeability. Unlabeled datasets are classed through the assignment of a class based on the similarity to neighboring data points. The K-nearest neighbors (KNN) algorithm computes the distances among the information points, namely the feature values, using metrics such as Euclidean distance or Manhattan distance. In the context where a desirable value of k is sought, it is necessary to evaluate multiple neighboring values. The decision to choose one of these neighbors has a significant influence on the general efficacy of the prediction system that is being constructed. Typically, the value of k is limited to an integer not exceeding 20 [19].

3) Logistic Regression (LR): Logistic regression is one of the most popular statistical models that uses a logistic function for binary dependent variables [14]. This algorithm comes under the tree of supervised machine techniques. LR is like linear regression as linear regression is used for regression problems and LR is used for solving classification problems.

4) Random Forest (RF): Random Forest (RF) is a machine-learning technique that is based on decision trees. The bootstrap resampling approach allows for the extraction of multiple samples from the original set of data. Following the choice of specimens, a prediction decision-making structure was constructed for each sample, which was subsequently aggregated through a voting mechanism to obtain the ultimate outcomes. Random Forest (RF) can be utilized to address both classification and regression problems. The primary advantage of the RF model is its ability to mitigate errors resulting from asymmetrical data during training, particularly when there is a substantial disparity between the two types of class compounds. Additionally, this model has superior performance in mitigating the overfitting phenomena, as well as exhibiting enhanced capability in effectively addressing outliers and noisy data [13].

5) Multi-Layer Perceptron (MLP): A multi-layer perceptron (MLP) refers to an artificial neural network characterized by a forward architecture, wherein it transforms a given set of input vectors into a corresponding set of output vectors. The MLP can be conceptualized as a directed graph including multiple tiers of nodes. The subsequent layer is interconnected with the preceding layer. Every node, except the input node, represents a neuron that possesses a non-linear activation function. [16].

6) Light Gradient Boosting Machine (LGBM): Gradient boosting decision trees are a popular machine learning algorithm that combines the strengths of decision trees and gradient boosting. This algorithm iteratively builds an ensemble of weak decision trees, where There are various manifestations of trees, one of which is LightGBM (GBDT). This technique is commonly employed for classification, regression, and efficient parallel training. The LightGBM algorithm is widely recognized as a rapid and efficient variation of the Gradient Boosting Decision Tree (GBDT) technique. The proposed approach involves partitioning the tree into individual leaves and thereafter identifying the leaf that exhibits the highest delta loss. Hence, under the LightGBM framework, the leaf-wise approach can minimize loss to a greater extent compared to the level-wise strategy when expanding on the identical leaf. [7]. The description of all the parameters applied to ML models is discussed below in Table I.

G. *Description of Datasets*

ML models are implemented on three BBB datasets. These datasets have two classes i.e., class 0 belongs to (BBB-) which specifies non-permeable compounds to BBB and class 1 belongs to (BBB+) permeable compounds to BBB. All the molecular compounds were in SMILES format. The datasets were randomly divided into 90% training and 10% testing data on which ML models were trained.

Dataset 1 contains 1072 (317 BBB+ and 755 BBB-) molecular compounds in SMILES format with a variety of 196 1D descriptors generated from RDKit library [25] which is a Python built-in library mainly used for molecular descriptors. The test dataset contains 266 molecular compounds with 196 1D descriptors that are extracted for each compound.

TABLE I. DESCRIPTION OF PARAMETERS FOR MACHINE LEARNING MODELS

Name	Value	Description
Kernel	Linear	Defines the type of kernel to be used in the algorithm
Random_state	None	Controls the creation of pseudo-random numbers used to shuffle the data used to calculate probabilities.
N_neigbors	7	The numbers of neighbours that k-neighbors queries will by default utilize.
Metric	Minkowski	Metric to employ for distance calculations that, when p = 2, yields the usual Euclidean distance.
P	2	Minkowski metric's power parameter
Solver	liblinear	The optimization problem's algorithm.
Random_state	None	Used when Solver = liblinear
Hidden_layer_sizes	(8, 8, 8)	The number of neurons in the ith hidden layer is represented by the ith element.
Activation	Relu	The buried layer rectified linear unit function's activation function gives the result f(x) = max (0, x)
Solver	Adam	A stochastic gradient-based optimizer is referred to in the solution for weight optimization.
Max_iter	2000	The maximum number of iterations.
n_estimator	100	It means how many numbers of trees can be generated.
Max_depth	None	The depth of trees.
Min_sample_split	2	The needed minimum number of samples
Random_state	42	It means how many times the function calls for the same instance.
Max_features	Sqrt	It means max_features= sqrt(n_features)

Dataset 2 contains 7162 (5453 BBB+ and 1709 BBB-) molecular compounds in SMILES format with 1119 1D and 2D descriptors that are extracted for each compound. The test dataset contains 74 (39 BBB+ and 35 BBB-) molecular compounds with 1119 1D and 2D descriptors that are extracted for each compound [23]. These features were generated using Dragon software (version 7.0.10) [26].

Dataset 3 was constructed by adding more chemical compounds in dataset 2 which contains 9230 (6852 BBB+ and 2378 BBB-) molecular compounds in SMILES format with 1119 1D and 2D descriptors that are extracted for each compound. The test dataset contains 74 (39 BBB+ and 35 BBB-) molecular compounds with 1119 1D and 2D descriptors that are extracted for each compound. These features were generated using Dragon software (version 7.0.10).

H. Evaluation Matrices

1) Confusion matrix: The utilization of the confusion matrix is frequently observed in machine learning to assess and illustrate the performance of algorithms in supervised classification tasks. The matrix in question is a square matrix whereby the rows correspond to the actual class and the columns correspond to the predicted class. The confusion matrix establishes a quantitative assessment of the concordance between observed and forecasted data.

2) Sensitivity: The sensitivity is defined as the percentage of chemical compounds that the model properly classifies as BBB+ [9] and it is calculated by the given formula as shown in Eq. (1).

$$Sensitivity = \frac{TP}{TP+FN} \times 100 \quad (1)$$

3) Specificity: The specificity is defined as the percentage of chemical compounds that the model properly classifies as BBB- [9] and it is calculated by the given formula as shown in Eq. (2).

$$Specificity = \frac{TN}{TN+FP} \times 100 \quad (2)$$

4) Accuracy: The accuracy shows the overall performance of the model [9] and it is calculated by the given formula as shown in Eq. (3).

$$Accuracy = \frac{TP+TN}{TP+TN+FP+FN} \times 100 \quad (3)$$

5) Receiving Operating Characteristics (ROC): The model was graphically evaluated using an ROC curve [27], which is a highly efficient approach for determining how well the model can accurately distinguish between classes [7].

6) AUC: The AUC is used to assess how well the classifier separates the classes by calculating the area under the ROC curve and its output will always be between 0 and 1 [9].

IV. Results and Discussion

Dataset 1 contains 1072 chemical compounds with 196 1D descriptors on which ML models were trained. The dataset was divided into 90% for training and 10% for testing with 10-fold cross-validation and 10 times iterated the whole process. The results are demonstrated below in Table II.

On cross-validation, the training dataset contains 964 chemical compounds whereas the testing dataset contains 108 chemical compounds. The results on Dataset 1 show that we achieved an overall accuracy of the RF of 93.52, an AUC of 0.97, a sensitivity of 95.95, and a specificity of 88.24 on 10-fold cross-validation. The higher AUC value indicates that our model has a high level of accuracy in predicting BBB permeability and is suitable for use in BBB prediction. In contrast with other ML models, the RF model outperforms other ML models as shown in Fig. 2. The results of ML models are demonstrated by using ROC Curve for cross-validation on dataset 1 as shown in Fig. 2.

For validation of the models, we test the ML models on an external dataset 1. Fig. 3 shows ROC curve of ML models for cross-validation of dataset 1. The RF model shows an accuracy of 78.38, an AUC of 0.83, a sensitivity of 94.29, and a specificity of 64.1. Comparing RF results with other ML models clearly shows that RF outperforms in the prediction of BBB permeability compounds.

The LightBBB dataset contains 7162 molecular compounds and was divided into 90% training and 10% testing. After the division of the dataset feature extraction process was applied. The LightBBB dataset contains 1119 1D and 2D descriptors extracted for each chemical compound. These descriptors were generated using Dragon software (version 7.0.10). The most well-known ML models i.e., the SVM, KNN, LR, ANN, and RF were applied to each chemical compound. ML models classify the dataset into two class labels i.e., BBB- (0) non-penetrating list and BBB+ (1) penetrating list. For evaluation and validation of results accuracy, specificity, sensitivity, precision, and recall, the F1-score has been computed. The results are demonstrated below in Table III.

TABLE II. Cross-Validation Results of ML Models on Dataset 1

Models	AUC	Specificity	Sensitivity	Accuracy
SVM	0.91	88.24	83.78	85.19
KNN	0.95	94.12	81.08	85.19
LR	0.91	85.29	85.14	85.19
MLP	0.91	76.47	79.73	78.07
LGBM	0.97	88.24	94.59	92.59
RF	0.97	88.24	95.95	93.52

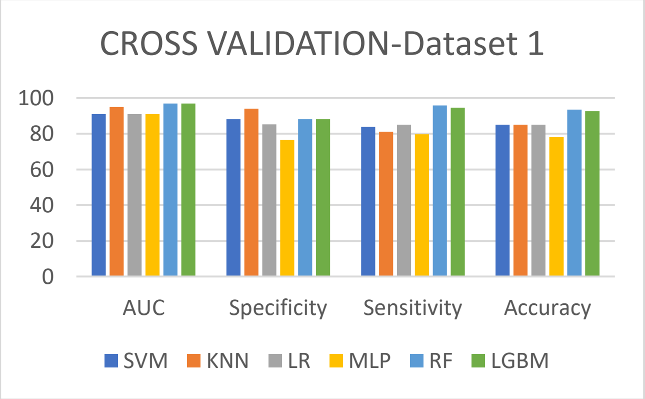

Fig. 2. Performance of ML models on cross validation dataset 1.

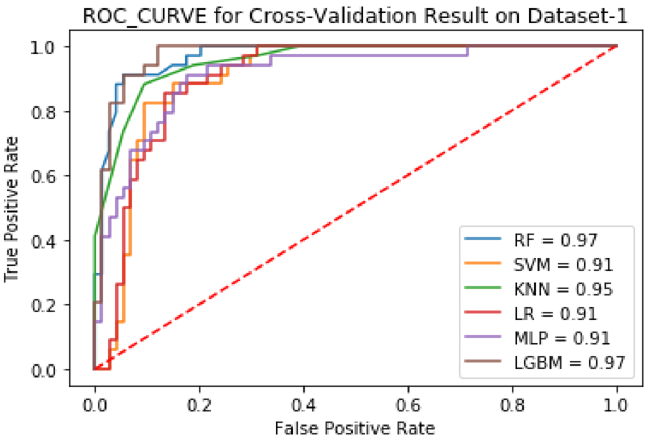

Fig. 3. ROC curves of ML models for cross validation on dataset 1.

TABLE III. CROSS-VALIDATION RESULTS OF ML MODELS ON DATASET 2

Models	AUC	Specificity	Sensitivity	Accuracy
SVM	0.90	93.49	73.78	88.98
KNN	0.92	96.02	62.8	88.42
LR	0.91	94.03	73.78	89.4
MLP	0.92	93.41	75.44	89.12
LGBM	0.94	0.77	0.93	89
RF	0.95	95.12	75.0	90.52

On cross-validation, the training dataset contains 6445 chemical compounds whereas the testing dataset contains 717 chemical compounds. The results on Dataset 2 show that we achieved an overall accuracy of the RF of 90.52, an AUC of 0.95, a sensitivity of 75.0, and a specificity of 95.12 on 10-fold cross-validation. The higher AUC value indicates that the RF model has a high level of accuracy in predicting BBB permeability and is suitable for use in BBB prediction. In contrast with other ML models, the RF model outperforms other ML models as shown in Fig. 4. The results of ML models are demonstrated by using the ROC Curve on cross-validation dataset 2 as shown in Fig. 5. For validation of the models, we test the ML models on an external dataset 2. The RF model shows an accuracy of 93.24, an AUC of 0.96, a sensitivity of 91.43, and a specificity of 94.87. Comparing RF results with other ML models clearly shows that RF outperforms in the prediction of BBB permeability compounds.

Dataset 3 contains 9230 molecular compounds and was divided into 90% training and 10% testing. After the division of the dataset feature extraction process was applied. The dataset contains 1119 1D and 2D features extracted for each chemical compound. The most well-known ML models i.e., the SVM, KNN, LR, ANN, and RF were applied to each chemical compound. ML models classify the dataset into two class labels. The results are demonstrated below in Table IV.

On cross-validation, the training dataset contains 8307 chemical compounds whereas the testing dataset contains 923 chemical compounds. The results on Dataset 3 show that we achieved an overall accuracy of the RF of 90.36, an AUC of 0.96, a sensitivity of 77.73, and a specificity of 94.74 on 10-fold cross-validation. In contrast with other ML models, the RF model outperforms other ML models as shown in Fig. 6. The results of ML models are demonstrated by using the ROC Curve on cross-validation dataset 3 as shown in Fig. 7. For validation of the models, we test the ML models on an external dataset 3. RF shows an accuracy of 91.89, an AUC of 0.94, a sensitivity of 91.43, and a specificity of 92.31. Comparing RF results with other ML models clearly shows that RF outperforms in the prediction of BBB permeability compounds.

While comparing our results with previously published BBB permeability prediction models it seems that our technique outperforms the existing methods. The uniqueness of our technique is the use of optimal hyperparameters and a high density of data. We compared the models by considering all the evaluation parameters i.e., AUC, specificity, sensitivity, and accuracy as shown in Table V.

V. CONCLUSION

In the proposed study five machine learning models were applied to highly accurate small and large datasets with a larger number of features. The dataset is balanced and free from inconsistent and redundant data with accurate class labeling. On the contrary, other ML models were trained on a smaller dataset and fewer features, leading to differing accuracy levels but being unable to compensate for the variety of molecular components. The model uses 10-fold cross-validation with 10 iterations to assure correctness. The dataset contains molecular compounds and features. It was concluded that our ML model RF for the prediction of BBB penetration shows more accurate results on both small and large datasets than other ML algorithms.

The higher accuracy achieved by RF on dataset 1 is 93.52, with an AUC of 0.97, a sensitivity of 95.95, and a specificity of 88.24 on 10-fold cross-validation.

The higher accuracy achieved by RF on dataset 2 is 90.52, with an AUC of 0.95, a sensitivity of 75.0, and a specificity of 95.12 on 10-fold cross-validation. On testing our model on an external dataset RF shows an accuracy of 93.24, an AUC of 0.96, a sensitivity of 91.43, and a specificity of 94.87.

The higher accuracy achieved by RF on dataset 3 is 90.36, with an AUC of 0.96, a sensitivity of 77.73, and a specificity of 94.74 on 10-fold cross-validation. On testing our model on an external dataset RF shows an accuracy of 91.89, an AUC of 0.94, a sensitivity of 91.43, and a specificity of 92.31. The greater the value of AUC, the higher the accuracy of the model will be. Our model outperforms previously reported models.

VI. FUTURE WORK

To encourage future study, it may focus on the features of BBB datasets which can also be increased. It may also focus on applying feature extraction techniques for finding the most important features that were highly influential to the prediction compounds and how these models can be applied to treatments of the brain. Moreover, it may also focus on applying DL models to large datasets and comparing their outcomes with other ML models. Future work may intend to combine two techniques i.e., swarm algorithms with RF to obtain more precise results for this problem.

Abstract—**Atrial Fibrillation (AF), a prevalent anomaly in cardiac rhythm, significantly impacts a substantial portion of the population, with projections indicating an escalation in its prevalence in the near future. This disorder manifests as irregular and accelerated heartbeats originating within the heart's upper chambers known as the atria. Neglecting to address this condition could potentially lead to serious consequences, particularly an elevated susceptibility to stroke and heart failure. This underscores the critical importance of developing an automated approach for detecting AF. In our study, an automatic approach was introduced for classifying short single-lead Electrocardiogram (ECG) recordings signals into four categories: Atrial fibrillation (AF), Normal rhythm (N), Noisy rhythm (~), or Other rhythms (O). The wavelet scattering network (WSN) is employed to extract morphological features from the ECG signals, which are then inputted into an Artificial Neural Network (ANN) with time windows selection and majority vote. The results from the testing data exhibit that our proposed model outperforms the state-of-art models, achieving a remarkable overall accuracy of 87.35% and an F1 score of 89.13%.**

Keywords—Electrocardiogram (ECG); Atrial Fibrillation (AF); Wavelet Scattering Network (WSN); Artificial Neural Network (ANN)

I. Introduction

The ECG is a recording of electrical potential differences on the body surface that result from the electrical activity in the heart [1]. An ECG is produced when a nerve impulse stimulates the heart, causing a current to spread across the body's surface. This current creates a voltage drop ranging from a few microvolts to millivolts, accompanied by variations in the impulse. Typically, these impulses have very low amplitude, necessitating thousands of times of amplification [2]. The ECG is typically a voltmeter that uses up to 12 different leads (electrodes) placed on designated areas of the body [3].

Because of its straightforwardness and non-intrusive characteristics, the ECG has been extensively utilized in the identification of heart diseases [4]. The detection of heart diseases typically involves the analysis of ECG signals, which unveil irregularities commonly known as arrhythmias. These manifestations signify deviations from a regular heart rhythm, potentially causing irregular or abnormal heartbeats, often experienced as palpitations. Arrhythmias are broadly categorized into two main types: ventricular and supraventricular. Atrial Fibrillation (AF), a prevalent condition, falls under the category of supraventricular arrhythmias due to its origination within the heart's upper chambers, the atria. In contrast, ventricular arrhythmias arise from the heart's lower chambers or ventricles. Understanding this differentiation is crucial for accurately identifying and subsequently treating various forms of arrhythmias. This distinction aids medical professionals in precisely classifying the type of arrhythmia observed in a patient, paving the way for more targeted and effective treatment strategies.

Early identification plays a pivotal role in addressing heart arrhythmias, potentially offering significant opportunities to save lives. Utilizing the ECG as a primary diagnostic tool becomes essential in achieving this imperative objective [5]. Nevertheless, the manual interpretation of prolonged ECG recordings introduces a multitude of escalating challenges. As these recordings extend in duration, the intricacies grow, rendering the process more time-consuming, intricate, and arduous. The exhaustive review demanded by these extended recordings not only prolongs the analysis but also heightens the complexity of the interpretation process, making it more challenging [6]. In response to these challenges, cardiologists turn to automated diagnostic algorithms, which streamline the analysis of extensive ECG data [7]. This incorporation of automated methodologies proves to be an invaluable solution, offering a streamlined approach to overcome the hurdles associated with manual interpretation. Consequently, the utilization of these automated tools not only enhances efficiency but significantly improves the precision and management of prolonged ECG recordings. Numerous research initiatives have concentrated on employing classical machine learning models to identify arrhythmias within ECG signals. These models have shown efficacy in analyzing both short-term and long-term ECG readings, primarily focusing on the scrutiny of individual heartbeats within the signal [8-9]. Nevertheless, these models require feature engineering and domain expertise, introducing aspects that are time-consuming and demanding. To address these challenges, deep learning models like Convolutional Neural Networks (CNN) and Long Short-Term Neural Networks have emerged, showcasing impressive performance in detecting arrhythmias [10-11].

AF is the prevailing prolonged cardiac irregularity, found in around 1-2% of the overall population [12-13]. This condition carries notable implications for both mortality and morbidity due to its strong links with various health risks. Individuals with AF face an increased likelihood of experiencing severe outcomes, including stroke, hospitalization, heart failure, and coronary artery disease. The association of AF with these risks underscores its profound impact on cardiovascular health [13-14]. AF's connection to an elevated risk of death further underscores its significance. The irregular heartbeat pattern in AF can lead to blood clots forming within the atria, which might subsequently travel to the brain, causing a stroke. Additionally, the erratic heart rhythm can strain the heart's function over time, potentially culminating in heart failure.

AF impacts more than 12 million people in Europe and North America, and this number is expected to triple in the next 30-50 years. This escalating prevalence underscores the need for increased efforts in diagnosis, treatment, and management to address the growing public health challenge [15]. More notably, AF becomes more common as individuals age. For those between 40-50 years old, the incidence is under 0.5%, while among those 80 and older, it ranges from 5-15%. This age-related rise in AF highlights the need for targeted monitoring and interventions to address the growing risk in the elderly [16]. Recognizing this trend, a multitude of research works and papers have emerged, aiming to develop automatic models utilizing Machine Learning (ML) techniques and Deep Learning (DL) [17]. These endeavors aim to facilitate the diagnosis and early detection of AF, potentially saving the lives of millions across the globe.

In the following sections of this paper, related works were explored, specifically focusing on Automated AF systems from previous endeavors in Section II. Subsequently, our materials and methods cover a data description, data preprocessing, and the features extraction method in Section III. A detailed account was presented to explain the classification model used and the evaluation metrics applied. Further Section IV encompasses the results, where our findings were analyzed and described. The discussion section follows, where our results were compared with existing automated AF detection models. Lastly, the conclusion summarizes our findings, outlines limitations, and suggests avenues for future research in Section V.

II. Related Works

In this paper, a comparison was conducted with state-of-art models designed for AF detection. Notably, Garcia et al. [18] introduced a method that utilizes surface ECG data, capturing variability in ventricular and atrial activities. The approach involves generating time series data from R_R intervals and morphological features of fibrillatory waves in T_Q intervals. The regularity of these time series is quantified using the Coefficient of Sample Entropy (COSEn), and a multi-class Support Vector Machine (SVM) distinguishes between AF, N and O. Their algorithm underwent validation in the PhysioNet Computing in Cardiology Challenge 2017.

Rajpurkar et al. [19] introduced an algorithm surpassing board-certified cardiologist’s proficiency, exhibiting exceptional accuracy in detecting a wide range of heart arrhythmias. The algorithm excels by applying to single-lead wearable monitor electrocardiograms. A sophisticated 34-layer CNN is crucial in mapping ECG sequences to rhythm classes. The study includes a gold standard test set annotated by board-certified cardiologists, serving as a benchmark where the algorithm outperforms individual cardiologists in both recall and precision.

Coppola et al. [20] introduced a data-driven model for automated AF detection from a single ECG lead. The model incorporates features such as heart rate variability, spectral power analysis, and statistical modeling to capture atrial activity nuances. Employing an over-sampling strategy for dataset balance, they crafted a hierarchical classification model predicting ECG signals into AF, N, noise interference or O. Their approach includes a hierarchical bagged ensemble classifier, achieving an average F1 score of 0.7855%.

Makinckas et al. [21] introduced a paradigm utilizing a Long Short Term Memory (LSTM) network, a neural architecture efficiently learning patterns from pre-computed QRS complex features for ECG signal classification. Despite its classification as a deep neural network, their architecture, with a mere 1791 parameters, achieves a remarkable balance between complexity and efficiency. The crux of their methodology lies in the LSTM network's unique ability to comprehend patterns in QRS complex features, facilitating accurate categorization of diverse ECG signals. Their LSTM based model demonstrated effectiveness with a commendable final challenge F1 score of 78% across N, AF, O and ~.

Schwab et al. [22] utilized a richly annotated dataset of 12,186 single-lead ECG recordings. Their approach involved constructing a diverse ensemble of Recurrent Neural Networks (RNN) proficient in discerning differences among N, AF, O, and ~. To enhance temporal learning, they introduced a novel task formulation leveraging ECG signal segmentation into heartbeats, reducing time steps per sequence significantly. Incorporating an attention mechanism further augmented their RNN, enabling the model to focus on specific heartbeats for decision-making. With attention mechanisms, their model achieved an average F1 score of 79%.

Andreotti et al. [23] classified ECG segments into AF, N, O and ~. They conducted a comparative analysis, pitting a feature based classifier against a CNN. Both were meticulously trained on challenge data and augmented with Physionet database. The feature based classifier achieved a 72.0% F1 score during training and 79% on the hidden test set. Meanwhile, the CNN scored 72.1% on the augmented database and 83% on the test set, resulting in a final score of 79%.

Jiménez-Serrano et al. [24] integrated a Feedforward Neural Network (FFNN) for classifying short single-lead ECG segments into N, AF, O and ~. Extracting 72 features from ventricular activity in 8528 ECG records, they conducted a meticulous Feature Selection (FS) process and a detailed grid search for FFNN training parameters. Filtering down to 50 features during FS improved the initial F1 score from 70% to 73%. The FFNN model achieved a final F1 score of 77 %on test data, demonstrating its efficacy in discriminating ECG patterns.

Pandey et al. [25] analyzed ECG data from PhysioNet/CinC Challenge 2017, aiming to differentiate cardiac rhythms, particularly AF, N, O and ~. Their approach combined traditional machine learning with deep neural networks, integrating a Residual Network (ResNet), CNN, Bidirectional LSTM (BiLSTM), and Radial Basis Function (RBF) neural network. The hybrid model achieved an F1 score of 80% and an accuracy of 85% in discerning AF rhythms within the ECG data.

Clifford et al. [26] utilized PhysioNet/CinC Challenge 2017 to distinguish AF from ~, N, or O in short-term ECG recordings. The extensive dataset included 12,186 ECGs, with 8,528 in the public training set and 3,658 in the hidden test set. Utilizing a combination of 45 algorithms, incorporating the LASSO technique, they achieved an F1 score of 86%.

While numerous related works have attempted to detect AF through diverse techniques, including ML, DL, and hybrid models, the prediction accuracy remains notably low. The highest F1 score, achieved by Clifford et al. [26] was 86%, underscores the significance of developing a new approach to enhance the accuracy of AF detection.

III. Materials and Methods

A. Database Description

The research utilizes a publicly available database accessible through this link (https://archive.physionet.org/pn3/challenge/2017/).

This database comprises 8,528 ECG recordings, which were made available as a public training set for utilization in the 2017 PhysioNet/Computing in cardiology challenge, Table I show the distribution of each class label of the dataset [27]. These recordings were captured using an AliveCor handheld device, which automatically uploads the recordings via a mobile phone application. The dataset includes both these recordings and an additional 3,658 recordings retained as a concealed test set. AliveCor provided these recordings for the Challenge. Each ECG recording was sampled at 300 Hz and underwent band-pass filtration through the AliveCor device.

TABLE I. Class Labels Distribution

Class Label	No. Instances
N	5050
AF	738
O	2456
~	284

B. Data Preprocessing

The challenge's dataset draws from a particular database. To ensure a fair basis for comparison with earlier studies that utilized a 20-second interval, each ECG recording was divided into segments. This approach was adopted to establish a uniform time window for analysis, in accordance with previous research practices. Furthermore, the dataset exhibited an imbalance, which could pose training challenges leading to inaccurate classification outcomes. To address this, the Synthetic Minority Over Sampling Technique (SMOTE) was employed [28]. SMOTE generates synthetic instances of the minority class to rebalance the data and enhance classification performance.

Following the application of the SMOTE technique on the 8,528 ECG recordings with segmentations, our dataset was transformed, resulting in 18829 ECG segments. The successful application of SMOTE effectively balanced the class distribution. This balance is pivotal, as it enables the model to achieve precise classification outcomes and effectively differentiate among the four distinct classes. As a consequence of this enhanced discriminatory capacity, our approach will yield elevated accuracy and F1 score results.

In Fig. 1, an ECG segment depicting AF is observed. Notably, the absence of a consistent sinus rhythm is evident through variable R_R intervals. Additionally, the ECG waveform reflects the absence of certain P waves, confirming the presence of AF.

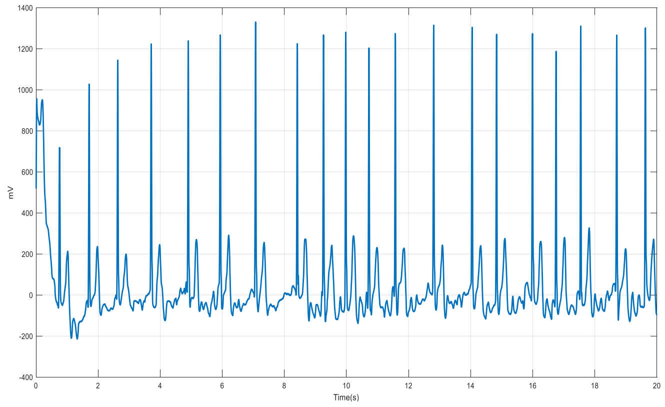

Fig. 1. ECG with atrial fibrillation.

Fig. 2 displays an ECG segment with a normal rhythm. The fixed R_R interval and the presence of all waves and complexes in the ECG waveform are noticeable, indicating the normalcy of the ECG segment.

Fig. 3 reveals an ECG segment with a variable R_R interval, signifying that the ECG segments cannot be classified as N. Notably, the presence of P waves in each ECG heartbeat suggests a deviation from AF. Instead, this ECG segment is categorized as another rhythm.

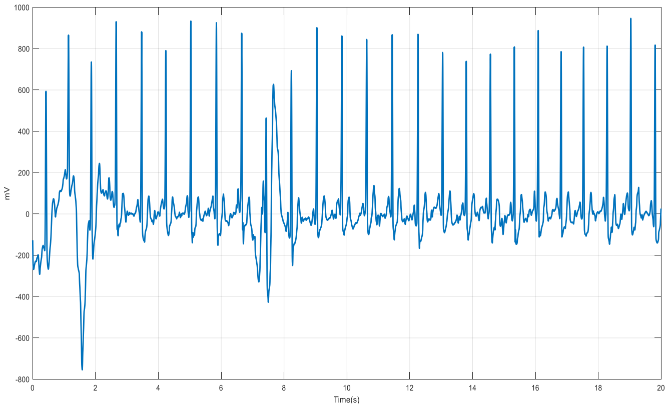

Fig. 2. ECG with normal rhythm.

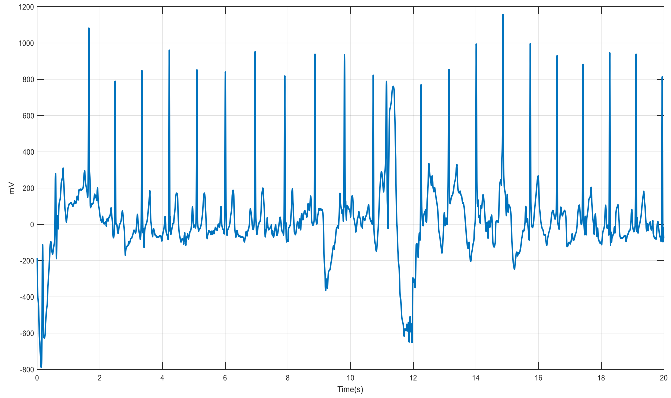

Fig. 3. ECG with other rhythm.

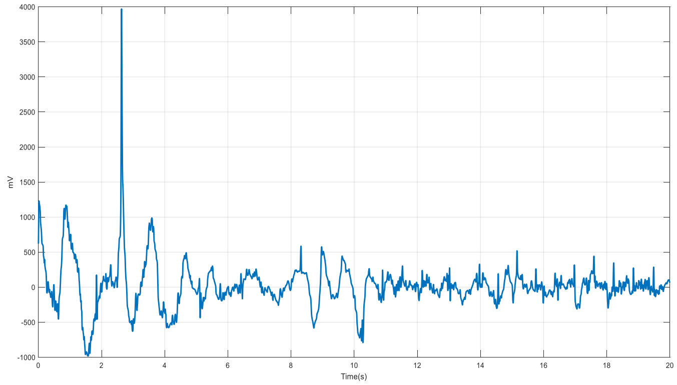

Fig. 4. ECG with noise.

Fig. 4 highlights the absence of identifiable waves or complexes in the ECG segment waveform, indicating that this ECG segment is noisy.

After addressing the imbalance in the dataset through the application of SMOTE, the data was divided into two distinct parts, employing an 80-20% split ratio. This division was carried out with a stratified approach, ensuring that each class label was proportionally represented in both the training and testing sets. Specifically, 80% of the data from each class was allocated to the training set, while the remaining 20% was set aside for testing purposes, which results in a total of 3764 ECG segments for testing and 15065 ECG segments for training. To further enhance the robustness of the model, the training set, constituting 80% of the data, underwent an evaluation process using a five-fold cross-validation technique. This technique involved partitioning the training data into five subsets, training the model on four of these subsets while using the 5th for validation, and then rotating the subsets iteratively. This meticulous combination of techniques facilitated the creation of a well-generalized model capable of effectively addressing the initial data imbalance and yielding reliable performance results.

C. Features Extraction

In this paper, the potential of the WSN was harnessed to meticulously extract an array of intricate morphological characteristics from ECG segments. The wavelet scattering approach is a distinguished member of the deep convolution network family crafted for signal processing, that serve as the linchpin for capturing multifaceted information.

What sets the wavelet scattering method apart is its unique capacity to seamlessly navigate through both the time and frequency domains of signals. By employing wavelets as the foundational building blocks, the network inherently grasps both the rapid fluctuations occurring in short time spans and the nuanced oscillatory patterns occurring over varied frequency ranges. The WSN provides features with translation and rotation invariance, making it suitable for image and audio analysis [29]. It offers stable features for denoising and enables dimensionality reduction for enhanced accuracy.

In this paper, the WSN with Gabor wavelets is utilized due to their morphological similarity to the QRS complex, making them suitable for extracting features from ECG segments [30]. The definition of a Gabor wavelet in Eq. (1) involves the multiplication of a Gaussian function by a complex exponential function. Fig. 5 shows the Gabor wavelet used with its real part, imaginary part, and its low pass filter.

$$\psi(t) = \frac{1}{\sqrt{2\pi\sigma^2}} e^{\frac{-t^2}{2\sigma^2}} e^{i\omega t} \tag{1}$$

where, t denotes time, σ represents the standard deviation of the Gaussian function. ω=2πf, where f is the center frequency of ψ and i is the imaginary unit. The Gabor complex wavelet's envelope is a low-pass filter, noted as Φ in Eq. (2).

$$\Phi(t) = |\psi(t)| \tag{2}$$

The scattering network is consisting of three stages as shown in Fig. 6. In the WSN: the 0th order S0, the signal with a low-pass filter Φ was convolved to analyze the slow variations and amplitude in the signal, and provide good time resolution but poor frequency resolution. Moving to the 1st order S_1, a specific-scale wavelet is employed to scrutinize high-frequency components within the ECG segments. And, the 2nd order S2 was proceed to further extract complementary high-frequency components from the analyzed signal. This process enhances our understanding of ECG characteristics.

$$S_0 x(t) = x(t) * \Phi \tag{3}$$

$$S_1 x(t) = |x * \psi_{\sigma_1}| * \Phi \tag{4}$$

$$S_2 x(t) = ||x * \psi_{\sigma_1}| * \psi_{\sigma_2}| * \Phi \tag{5}$$

$$Sx(t) = \{S_0, S_1, \dots, S_n\} \tag{6}$$

After applying the WSN with an invariance scale of 10 seconds and utilizing Q_1=8 and Q_2=1 as the quality factors for the 2 filter banks, a tensor of size 12x205 was obtained for each ECG segment. Fig. 7 shows the frequency bands of first and second filter banks.

In this tensor, columns correspond to the scattering paths within the network, while rows represent time windows. This showcases the WSN's capability to achieve a 59% dimensionality reduction.

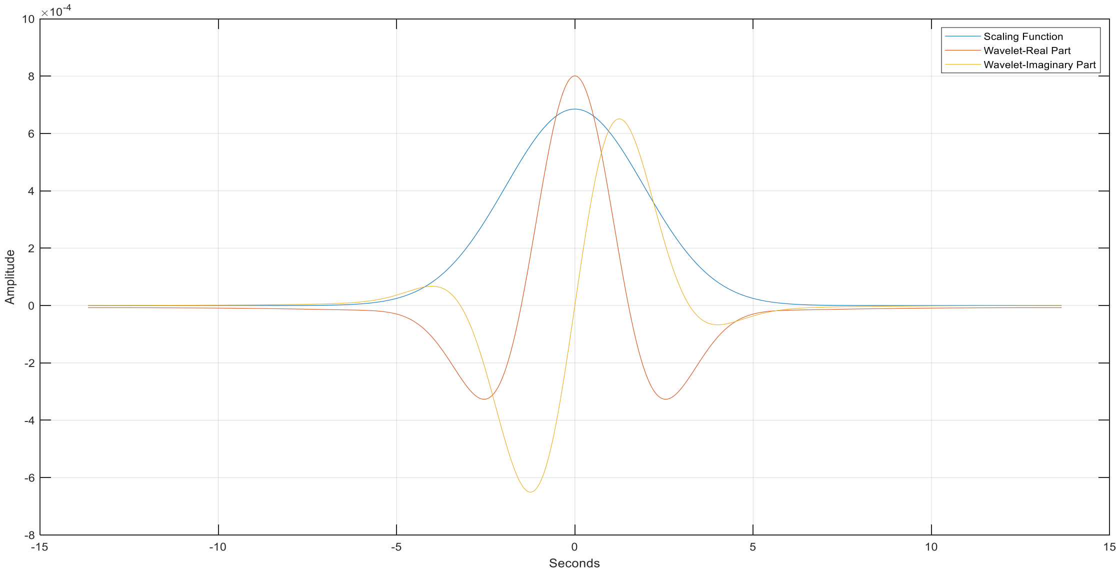

Fig. 5. Gabor complex wavelet.

$||x * \psi_3| * \psi_3| * \phi$
Scattering coefficients

Fig. 6. Scattering network.

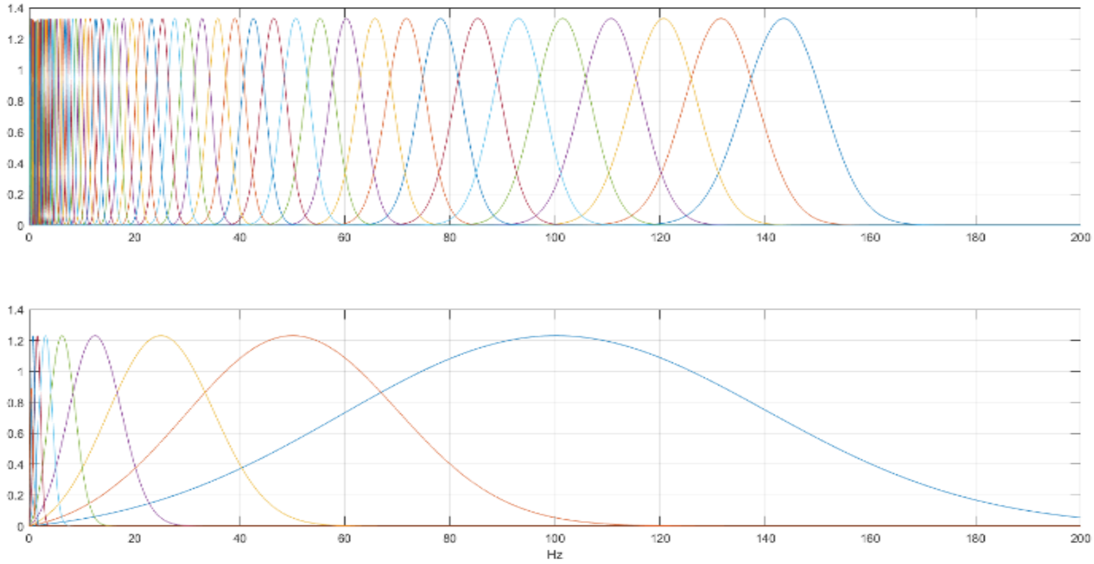

Fig. 7. Frequency band of the first and the second filter bank.

Consequently, the training dataset becomes 15065x12x205, and the testing dataset becomes 3764x12x205 in tensor dimensions. Subsequently, reshaping the training and testing datasets into an appropriate format for classifiers result in feature matrices of size 180780x205 and 45168x205 for training and testing, respectively.

The scalogram coefficients depicted in Fig. 8 showcase the outcomes of convolving the AF in ECG segment, as depicted in Fig. 1, with the real and imaginary components of Gabor wavelets within the initial filter bank.

This visual representation is exceptional in its ability to delineate the various frequencies present within the signal while associating each frequency with its respective temporal occurrence.

Moreover, the convolution process with these filters allows for the computation of similarity between the signal and the wavelets. These features are instrumental in providing insights into the amplitudes and frequencies within the signal, which in turn play a crucial role in accurately predicting atrial fibrillation.

The preceding WSN was implemented in the MATLAB environment, with an invariance scale set to 10 seconds and a sampling frequency of 300 Hz utilized.

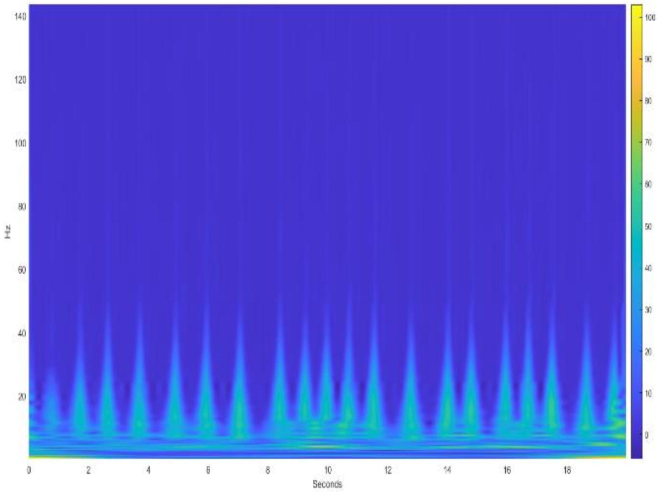

Fig. 8. Scalogram coefficients for the first filter bank.

D. Classification Model

In our study, an ANN was constructed with a single hidden layer containing 200 neurons. The goal was to effectively differentiate among classes A, N, O, and ~. The ReLU was used as activation function layer and Softmax as output activation layer. To enhance the model's performance, the Limited-memory-Broyden–Fletcher–Goldfarb–Shanno (LBFGS) solver was adopted, setting the maximum number of iterations to 1000. Throughout our analysis, we focused on refining the accuracy and efficacy of our approach.

The first hidden layer equation for each neuron j can be described as follows:

$$Z_j = \sum_{i=1}^{n} W_{ij}\, X_i + \; b_j \tag{7}$$

$$a_j = \max(0, Z_j) \tag{8}$$

where, n is the number of input features, W_{ij} is the weight between input features i and hidden neuron j, b_j is the bias term of hidden neurone j, and a_j is the output of neuron j after applying the ReLU activation function.

For each class c of the output layer:

$$Z_c = \sum_{j=1}^{200} W_{jc}\, a_j + \; b_c \tag{9}$$

$$Y_c = \frac{e^{Z_c}}{\sum_{k=1}^{4} e^{Z_K}} \tag{10}$$

where, Y_c is the predicted probability for class c after applying the Softmax activation function.

The ANN was constructed within the MATLAB environment, with initial weights determined using the 'glorot' method and initial biases set to zeros. The maximum number of iterations was set at 1000, and the gradient tolerance was established as 10^{-6}. The lambda parameter remained fixed at 0.

E. Evaluation Metrics

Our classifier model's performance was evaluated using metrics like accuracy, precision, recall, specificity, and the F1 score. Accuracy measures correct classifications, precision gauges accurate positive predictions, recall assesses positive instances captured, specificity measures accurate negative predictions, and the F1 score balances precision and recall.

Accuracy: It evaluates the ratio of accurate forecasts generated by the model among all the predictions it makes.

$$\text{Accuracy} = \frac{\text{TP+TN}}{\text{TP+TN+FP+FN}} \tag{11}$$

Precision: It evaluates how well the model correctly identifies positive cases, indicating the ratio of true positives to all positive predictions.

$$\text{Precision or PPV} = \frac{\text{TP}}{\text{TP+FP}} \tag{12}$$

Sensitivity: It measures the percentage of real positive instances accurately detected by the model and also referred as recall or the true positive rate.

$$\text{Recall or Sensitivity} = \frac{\text{TP}}{\text{TP+FN}} \tag{13}$$

Specificity: It evaluates the model's capability to correctly recognize negative cases through the measurement of true negative prediction’s proportion.

$$\text{Specificity} = \frac{\text{TN}}{\text{TN+FP}} \tag{14}$$

F1 Score: It calculates a balanced evaluation of the model's performance by taking the harmonic mean of both precision and recall, merging them into a single metric.

$$\text{F1 score} = \frac{2*\text{precision}*\text{sensitivity}}{\text{precision+sensitivity}} \tag{15}$$

F. System Description

The implementation of all algorithms was carried out using MATLAB version R-2021b on a Windows server. The system employed for execution featured an Intel (R), Core (TM), i5, CPU 6300U, processor clocked at 2.40 GHz, with a 12 GB RAM capacity and operating on a 64 bits architecture.

IV. Results and Discussion

A. Results

The objective of our paper was to classify ECG signals into four classes: AF, N, O, and ~. Numerous ML models were tested to assess their effectiveness in distinguishing these classes. Our findings, as indicated in Table II, revealed that an ANN with a single hidden layer and a size of 100 neurons yielded the best classification results. This architecture achieved an accuracy of 87.2% on the validation data and 81.1% on the testing data.

Interestingly, our observations also highlighted that increasing the size of the first hidden layer led to improved accuracy in both training and testing data. To delve deeper into this phenomenon, the impact of various hidden layer sizes was examined on classification outcomes. The results, depicted in Fig. 9, confirmed that accuracy consistently improved with larger layer sizes. However, it's important to note that excessively increasing the layer size can result in heightened computational costs and reduced prediction speed. Therefore, the layer size was adjusted at 200 neurons, which balanced accuracy and computational efficiency. With this configuration, a remarkable accuracy rates were achieved: 90.35% on the validation data and 82.10% on the testing data.

Upon applying the WSN to each ECG signal, a tensor of dimensions 12x205 was obtained. After reshaping the data for training and testing, an ANN was employed with a hidden layer size of 200. The ANN produced 12 results corresponding to different time windows. Consequently, each time window exhibited distinct validation and testing accuracies.

In Fig. 10, the impact of these time windows on validation and testing accuracy was analyzed. The results revealed that the 5th time window yielded the highest classification performance, achieving 91.85% accuracy on validation data and 83.95% accuracy on testing data.

This proposed approach, known as Time Window Selection showcased a noteworthy enhancement in accuracy. Validation accuracy improved from 90.35% to 91.85%, while testing accuracy saw an increase from 82.10% to 83.95%.

Enhancing the testing accuracy is achievable through the strategic selection of optimal time windows for classification, followed by applying a majority vote approach. Fig. 10 illustrates that starting from the 3rd time window, there is a noticeable improvement in validation accuracy.

To harness this insight, the results from the ANN with a 200-layer size across 12-time windows were utilized, focusing on the 3rd through the 10th time windows, which displayed superior validation accuracy. Employing a majority vote technique on these eight selected time windows, we observed a significant enhancement in testing accuracy and F1 score.

TABLE II. Performance Comparaison of Different Machine Learning Models

Models / Accuracy	Decision Tree	Narrow Neural Network layer size: 10	Medium Neural Network layer size: 25	Wide Neural Network layer size: 100	Bilayered Neural Network First layer size: 10 Second layer size: 10
Validation Data %	61.8	75.2	80.2	87.2	75.8
Testing Data %	62.1	74.4	78.0	81.1	72.1

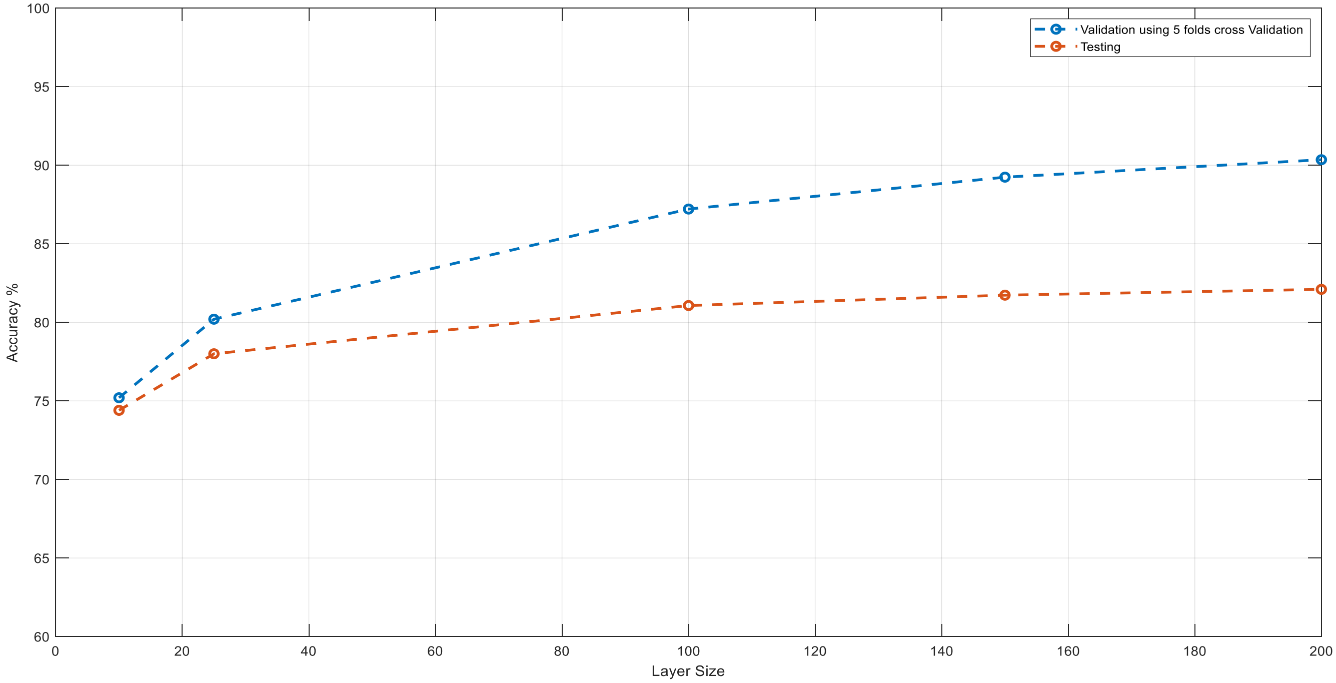

Fig. 9. ANN layer and its impact on validation and testing accuracy.

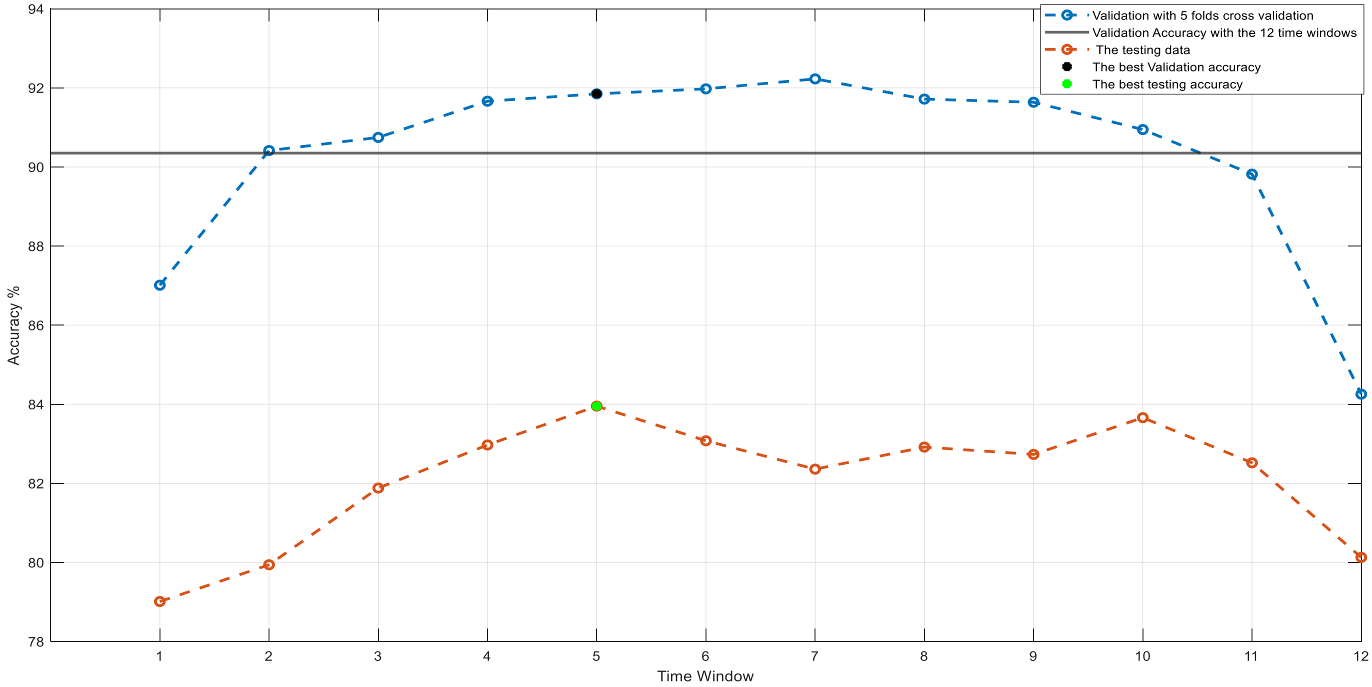

Fig. 10. Time windows impact on validation and testing accuracies.

TABLE III. TESTING RESULTS USING WSN + ANN + TIME WINDOWS SELECTION + MAJORITY VOTE

Class Name	Precision %	Recall %	Specificity %	F1 score %
AF	89.05	93.23	98.11	91.09
N	85.19	89.37	89.86	87.23
O	84.19	76.73	93.48	80.29
~	97.40	98.43	99.53	97.91
Average	88.96	89.44	95.24	89.13

TABLE IV. SUMMERIZED RESULTS ON THE VALIDATION AND THE TESTING DATASETS

	Methodology	**Accuracy %**	**F1 score %**
5 Folds Cross Validation on the Training Dataset	***WSN + ANN with 12 Time window***	90.35	91.53
	WSN + ANN + 5th Time window	91.85	93.02
Testing Dataset	***WSN + ANN with 12 Time window***	82.10	84.22
	WSN + ANN + 5th Time window	83.95	85.94
	WSN + ANN + Time Windows selection + Majority Vote	87.35	89.13

This approach led to a testing accuracy of 87.35% and an F1 score of 89.13%.

Detailed testing results are available in Table III, while Table IV provides a concise summary of the outcomes obtained through various methodologies.

Fig. 11 displays the various steps outlined in this paper for classifying ECG signals as N, AF, ~, or O.

B. Discussion

In this study, we compared the outcomes produced by our classification method with those of previously established state-of-the-art models. Our model, which combines WSN, ANN, Time window, and Majority vote technique, achieves the highest overall accuracy. When contrasted with the findings of Pandey et al. [18], as presented in Table V, our model outperforms the state of art models in term of accuracy.

A comparative analysis of our results with those of other studies was conducted, specifically focusing on the F1 score.

The highest F1 score, 89.13%, was attained in our paper. Nonetheless, as shown in Table VI, it remains evident that our proposed methodology surpasses the performance of preceding works in terms of F1 score.

An extensive examination of the model's complexity was conducted, encompassing the neuron count in the ANN and the overall count of learnable parameters. Additionally, the time taken for feature extraction from a single ECG segment, quantified at approximately 67.3 milliseconds as displayed in Table VII. The predictive speed of our ANN successfully attains a rate of 22,584 ECG segments per second, showcasing a remarkably high prediction speed for detecting atrial fibrillation within ECG segments.

Prediction Speed of ANN	22584 ECG segment/s
Training Time	240.7 minutes

V. CONCLUSION

In our research, an innovative approach for the automated classification of ECG signals and the detection of atrial fibrillation was presented.

Our technique leverages a combination of WSN with ANN, Time Windows Selection, and Majority Vote to yield promising results when compared to prior studies, achieving an accuracy of 87.35%, a precision of 88.96%, a recall of 89.44%, a specificity of 95.24%, and an F1 score of 89.13%.

Although, our proposed approach has shown a good performance, it still has some limitations. Firstly, the ANN performance was dependent on the accuracy and reliability of the features derived from the raw ECG data before being inputted. Secondly, the current method is challenged by a significant computational burden due to the feature extraction process.

In forthcoming work, we intend to explore a technique that mitigate the computational costs associated with our proposed model

To addressing these identified constraints, future endeavors will focus on enhancing the proposed model through the application of dimensionality reduction techniques utilizing machine learning. This enhancement aims to streamline the feature space, thereby lowering the computational load in the classification process without compromising the ANN efficacy.

Abstract*—In response to ongoing concerns about road accidents linked to overspeeding and drunk driving, this study introduces a groundbreaking solution: The Integrated Driver Safety system. It is a comprehensive vehicle safety system designed for real-time prevention. Crafted with cutting-edge components including ESP32, MQ3 sensor, relay, and GPS, this system operates on a dual framework. It swiftly detects instances of over speeding, triggering immediate email alerts, while concurrently inhibiting engine ignition upon detecting alcohol consumption, actively thwarting drunk driving attempts. This proactive approach not only provides real-time notifications but physically prevents intoxicated driving, drastically reducing accidents caused by these factors. With an impressive overspeed detection accuracy surpassing 95% and an efficient alcohol monitoring system, this technology cultivates responsible driving habits. Its potential widespread adoption foretells a future where road safety reaches unprecedented levels, underscoring the industry's dedication to innovation and safer driving experiences. Through this research, a compelling case emerges for the global embrace of these innovative preventive measures, illuminating a path toward significantly enhanced road safety standards.

Keywords*—Integrated driver safety; overspeed detection system; alcohol monitoring technology; comprehensive vehicle security; real-time accident prevention; ESP32 GPS safety; responsible driving solutions

I. Introduction

In the global landscape, road safety remains a paramount concern, with traffic accidents claiming millions of lives annually. The alarming rise in traffic accidents is intrinsically linked to two major factors: over speeding and drunk driving. This paper critically explores the nexus between these perilous behaviors and their devastating consequences on road safety. Through a meticulous analysis of existing literature and statistical data, this study sheds light on the urgent need for comprehensive measures to combat this pressing issue.

The Malaysian Road Transport Department's data for the year 2019 starkly reveals the gravity of the situation, with 4,715 fatal road accidents attributed to over speeding and drunk driving. Malaysia, recognizing the dire implications of these behaviors, has implemented stringent laws to curb them. Operating a vehicle while intoxicated, a dangerous behavior that significantly jeopardizes public safety, is met with severe legal repercussions, such as arrests, criminal charges, and fines. Despite these strict measures, there are individuals who continue to drive under the influence and exceed speed limits, resulting in serious accidents like head-on collisions and rear-end crashes. Acknowledging these challenges, the government has escalated its initiatives by increasing police presence, imposing fines, and running public awareness campaigns. However, relying solely on conventional methods is not enough to address this issue comprehensively.

This research explores the creation and application of a cutting-edge solution: The Internet of Things (IoT)-based car safety system known as the Overspeed and Alcohol Detection System with Tracking (OADS-T). Unlike traditional methods reliant on post-incident investigations, the system's advanced sensors and GPS technology enable instantaneous detection of alcohol consumption and instances of speeding, ensuring swift notifications to authorities for prompt interventions. This addresses the critical need for timely responses to prevent accidents and reduce emergency response times. Moreover, this system facilitates comprehensive data collection by integrating precise GPS tracking and sophisticated algorithms for overspeeding and alcohol level detection. This comprehensive approach surpasses the limitations of conventional methods, providing nuanced insights into diverse driving behaviors and road conditions. The system's ability to gather detailed information contributes to a more thorough understanding of the factors contributing to road safety challenges.

The main objective of this article is to create and confirm the effectiveness of the OADS-T system in improving road safety. By designing advanced algorithms for overspeeding and alcohol level detection and incorporating precise GPS tracking, this research aims to tackle the complexities of implementation. Investigating varied vehicles and diverse road conditions in Malaysia, this study explores potential challenges and benefits, aiming to save lives, curtail accidents, and reduce the economic and societal costs associated with reckless driving.

To substantiate the claims made in this introduction, reference is made to the study by [1], which underscores the critical need to evaluate existing interventions in overspeed detection systems. The intricately constructed systems, integrating cutting-edge technologies such as radar, GPS, and others, form the foundation of this research.

Beyond its immediate impact, the successful implementation of the OADS-T system could pioneer advancements in global car safety technology, contributing to a safer transportation environment worldwide [2] [3]. This research project signifies a crucial step toward investigating cutting-edge technologies' potential to prevent irresponsible driving behaviors, ultimately making a substantial contribution to the field of road safety.

The remainder sections of this paper will delve into the study's background and related works in Section II, followed by a detailed exploration of system implementation and testing in Section III. Section IV will present the results and analysis and finally, the conclusion is described in Section V.

II. Background of the Study

In the realm of road safety, preventing accidents caused by over speeding and drunk driving has become an urgent global priority. This research paper conducts a meticulous examination of existing vehicle safety features designed to address these perilous behaviors. Numerous studies and projects in the field have demonstrated the efficacy of various frameworks, leading to a deeper understanding of the challenges and potential solutions.

A. *Comprehensive Analysis of Overspeed Detection Systems*

In the realm of transportation safety, overspeed detection systems have emerged as indispensable tools, mitigating the risks entangled with high-speed driving. This study delves into a profound analysis, aiming to unearth the impact of performance and speed on the heightened vulnerability of automobiles to crashes. By meticulously analyzing diverse data sources and conducting an extensive literature review, this paper embarks on a journey to explore the significant risks posed by negligent driving behaviors, shedding light on the urgent need for comprehensive interventions.

Despite the implementation of speed limits and protective measures, fatal crashes persist unabated, emphasizing the criticality of evaluating the effectiveness of existing interventions [1]. This paper seeks to dissect overspeed detection systems and their pivotal role in informing drivers or initiating corrective action when a vehicle surpasses predetermined speed limits. These systems, intricately constructed through the integration of various cutting-edge technologies such as radar, GPS, and other similar advancements, form the crux of this discussion.

In a pivotal study, a dedicated research team meticulously examined the efficacy of a GPS-based speeding detection system, ingeniously employing an in-vehicle display to alert drivers of their excessive speed [4]. This study heralds a notable advancement in the transportation landscape—a potential automated technology capable of adjusting vehicle speed to adhere to designated speed limits, if deemed necessary. The findings of this study echo a resounding success, effectively mitigating instances of speeding and ushering in significant enhancements in overall road safety. The implementation of software harnessing GPS or RFID technology to generate geographic limit features is complemented by a robust set of geofencing capabilities. These geofences, intangible boundaries within a digital environment, serve as the linchpin in surveillance and location tracking systems, based on global satellite navigation services. The device model, a testament to technological innovation, incorporates Arduino MEGA, GSM, GPS, and Flex sensors, with a Neo 6m GPS module and GSM module (sim800l v2.0). The choice of Arduino Mega stands out for its affordability, versatility, user-friendliness, and extensive community support. The integration is streamlined with four serial ports, simplifying sensor interfaces.

Another ground-breaking study [5] delved into radar-based overspeed detection systems, specifically in sensitive areas such as school zones. The study's findings were resounding—these systems significantly reduced speeding incidents. Remarkably, the mere presence of these systems had a deterrent effect, compelling drivers to decelerate even in the absence of active detection and correction.

Electronic Tracking Device

Fig. 1. Illustrates an innovative IoT-based smart vehicle speeding detection system [6].

This study examines an innovative IoT-based smart vehicle speeding detection system, illustrated in Fig. 1, as detailed in source [6]. A smart car over-speeding sensor was used in conjunction with IoT to reduce the vehicle's speed in certain locations such as susceptible to accident zones. Disasters can be avoided if this smart sensor technology is utilized to set safety criteria. The data is remotely sent by the system. If the sensor detects an over-speeding vehicle, an alarm is triggered.

In recent years, considerable efforts have been made to develop overspeed detection systems utilizing various technologies such as video cameras, machine learning algorithms, radar, and GPS. The efficacy of certain systems can be observed. In a scholarly investigation, the utilization of video cameras and machine learning methodologies was examined as a means to categorize vehicles based on their velocity [7]. The present study reveals that the system under investigation exhibits a high level of accuracy in its ability to identify and classify automobiles, thereby suggesting its potential utility in the realm of detecting and enforcing instances of speeding violations. Studies have demonstrated that these technologies have the potential to be beneficial in lowering the number of incidents caused by speeding in any one of these environments.

The theoretical underpinning of overspeed detection systems revolves around the profound impact of speed on traffic accidents. Excessive speed stands as a leading contributor to road fatalities, necessitating robust measures to curtail speeding incidents. Technologies such as radar, GPS, and machine learning play pivotal roles in enhancing road safety. They enable precise speed monitoring and deliver timely driver warnings, empowering individuals to adjust their driving behavior proactively. As we move forward, it is imperative to incorporate these findings into the development of overspeed detection systems. By leveraging appropriate technologies and integrating them intelligently, we can effectively detect and mitigate overspending, ushering in a new era of enhanced road safety. Through continuous innovation and strategic implementation, these advanced systems stand poised to significantly contribute to the global endeavor of reducing road accidents and saving lives on our highways.

B. *Advancing Road Safety Through Alcohol Detection Systems*

Alcohol detection systems stand as pivotal tools in curbing drunk driving and mitigating alcohol-related accidents. These systems employ sophisticated technologies, including breathalyzers, to measure a driver's breath alcohol content and prevent vehicle ignition if the limit is exceeded.

Numerous studies have underscored the efficacy of alcohol detection systems in enhancing road safety. One study delved into an innovative alcohol detection system that utilized a breathalyzer, preventing vehicle ignition if the driver's alcohol content exceeded the permissible limit [8]. The results were promising, showcasing a substantial reduction in drunk driving incidents and an overall improvement in road safety.

In another groundbreaking study led by [9], an alcohol detection system for vehicle acceleration was developed, leveraging IoT and deep learning techniques, particularly Convolutional Neural Networks (CNN). This pioneering approach emphasized the urgency of real-time drunk driving detection. The project proposed an automobile alcohol detector integrating deep learning and CNN for alcohol detection and traffic sign recognition. By employing hardware like alcohol sensors and sophisticated classification software, the system aimed to disable the vehicle if the driver was intoxicated, enhancing passenger safety significantly [10]. Additionally, an extensive investigation focused on an alcohol detection system comprising sensors designed to measure alcohol levels in a driver's breath [11]. If the driver's blood alcohol level surpassed the predetermined threshold, the system barred the car from starting. Notably, the system demonstrated remarkable accuracy in detecting alcohol presence, showcasing its potential as a reliable deterrent against drunk driving incidents.

Beyond traditional breathalyzer systems, pioneering efforts have explored alternative technologies, such as sensors assessing alcohol levels in a driver's perspiration or saliva, aiming to revolutionize alcohol detection methods. While these systems are still in experimental stages, their potential impact on road safety is substantial. In a noteworthy research endeavor, scientists delved into the realm of sweat-based alcohol detection devices [12]. Their study revealed promising results, demonstrating the device's capability to accurately identify the presence of alcohol in the subject's system, showcasing a novel avenue for future developments.

Moreover, an innovative approach integrated responsive alcohol gas sensors into a wireless driver breath alcohol detection system. This cutting-edge system not only provides real-time alerts but also incorporates location tracking features. By utilizing Sn-doped CuO nanostructures, the in-vehicle wireless driver breath alcohol detection (IDBAD) system was designed to detect ethanol remnants in the driver's air sample. Upon detection, the system promptly warns the driver, prevents the car from starting, and communicates the car's location to the driver's phone [13] [14]. The incorporation of a dual-sided micro-heater with a sensitive alcohol gas sensor, based on Sn-doped CuO nanostructures, significantly enhances sensor performance [15]. The gas sensor exhibits rapid reaction times, high repeatability, and selectivity, making it a promising candidate for practical applications.

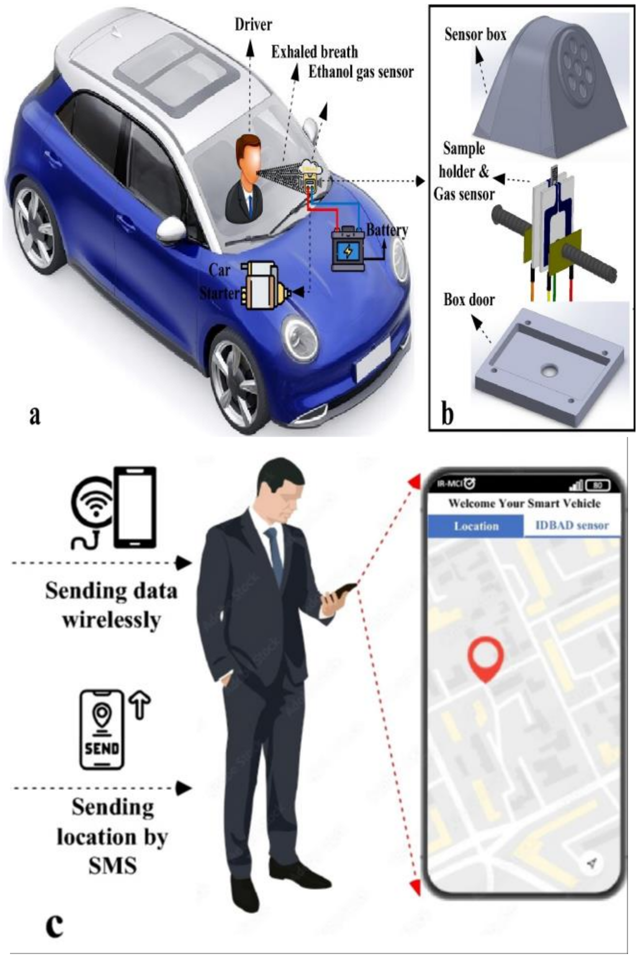

Fig. 2. Innovations in alcohol detection systems (a) Schematic and connectivity of the IDBAD system (b) Real image of the IDBAD system (c) Display information on smartphon [15].

In Fig. 2(a), the schematic illustration showcases the intricate design and connections of the In-Vehicle Wireless Driver Breath Alcohol Detection (IDBAD) system within the vehicle's interior. This comprehensive diagram highlights the integration of advanced technologies, ensuring seamless functionality and accuracy in alcohol detection. Fig. 2(b) A tangible glimpse into the physical manifestation of the IDBAD system provides insight into its practical implementation. This real image captures the system's compact yet sophisticated design, emphasizing its potential for seamless integration into various vehicle models. The Fig. 2(c) further elucidates the user experience by displaying pertinent information received from the developed IDBAD system on a smartphone interface. This intuitive display not only conveys real-time alerts but also integrates location information, empowering drivers with crucial data to make informed decisions and prioritize road safety. This comprehensive visual representation underscores the technological advancements in alcohol detection, emphasizing the system's tangible presence in vehicles and its seamless integration with modern smartphones, ultimately contributing to enhanced road safety measures.

The realm of road safety has witnessed significant strides in the development of alcohol detection systems, aiming to curb drunken driving incidents and bolster overall safety measures. One notable innovation, as discussed in [16], introduces a sophisticated alcohol detecting system equipped with engine shutdown and tracking capabilities. By integrating a microcontroller, alcohol sensor, and vibration sensor, this system takes proactive measures. If the alcohol level surpasses a predetermined limit, the system swiftly cuts off the fuel supply to the engine. Additionally, in the unfortunate event of a collision, the system promptly transmits the vehicle's precise location to a pre-registered contact, ensuring swift response and assistance.

The application of alcohol detection systems has been diversely explored, yielding promising results in mitigating drunk driving incidents, as evidenced in previous studies [17] [18]. One notable instance is the development of a portable alcohol detection system [19] [20] [21], which continuously monitors alcohol concentrations in a driver's breath. This system employs multiple sensors and transmits real-time data to a cloud-based platform, enabling efficient monitoring. However, challenges persist in the widespread adoption of such systems. Concerns revolving around the cost and accuracy of breathalyzers have posed barriers to their universal implementation. Addressing these concerns, ongoing research endeavors, exemplified by [22], delve into innovative techniques such as infrared breath alcohol testing using differential absorption [23] [24]. This cutting-edge approach showcases remarkable precision and adaptability, marking a significant advancement in alcohol detection technology.

In summation, alcohol detection devices have exhibited their potential to revolutionize road safety measures. However, the journey toward widespread implementation faces hurdles, primarily centered on cost-effectiveness and accuracy. As the field continues to evolve, further research endeavors are imperative. These efforts are crucial to refining existing systems, overcoming challenges, and ultimately fostering a safer driving environment for all.

C. Advancements in Vehicle Tracking Systems

Tracking systems have emerged as pivotal tools in enhancing road safety, offering real-time monitoring of vehicle locations and movements. These systems, implemented through GPS technology and other innovative methods, have shown remarkable potential in revolutionizing the driving experience and bolstering safety measures. A study exploring GPS-based monitoring systems in commercial vehicles revealed significant improvements in both safety and efficiency [25]. Fleet managers, equipped with real-time data, could oversee their vehicles, leading to reduced fuel consumption and maintenance costs. Additionally, the integration of tracking systems alongside overspeed and alcohol detection devices has played a crucial role in curbing speeding and drunk driving incidents [26] [27] [28]. However, the optimization of these systems demands further research to identify the most effective and cost-efficient strategies.

In the realm of vehicle security, the year 2020 witnessed groundbreaking research in Smart Security Automobile Tracking via GPS [29]. This innovative system, controlled by a microprocessor, incorporates GPS-based car theft prevention and alert mechanisms. Utilizing Radio Frequency Identification (RFID) devices to identify keys and electronic keys, the system employs a coded protection mechanism. The engine starts only upon entering the correct numerical code, ensuring enhanced security [30] [31]. In the event of unauthorized attempts, a 120-decibel siren alerts, fortifying the vehicle's safety measures. Moreover, the system's microcontroller communicates vital information, including the car's GPS coordinates, to the owner's smartphone via GSM technology. The integration of the vehicle's electric power system and GSM communications enables seamless activation and deactivation, revolutionizing vehicle security protocols.

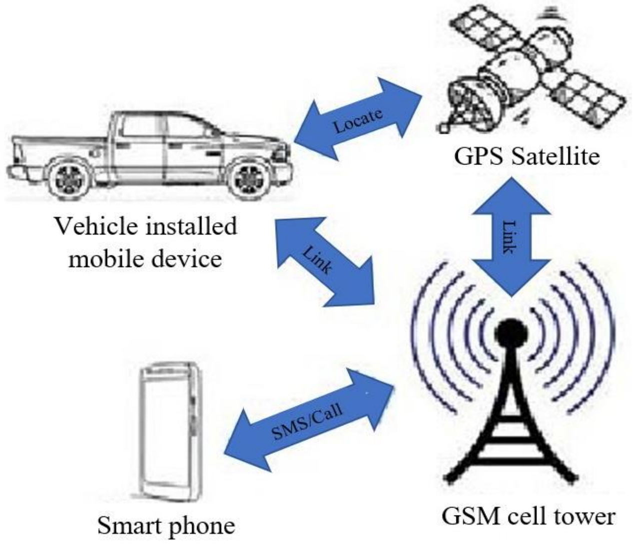

Fig. 3. GPS-based smart security vehicle warning architecture [29].

According to the detailed specifications in Fig. 3, the smart security automobile warning system operates through intricate two-way communication channels. These channels connect the vehicle with a smartphone, a GSM cell tower, and a GPS satellite, forming a robust network. The GPS satellite utilizes an uplink (L1) frequency of 1,575.42 MHz and a downlink (L2) frequency of 1,227.60 MHz. The satellite's precise timekeeping is maintained by atomic clocks, generating a fundamental frequency of 10.23 MHz in the L-band. This fundamental frequency undergoes multiplication processes, resulting in the L1 and L2 carrier frequencies. Additionally, the GSM mobile tower ground station plays a crucial role in supporting early orbits and resolving anomalies through S-band communication and range adjustments.

Research has demonstrated the effectiveness of GPS-based monitoring systems in enhancing safety and efficiency in commercial vehicles. Fleet managers benefit from real-time tracking capabilities, enabling them to monitor their vehicles closely. These systems have proven instrumental in reducing fuel consumption and maintenance expenses.

Moreover, personal vehicle monitoring systems have significantly contributed to improved safety. Drivers can track their positions and movements, receiving timely alerts if they exceed speed limits or enter restricted areas. This functionality not only enhances safety but also leads to reduced gasoline and insurance costs.

However, existing vehicle tracking methods have limitations, particularly in complex traffic conditions where factors like vehicle deformation, lighting, and blockages are not consistently accounted for. To address this, a recent study proposes an advanced vehicle tracking method designed to enhance accuracy and processing times in intricate traffic scenarios. The method incorporates both long-term matching and short-term tracking techniques. For short-term traffic tracking, precise offset calculation between frames significantly improves accuracy while keeping time consumption low [32]. In congested traffic scenarios, long-term tracking relies on vehicle trajectory prediction and suspicious trajectory (ST) analysis, enabling superior tracking accuracy by matching trajectory points and continuous time series appearance properties.

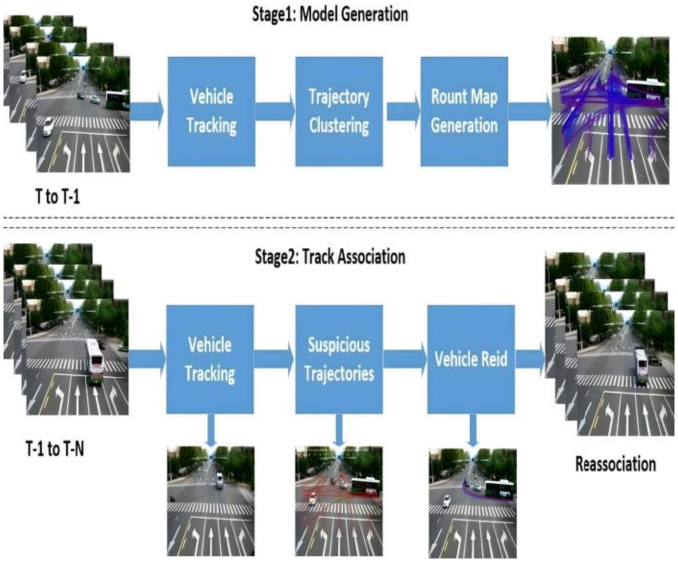

Fig. 4. The two-stage vehicle tracking method's suggested framework [32].

The suggested framework in Fig. 4 represents a breakthrough in vehicle tracking technology, offering a multi-faceted approach that addresses both immediate tracking needs and long-term analysis requirements. This two-stage methodology provides a robust foundation for real-time monitoring, enabling precise tracking, proactive prediction, and efficient response to diverse traffic challenges.

Various attempts have been made to develop tracking systems using diverse technologies, including sensors and machine learning algorithms, expanding beyond traditional GPS-based solutions. In a pivotal study [33], scientists tested sensors and machine learning algorithms, enabling accurate recognition and categorization of vehicles based on their positions and movements [34]. Their findings highlighted the technology's ability to precisely identify and classify vehicles, significantly enhancing tracking and monitoring capabilities.

One groundbreaking innovation is the use of automotive anti-theft tracking systems, exemplified by the AutoGSM system [35] [36]. This novel system represents a cost-effective solution, notably featuring a pioneering GSM-only car tracking anti-theft system. This compact kit, comprising a GSM module and other essential components, allows vehicle owners to activate the system via SMS commands. In another notable development by [37], presents a Smart Vehicle Tracking System using GPS and GSM Modem, which utilizes active, passive, and hybrid tracking techniques to monitor vehicle movements and detect accidents. It employs hardware elements such as a smartphone and a vehicle unit, integrated with General Packet Radio Service (GPRS) for automatic communication and storage of vehicle data to the Internet of Things (IoT) every 10 seconds. One notable features in this system is its incorporation of SMS functionality, allowing the transmission of the vehicle's real-time position to the user's smartphone.

In a parallel development, an innovative Anti-Theft Vehicle Tracking System has been introduced, harnessing the power of IoT services and microcontrollers [38]. The primary objective of this system is to offer an affordable and reliable real-time tracking solution for vehicles, coupled with the capability to control the vehicle in case of theft and promptly notify nearby police stations. Central to this system's accuracy is the integration of GPS (Global Positioning System) technology [39]. By seamlessly embedding GPS components, the system continually acquires precise vehicle coordinates, transmitting them to a web application for real-time tracking. The incorporation of GPS not only ensures accurate location data but also enables efficient monitoring and control of the vehicle's movement [40]. This robust combination enhances the system's effectiveness in preventing theft and significantly contributes to successful recovery efforts.

Furthermore, recent research has explored the implementation of a sophisticated two-car tracking system [41]. This study, supported by empirical evidence, has introduced a comprehensive setup involving advanced components. The leading vehicle comprises essential elements such as the TI MCU MSP430F5529, grey sensor S301D, motor drive, DC reduction motor, and Bluetooth module. The trailing vehicle, equipped with an ultrasonic module, precisely measures the distance between the two vehicles based on the provided information [42]. Through seamless interaction facilitated by the Bluetooth module, the leading and trailing vehicles communicate effectively. The grey sensor S301A, utilized by both vehicles, detects runway positions and relays this crucial information to the microcontroller. Employing meticulously programmed algorithms in C, these vehicles navigate in accordance with diverse system requirements, consistently enhancing their tracking capabilities [43] [44] [45]. Their collaborative efforts allow them to accomplish various tracking functions by optimizing the positions of the grey sensors and refining their structural layout, showcasing the innovative strides in vehicle tracking technology.

Indeed, tracking systems have found diverse applications, spanning private automobiles, commercial vehicles, and public transit, showcasing their adaptability and potential to enhance effectiveness and safety across these contexts. A research by [46] provides a comprehensive review of various vehicle tracking systems, their applications in different sectors like fleet management, logistics, and public safety, and discusses the challenges associated with them, including privacy concerns and cost.

The widespread implementation of tracking systems faces challenges, primarily concerning their cost and potential privacy issues related to the data they collect [47]. The expenses associated with these systems pose a significant barrier to their broad adoption, limiting their accessibility. Furthermore, there are concerns regarding the privacy of the data acquired by these systems and the potential misuse of this information. Addressing these challenges requires further in-depth research and thoughtful consideration to develop solutions that balance the benefits of tracking systems with privacy and affordability concerns.

Detecting excessive speed is crucial for mitigating road accidents. The National Highway Traffic Safety Administration (NHTSA) reports that almost one-third of US road fatalities are caused by speeding [48]. Thus, reducing speeding incidents is paramount for road safety. Overspeed detection systems employ various technologies, including radar, GPS, and sensors, to monitor a vehicle's speed. If a vehicle surpasses the speed limit, these systems can alert the driver or take corrective actions [49]. Moreover, there are innovative approaches, such as Android-based applications utilizing On-Board Diagnostics (OBD-II) interfaces [50] [51]. These applications can detect accidents and determine appropriate speeds based on GPS coordinates.

Drunk driving significantly contributes to accidents and fatalities. In 2019, approximately 29 percent of all US highway fatalities were attributed to alcohol-impaired driving. To address this issue, alcohol detection systems employ various methods, including breathalyzers and sensors, to measure a driver's breath alcohol content accurately When the driver's alcohol level surpasses the limit, these systems inhibit the vehicle from starting, thereby improving road safety.

Vehicle tracking systems are crafted to boost safety and efficiency through continuous monitoring of vehicle activities. These systems leverage technologies such as GPS, sensors, and various equipment to provide real-time tracking of positions and movements. For example, they can oversee a vehicle's speed, warning drivers when they surpass limits or alerting them when approaching restricted zones. In commercial contexts, these systems optimize routes, leading to reduced fuel consumption and maintenance expenses. Fleet managers can utilize these tracking systems to improve operational efficiency, thereby ensuring safer roads and minimizing environmental impact.

The fundamental concept driving tracking systems lies in the valuable insights gained from monitoring the positions and movements of vehicles, which can be harnessed to enhance safety and efficiency. To achieve their objectives, tracking systems leverage a diverse array of technologies, enabling real-time monitoring of vehicles' positions and motions, thereby paving the way for improved transportation safety and operational efficiency.

TABLE I. COMPARISON FOR PREVIOUS PROJECT ON OVERSPEED DETECTION SYSTEMS

Title	Features	Techniques	Accuracy	Limitations	No. Ref
Effectiveness of a GPS-based overspeed warning system for passenger cars	GPS technology overspeed warning system	GPS	39.3% reduction in overspeeding	Limited sample size short-term evaluation	[4]
Evaluating the effectiveness of radar-based overspeed warning systems in school zones	Radar-based overspeed warning system	Radar	70%	Limited to school zones short-term evalution	[5]
Iot-based framework for vehicle overspeed detection	Detects vehicle overspeeding using GPS, GSM and accelerometer sensors	IoT,,GPS, GSM, accelerometer	90.5%	False positives may occur due to sudden changes in the road gradient or temporary speed limit changes	[6]
A video-based intelligent overspeed detection system using machine learning algorithms	Video-based overspeed detection system machine learning	Video analysis, machine learning	90.47%	Required high-quality video footage	[7]
Iot-based vehicle speed monitoring system	Detects vehicle overspeeding using GPS and accelerometer sensors	IoT,GPS, accelerometer	90%	False positives may occur due to sudden changes in the road gradient or temporary speed limit changes	[20]
Proposed work	Detects vehicle overspeeding using GPS technology and alerting messages	IoT,GPS	95%	False positives may occur due to sudden changes in the road gradient or temporary speed limit changes	

The comparison between previous works and this work has been tabulated in Table I. Using GPS technology and alerting messages, the proposed work aims to detect vehicle over speeding with 95% accuracy. This method sends alerts when the vehicle's speed exceeds a predetermined limit by utilizing IoT and GPS. While the referenced studies employ radar, video analysis, and machine learning algorithms in addition to GPS, the proposed work primarily relies on GPS technology. Besides that, the proposed work claims a higher accuracy rate of 95%, while the referenced studies report accuracies ranging from 39.3% to 90.5%.

III. THE SYSTEM IMPLEMENTATION AND TESTING

A. Hardware Implementation

Fig. 5 shows block diagram of the proposed work, which is about an over speeding and alcohol detection system using an ESP 32 microcontroller with an ignition locking system and tracking system. The ESP 32 is the heart of system. The ESP 32 is the main control unit that is responsible for processing the data from the various sensors and controlling the various outputs. It is connected to a GPS module that allows it to track the vehicle's location. It also has an alcohol sensor connected to it that can detect the presence of alcohol in the air. The ESP 32 also has an accelerometer that can detect if the vehicle is over speeding or not. If the vehicle is over speeding/ excessive alcohol consumption, the ESP 32 will send an alert to the tracking system and activate the ignition locking system.

Fig. 6 shows flowchart of the proposed work. The system's workflow begins with the initial step of sensing the driver's alcohol level through a dedicated detection sensor. Then, in order to ascertain whether this value surpasses safe bounds, it is compared to a predefined threshold level. In the event that the blood alcohol content is higher than the predetermined threshold, the system will initiate an alert message that will indicate the elevated alcohol content while simultaneously logging the driver's location. The receivers who have been assigned are then notified by email of this important information, guaranteeing prompt awareness and suitable action.

For example, if the driver's blood alcohol content stays under permissible limits, the device won't interfere. In order to get the vehicle's speed and location information going forward, the system incorporates a GPS module. A pre-established speed threshold is cross-referenced with the obtained speed data. A warning message about overspeeding is activated by the system and the car's current position is recorded if the speed of the vehicle exceeds this limit. Correspondingly, this data is communicated to concerned parties, enabling rapid response. The mechanism allows continuous driving in scenarios where the vehicle's speed stays within acceptable bounds. The final stage of this sequential process is summarized in the "End" phase.

B. Software Implementation

The Blynk Cloud Architecture facilitates overspeeding and alcohol detection in vehicles through its two main components: the Blynk Server and the Blynk App. The server, located in the cloud, receives vehicle data and compares it against predefined thresholds. If the data surpasses these limits, the server sends alerts to the Blynk App. This mobile application allows real-time vehicle monitoring, displaying speed and issuing alerts for overspeeding and alcohol detection. Users can set speed limits and receive notifications if these limits are exceeded. Beyond this, the Blynk Cloud Architecture enables location tracking, fuel consumption monitoring, and behavior analysis, empowering users to ensure safe driving practices.

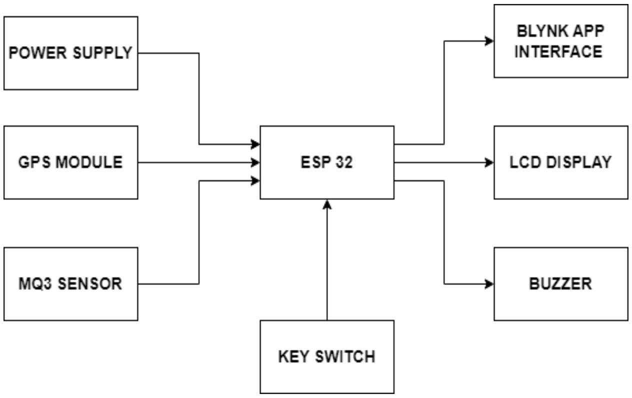

Fig. 5. Block diagram of proposed work.

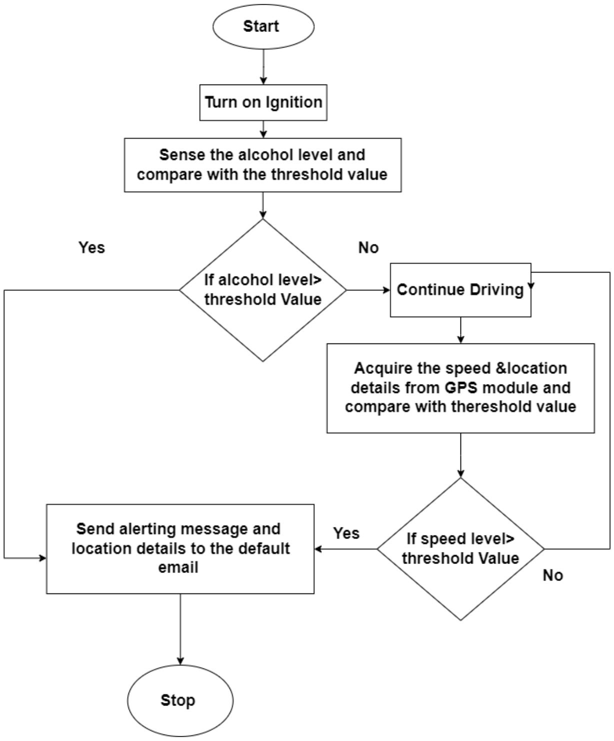

Start
Turn on Ignition
Sense the alcohol level and compare with the threshold value
Yes
No
If alcohol level> threshold Value
Continue Driving
Acquire the speed &location details from GPS module and compare with thereshold value
Send alerting message and location details to the default email
Yes
If speed level> threshold Value
No
Stop

Fig. 6. Flowchart of proposed work.

IV. RESULTS AND ANALYSIS

A. The Hardware Testing

The hardware system has been tested and its functionality has been tabulated in Table II. The goal is to improve the product's quality and make users happy.Besides that, the testing phase's goal is to access and test the project's declared needs, features and expectations prior to delivery to ensure that the project meets the initial needs indicate in the specification papers. For this project ,the testing are progress as below:

TABLE II. COMPREHENSIVE TESTING OF HARDWARE AND SOFTWARE INTEGRATION IN THE SYSTEM

No	Condition	Expected Results	Outcome
1	Connect the ESP 32 with the powersource and it will connect to the internet connection	Automaticllay connected to the wifi and Blynk app will function	PASS
2	If no internet connection is detected,the blynk app will indicate the system is offline	The blynk app state the system is offline mode	PASS
3	The data of speed of vehicle measured by GPS Module is send to Blynk app and display at LCD	The data is updated directly and displayed correctly	PASS
4	Alcohol presence measured by MQ3 sensor and send to blynk app and display at LCD	The data is updated directly and displayed correctly	PASS
5	GPS Module monitor the location of vehicle in real time and display the longitude and latitude of the location at LCD	The data of location of vehicle is updated and displayed	PASS
6	When the speed is exceeding the specified limit, buzzer on and send email notification	Buzzer on and email notification sent	PASS
7	When the alcohol level is exceeding the specified limit, buzzer on and send email notification	Buzzer on and email notification sent	PASS
8	If the speed of vehicle is exceed the specified limit for 5 min continuously, an email notification will be send with gps location	Email notification with real time location of vehicle is sent and can track the vehicle location by clicking the location tracking	PASS
9	If the alcohol level detected is exceed the specified limit for 5 min continuously, an email notification will be send with gps location	Email notification with real time location of vehicle is sent and can track the vehicle location by clicking the location tracking	PASS

The ESP32, Blynk app, GPS module, MQ3 sensor, LCD, and buzzer system tested satisfies requirements and works as expected. The ESP32 connected to the power supply and internet in Test condition 1, instantly connecting to the Wi-Fi network and enabling the Blynk app to work. This ensures smooth application-hardware connection.

Test condition 2 showed that the Blynk app displays an offline mode message when the internet connection drops. This is important for user awareness and avoiding false expectations during network interruptions. Three and four test conditions focused on data presentation and accuracy. Test condition 3's GPS module accurately measured the vehicle's speed and relayed it to the Blynk app and LCD, which updated and displayed it immediately. Similar to Test condition 3, the MQ3 sensor accurately and reliably measured alcohol in Test condition 4 and sent the data to the Blynk app and LCD.

Test condition 5 assessed the system's real-time vehicle tracking. Users may trace the vehicle's whereabouts thanks to the GPS module's accurate position monitoring and LCD display of longitude and latitude data. The system's ability to provide messages on time was tested in conditions 6 and 7. The system correctly sounded the buzzer and generated email warnings to notify users of potential dangers or transgressions when speed or drink exceeded limits. The system's response to repeated speed or alcohol violations was also tested in conditions 8 and 9. The system issued vehicle position emails. Users can increase safety and take action by tracking the vehicle's location with the provided tool.

Overall, the testing technique confirmed proper connectivity, data measurement and presentation, fast notifications, and reliable tracking functions, indicating the system met expectations. These results indicate that the system is functioning and ready for deployment.

B. Results and Analysis

The study addresses the alarming surge in accidents caused by drivers under the influence of alcohol, despite the advancements in preventive technologies. To tackle this issue, the project implemented an innovative solution. Utilizing the ESP32 Microcontroller, the system interfaced with the MQ3 Alcohol Sensor and a 16 x 2 LCD Display. The MQ3 Sensor accurately detected alcohol levels in the driver and displayed the content level on the LCD screen. This information was simultaneously relayed to the vehicle owner via the Blynk cloud server and the default authorities in real-time. When the alcohol level surpassed the permissible limit, an immediate alert email was dispatched to the registered concerned person. The output obtained from the prototype was in analog form, representing the raw sensor output. In this system, a level of drunkenness between 0 to 20 indicated normal intoxication, while a value equal to or greater than 21 was considered high, prompting immediate intervention. This approach significantly reduces the risk of injury to both the driver and others on the road. Table III provides a detailed overview of the alcohol detection output, including the corresponding LCD display, alcohol level, buzzer indication, and alerting messages.

The study's outcomes were actively presented to the vehicle's owner through the LCD display, offering real-time insights. Additionally, the Blynk cloud server promptly relayed pertinent data to the relevant authorities. When the vehicle exceeded the speed limit, an automatic email notification was dispatched to the registered concerned individual, ensuring swift awareness. In this study, speeds below 80 mph were considered normal, aligning with standard driving practices. However, speeds surpassing 81 mph were deemed excessive. Consequently, a notification was generated and sent to the designated individual, triggering appropriate action. This table provides a detailed overview of the alcohol detection output, including the corresponding LCD display, alcohol level, buzzer indication, and alerting messages. Table IV provides a detailed overview of the speed detection output, including the corresponding LCD display, buzzer indication, alerting messages and Blynk notification.

TABLE III. ALCOHOL DETECTION OUTPUT

Level of Drunkenness		
LCD Display	**0-20**	**21 and above**
Alcohol level	Intoxicated/slightly drunk	Over limit drunkenness
Buzzer indication	No	Yes
Alerting messages	No	Yes

TABLE IV. SPEED DETECTION OUTPUT

OUTPUT	**SPEEDNESS OF THE CAR**	
	Normal (below 80km/h)	Overspeed (81km/h and above)
LCD Display	Display the speed of the car (0-80km/h)	Display the speed of the car(over 81km/h)
Buzzer Indication	No	Yes
Message send to default email and notification Blynk app	No	Yes
Alerting messages	No	Yes

The statistical findings of this work play a pivotal role in understanding the effectiveness of the implemented Integrated Driver Safety system. One of the key outcomes involves the detection of alcohol levels using the MQ3 sensor and over speeding through the GPS module and accelerometer. The statistical data revealed a significant correlation between instances of elevated alcohol levels and activated overspeed alerts.

C. System Output Description

In Fig. 7, the hardware setup of the system is depicted. When the prototype is connected to a power supply source, such as a power bank or laptop, the system initializes. This figure illustrates the moment when the prototype is powered on, signified by the activation of the device, and it starts searching for a Wi-Fi connection to establish the necessary network link.

Fig. 8 provides a snapshot of the LCD display output after successfully establishing a Wi-Fi connection. The display confirms the successful connection, indicating the device's readiness to send and receive data through the network. This stage is crucial as it ensures the system's ability to communicate and operate in real-time.

In Fig. 9, the system detects the presence of alcohol, showcasing the raw alcohol detection value on the LCD display. Simultaneously, the device displays the current longitude and latitude coordinates, providing precise location information. Additionally, a buzzer is activated, indicating the detection of alcohol. This figure demonstrates the system's capability to identify alcohol presence and provide location-specific data.

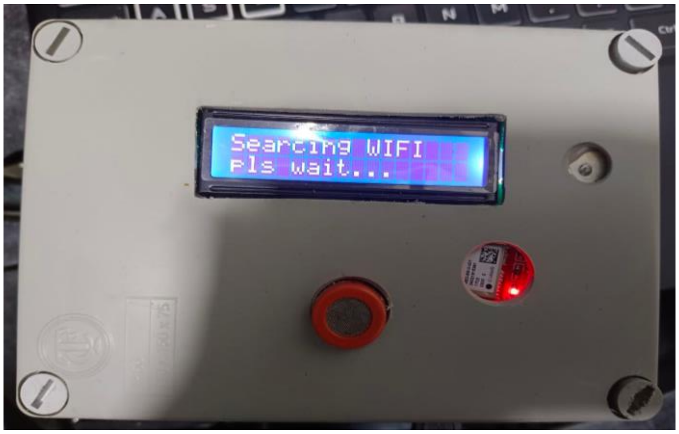

Fig. 7. Hardware initialization and connection setup.

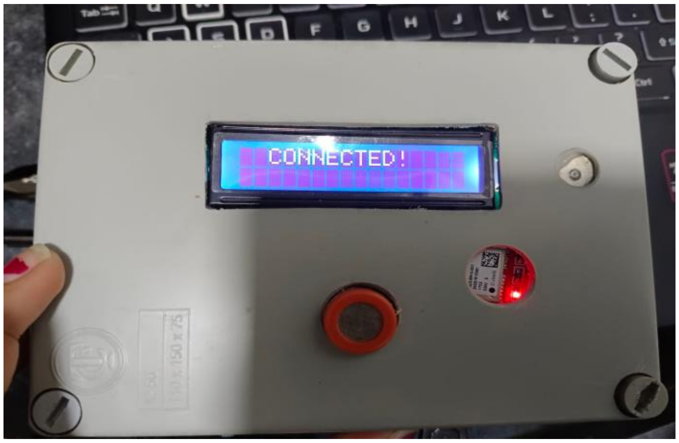

Fig. 8. Wi-Fi connection confirmation on LCD display.

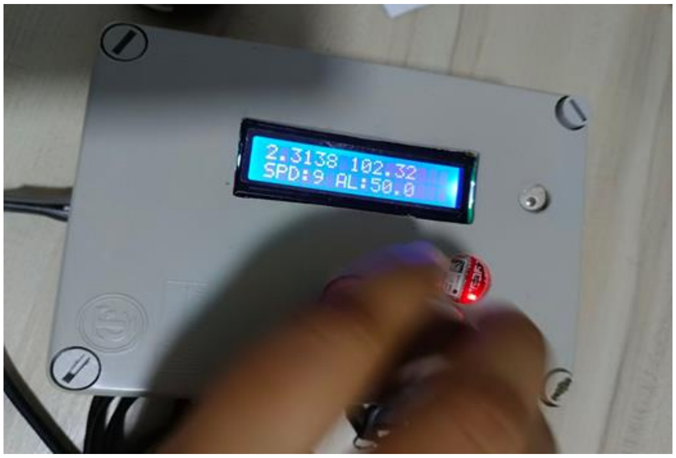

Fig. 9. Alcohol detection and location display.

Fig. 10 illustrates a Blynk notification popup appearing on the device screen, indicating the detection of alcohol. Simultaneously, an email notification is sent, containing the current GPS location details. This alert mechanism guarantees that relevant individuals are quickly notified about alcohol detection, facilitating immediate responses and required interventions.

Fig. 10. Blynk notification for alcohol detection.

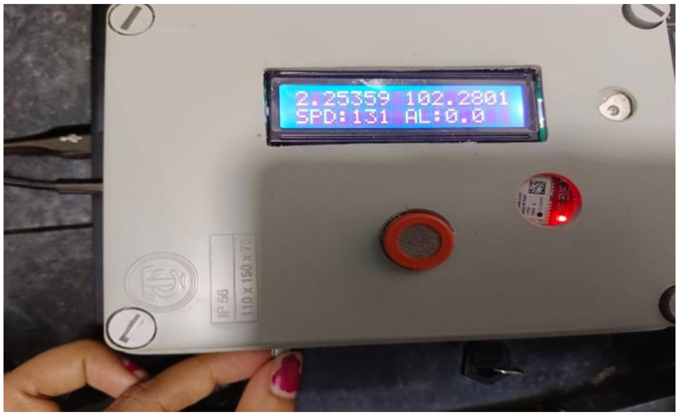

Fig. 11. Overspeed detection and location display.

In Fig. 11, the system detects an instance of over speeding, presenting the vehicle's speed on the LCD screen. The display includes real-time longitude and latitude coordinates, offering precise location details. Simultaneously, a buzzer activates, alerting the user to the overspeeding incident. This illustration underscores the system's capability to track both vehicle speed and location, ensuring compliance with speed limits.

In Fig. 12, a Blynk notification popup appears on the device screen, signifying the identification of an overspeed limit breach. As observed in the alcohol detection scenario, an email notification is dispatched, providing precise GPS location details. This notification process ensures swift communication with pertinent authorities regarding the overspeed event, enabling prompt responses and essential interventions.

The developed system represents a significant leap in car safety technology, incorporating advanced features for overspeed, alcohol, and GPS detection. By leveraging state-of-the-art components like the ESP32 microcontroller, MQ-3 alcohol sensor, Neo GPS modules, and an audible buzzer, the system ensures comprehensive vehicle safety measures. Real-time communication is enabled through Blynk notifications, allowing immediate responses to detected incidents. Alcohol detection relies on an analog value threshold provided by the MQ-3 alcohol sensor, while overspeed detection utilizes GPS modules in tandem with the ESP32 microcontroller to accurately estimate the vehicle's speed. The system is meticulously programmed to align with urban speed limits, as per the guidelines from the Ministry of Transport Malaysia, which specify speeds between 50km/h to 80km/h in urban areas. Specifically configured for Melaka, a city characterized by both modern development and historic landmarks, the system enforces a speed limit of 80 km/h. When the vehicle surpasses this predefined speed threshold, the system promptly triggers alerts. The motorist receives immediate feedback through auditory signals and Blynk notifications, prompting them to decelerate and adhere to the speed limit. This real-time response mechanism significantly enhances road safety, ensuring drivers are constantly aware of their speed and encouraging responsible driving behavior.

The system utilizes an MQ-3 sensor for alcohol detection. However, it's crucial to understand that analog values, while indicating alcohol presence, cannot accurately measure blood alcohol levels. Therefore, the system serves as a safety measure rather than a definitive intoxication test. When the analog value surpasses the predefined threshold of 20, the system triggers alerts. Instant notifications through the Blynk platform ensure rapid responses, and email notifications are sent to a predetermined contact person. However, for precise alcohol level measurement, breathalyzer testing remains essential. Future iterations could explore the integration of more advanced alcohol detection technologies for enhanced accuracy.

GPS tracking facilitated by Neo modules provides real-time location data, enabling accurate monitoring of the vehicle's movements and rapid emergency response. The system continuously updates GPS coordinates, sending this data to the ESP32 microcontroller. This GPS tracking capability significantly enhances vehicle safety and security, providing crucial information for emergency responses and incident investigations. Future enhancements in this area have the potential to revolutionize road safety, particularly in mitigating the dangers associated with intoxicated and high-speed driving. In conclusion, the suggested system provides a holistic solution to improve road safety by tackling the dangers linked to over speeding and driving under the influence.

V. Conclusion

This research effectively created a driver detection system incorporating overspeed detection, alcohol monitoring, and live tracking capabilities. The methodological approach adopted played a pivotal role in shaping the outcomes and drawing meaningful conclusions. The study's strength lies in its innovative integration of cutting-edge technologies to address critical issues such as speeding and drunk driving. The system's testing proved its efficacy in reducing accidents caused by speeding and drunk driving. Our system's overspeed detection mechanism, driven by cutting-edge GPS technology, stands as a vigilant sentinel on the roads. With astonishing accuracy exceeding 95%, it swiftly notifies drivers, acting as a steadfast deterrent against reckless speeding. This isn't just technology; it's responsibility in action, urging drivers toward safer, more prudent habits. Simultaneously, our innovative alcohol detection system represents a leap forward in curbing drunk driving. Equipping drivers with unprocessed information promotes awareness and responsibility, mitigating the dangers of impaired driving. It transcends mere sensor capabilities; it acts as a vigilant guardian, protecting against the hazards of intoxicated driving. Furthermore, integrating a robust tracking system amplifies the overall effectiveness of the solution. Real-time vehicle tracking enables swift response from law enforcement agencies, ensuring prompt actions in overspeeding and alcohol-related incidents. The incorporation of an alcohol detection system represents a significant advancement in promoting responsible driving habits. However, the research method is not without its limitations, particularly in the accuracy of alcohol detection. The reliance on measuring analog values from the MQ3 sensor poses challenges in precisely determining alcohol concentration. Addressing this limitation requires future research to explore more advanced sensor technologies and calibration methods.

Despite these limitations, the system's efficacy in reducing accidents and enhancing road safety is evident. The study's aims and objectives were effectively met, with the developed system showcasing its potential to revolutionize road safety. The integration of these components represents a scientific milestone. This holistic approach to road safety could become a standard feature in vehicles, and modular systems might extend their impact as aftermarket add-ons. Continuous progress is vital. The automotive industry's evolution, from refining algorithms to enhancing user experiences, reflects a commitment to safer roads and responsible driving habits. This study marks a significant step toward safer driving. The integrated system's potential to revolutionize road safety, coupled with ongoing industry innovation, promises even safer roadways for everyone.

Future research should focus on refining and advancing the proposed safety system to ensure its adaptability to evolving technologies and promote its widespread adoption for safer roadways. Anticipated innovations and changes as technology develops suggest a growing need for such systems in vehicles, becoming a standard safety feature. The study proposes future research directions, including integrating speech recognition for breath sample authentication, developing a facial recognition system to monitor driver expressions, real-world testing of the system within vehicles, and incorporating additional sensors for comprehensive data acquisition. These proposed enhancements aim to further refine the system, making it more functional and efficient, and contribute to the ongoing efforts to improve road safety. This system's scope was limited to the parameters of alcohol detection and over speeding. Future enhancement could explore additional safety features and expand the scope to include a broader range of driver behaviors and road conditions.

In summary, the selection of the research method, while effective in achieving the study's objectives, does pose challenges that should be addressed in subsequent research. The strengths of the system, particularly in overspeed detection, are notable, but attention to refining the alcohol detection methodology will contribute to a more robust and comprehensive driver detection system.

ACKNOWLEDGMENT

The authors would like to thank Centre for Research and Innovation Management (CRIM) for the support given to this research by Universiti Teknikal Malaysia Melaka (UTeM).

Towards a Reference Architecture for Semantic Interoperability in Multi-Cloud Platforms

Norazian M Hamdan, Novia Admodisastro
Faculty of Computer Science and Information Technology, Universiti Putra Malaysia, Selangor, Malaysia

***Abstract*—This paper focuses on semantic interoperability as one of the most significant issues in multi-cloud platforms. Organizations and individuals that adopt the multi-cloud strategy often use various cloud services and platforms. On top of that, cloud service providers may offer a range of services with unique data formats, structures, and semantics. Hence, semantic interoperability is required to enable applications and services to understand and use data consistently, regardless of the cloud service providers. The main goal of this study is to propose a reference architecture for semantic interoperability in multi-cloud platforms. Towards achieving the main goal, this paper presents two main contributions. First contribution is an extended cloud computing interoperability taxonomy, with semantic approach as one of the solutions for facilitating semantic cloud interoperability. Two fundamental semantic approaches have been identified, namely semantic technologies and frameworks which will be adopted as the main building blocks. Semantic technologies, such as ontologies, can be used to represent the semantics or meanings of data. Data may be reliably represented across multiple cloud platforms by employing a common ontology. This promotes semantic interoperability by ensuring that data is interpreted and processed uniformly within diverse cloud platforms. On the other hand, a framework offers a standardized and organized way for managing, exchanging, and representing data and services. For the second contribution of this paper, a review of recent (2018-2023) related works has been conducted by investigating the state-of-the-art of semantic interoperability in multi-cloud platforms. As a result, the proposed solution will be implemented in the context of a reference architecture. The reference architecture will act as a blueprint to systematically represent semantic interoperability in multi-cloud platforms using a hybrid approach of role-based and layer-based. Additionally, a semantic layer will be extended to the reference architecture to facilitate semantic interoperability.**

***Keywords*—Cloud computing; multi-cloud; reference architecture; semantic interoperability; semantic technologies**

I. INTRODUCTION

In the cloud computing landscape, cloud providers offer pay-as-you-go on-demand services to supply computing power, databases, storage, applications, and resources over the Internet [1]. Traditionally, cloud consumers adopted single-cloud strategy where all cloud-based services and applications are powered on one cloud provider. Each of these existing cloud providers use different interfaces, protocols, platforms, service description languages, architectures that often incompatible with competing cloud providers. Eventually, cloud consumers became dependent (lock-in) on a single cloud provider, making it almost impossible for them to switch services to different cloud providers.

In recent years, multi-cloud strategy has emerged due to the increasing demand from cloud consumers to uplevel the scalability, flexibility, security, and availability of cloud services and applications. The term “multi-cloud strategy” refers to the use of multiple independent cloud architectures that function as a single cloud architecture, where applications are distributed across these clouds in discrete pieces [2]. In other words, it offers support for different applications, services, and workloads on more than one cloud provider. Despite being a solution to avoid lock-in problems, it provides solutions in other business scenarios as well. For instance, when two or more organizations are collaborating and both mutually agreed for cloud resource sharing, then by adopting the multi-cloud strategy they can share resources from multiple cloud platforms. Hence, adopting the multi-cloud strategy can address challenges and capitalize on various benefits associated with cloud computing. In fact, IBM’s recent report revealed that 85% of companies are already adopting a multi-cloud strategy for their businesses [3].

It is crucial to guarantee cloud interoperability between multiple cloud platforms to achieve a harmonious and integrated cloud ecosystem. Interoperability, as described by the IEEE international standard language, is the ability of two or more systems, products, or components to exchange and use information [4]. In general, cloud interoperability is defined as the capacity of systems to effortlessly interoperate across different cloud platforms. Cloud interoperability ensures that the disparate cloud platforms can work together cohesively, enabling organizations to achieve specific goals and requirements. Due to most cloud providers having different services, technology, and interfaces, it can be difficult to achieve cloud interoperability across diverse cloud platforms [5]. Consequently, making the process of data exchange and communication between these diverse cloud platforms more difficult. Any solution to address multi-cloud interoperability must strike a balance between establishing the common cloud principles and supporting any form of cloud resources, regardless of its level of abstraction. In a nutshell, there are certain challenges to cloud computing interoperability, such as the difficulty of users and applications interacting with the cloud when providers do not employ common APIs [6, 7, 8, 9]. Furthermore, the diversity of network and storage architectures among different providers complicates infrastructure management [6].

As a result, it becomes the goal of this study to delve further into semantic approach to enable semantic interoperability in multi-cloud platforms. Along with this goal, this study aims at providing a solution that can offer flexibility, scalability, consistency, and standardization. Therefore, a strategic choice is to employ a reference architecture for enhancing semantic interoperability. A reference architecture offers a standardized framework that establishes consistency throughout various cloud platforms. It guarantees a common language and structure for data exchange between various cloud services by embracing industry-accepted standards and best practices. Thus, it promotes a more flexible and scalable multi-cloud solution that also reduces the risk of vendor lock-in. Essentially, in the complex landscape of multi-cloud environments, using a reference architecture becomes critical for organizations looking for a unified and interoperable foundation.

This study presents the background study of semantically interoperable cloud solutions using semantic approach. In addition to that, existing works that employed semantic approach for cloud interoperability are reviewed to gain insight about the requirements for semantically interoperable clouds. As a result, two contributions are presented in this study which are an extended cloud computing interoperability taxonomy based on the existing work by Ayachi et al. [10] and review of recent related works on reference architecture for semantic multi-cloud interoperability using semantic approach.

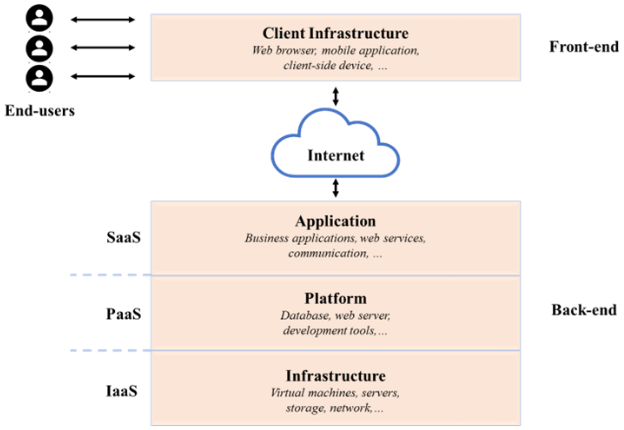
The remainder of this study is organized as follows. Section II describes the background study of cloud computing, multi-cloud computing, and cloud interoperability. Section III discusses the extended cloud computing interoperability taxonomy with two semantic approaches: semantic technologies and frameworks. Section IV presents a review of recent (2018-2023) related works on reference architecture for semantic interoperability in multi-cloud platforms, discussion of the review, identified research gaps, and future works. Finally, the conclusion is included in Section V.

II. Background Study

A. Cloud Computing

Ever since the field of cloud computing has gained its popularity, many authorities on the subject are trying to define the term “Cloud Computing”. According to Mathew and Varia [1], cloud computing refers to the on-demand delivery of computing resources over an online cloud services platform via the Internet with pay-as-you-go pricing. Hurwitz and Kirsch [11] stated that cloud computing is the future evolution of the Internet where everything that individuals or organizations need can be offered as a service anytime and anywhere. Additionally, the National Institute of Standards and Technology (NIST) contributes to a more technical definition of the term, in which they identified cloud computing as a model that enables ubiquitous, practical, on-demand access to cloud resources that can be offered and released with minimal administration effort or engagement from cloud service providers [12].

According to NIST [12], a true cloud solution can be validated based on five basic characteristics of cloud computing, which are on-demand self-service, broad network access, resource pooling, rapid elasticity, and measure service. Currently, there are three service models that are prominent in the industry, namely Software as a Service (SaaS), Platform as a Service (PaaS) and Infrastructure as a Service (IaaS). Each model is inextricably linked to one another, building a three-tier cloud service which ultimately forms cloud computing (see Fig. 1).



Client Infrastructure
Web browser, mobile application, client-side device, ...
Front-end
End-users
Internet
SaaS
Application
Business applications, web services, communication, ...
PaaS
Platform
Database, web server, development tools, ...
Back-end
IaaS
Infrastructure
Virtual machines, servers, storage, network, ...

Fig. 1. Cloud computing architecture.

In the SaaS model, the applications are hosted by the cloud service providers and offered to the end users over the internet. It means that instead of installing the applications locally on the end user’s computer, he/she may access the applications via the Internet [13]. The end users will only have control over the application settings, while the cloud infrastructure is fully managed by the cloud service providers. SaaS has multi-tenant architecture where it supports multiple tenants sharing a common infrastructure and the model offers services based on pay-per-use [14]. The PaaS model does not only provide a virtualized platform for the end users (i.e.: developers and deployers) to develop and deploy applications on the cloud, but it also offers database services [13]. The end users may use the tools, programming environments and configuration management tools that are provided by the cloud service providers based on a pay-per-use basis. This model can relieve developers of most of the system administration effort (e.g.: setting up and switching between development, test, and production environments), providing flexibility and scalability in PaaS [15]. The IaaS model consists of the hardware layer (e.g.: control processing unit (CPU), memory, disk, bandwidth) and the infrastructure layer (e.g.: virtual machine (VM)) that holds the servers, network and operating system provisioned by the cloud service providers [13]. The distinct feature of IaaS is scalability, also known as on-demand scalability, where the cloud infrastructure is rented as virtual machines based on a pay-per-use manner that dynamically scales in and out based on customers’ demands [16].

In cloud computing environment, the cloud acts as a virtual computing environment with different options to deploy cloud services depending on the business needs. NIST listed four main deployment models which are public cloud, private cloud, community cloud, and hybrid cloud [12]. The public cloud offers general and public access to the cloud services and due to its open access, the security challenges for this model are critical because the resources are shared among multiple cloud consumers [17]. One simple example of a public cloud service is Google Drive that offers storage spaces located on the cloud for public users to access anytime and anywhere with internet access. The private cloud offers services to be deployed within an organization and is treated as an intranet functionality with the billing is subscription bases. Some examples include Amazon Web Services (AWS) Outposts, OpenStack, Microsoft Azure Stack, and others. The community cloud works in a similar way to the private cloud, but the model is exclusive to a group of organizations that share common interests, like compliance policies, security, and mission objectives. For instance, three companies shared the storage between them and therefore, reducing the installation costs if they shared a common infrastructure. Lastly, in the hybrid cloud model, the cloud infrastructure is set up of two or more types of cloud models (private, public, or community), each of which remains a separate legal entity, but are connected by standardized technology that enables the portability of data and applications [12].

In addition to the previous four deployment models, multi-cloud is a deployment model that deploys cloud services on multiple clouds and uses multiple cloud providers. One of the benefits of this deployment model is it allows redundancy, where resources are made available on different platforms to prevent data loss or a malware attack [18]. This study will be focusing on multi-cloud deployment model that will be explained further in the next section.

B. Multi-Cloud Computing

Multi-cloud computing refers to the adoption of multiple independent cloud architectures that act as a single cloud architecture, where applications are distributed across these clouds in discrete pieces [2]. As opposed to hybrid clouds, the components of a multi-cloud system are all distinct cloud systems rather than deployment models [19]. For example, a multi-cloud system is composed of two or more public clouds (see Fig. 2(a)), while a hybrid cloud system is a combination of a public cloud and a private cloud (see Fig. 2(b)).

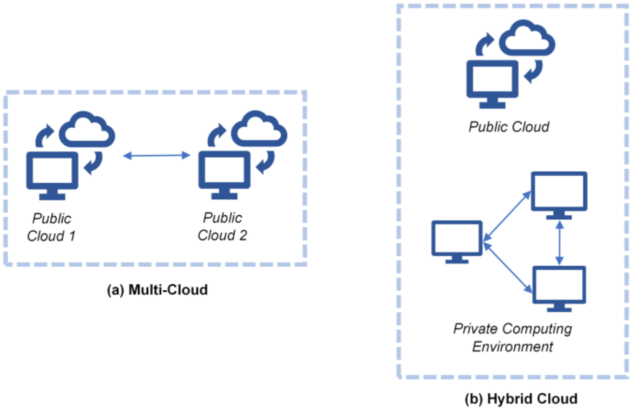


Fig. 2. Multi-cloud vs hybrid cloud deployment model.

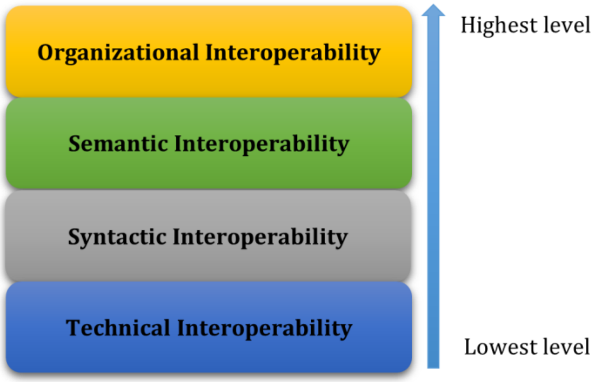
Varghese and Buyya [6] emphasized that the changes in cloud computing environment are inevitable, and this leads to the changes of cloud infrastructure. Many existing cloud applications are hosted on data centers of a single provider, and thus creating several challenges like high energy consumption by a single large data center, centralized cloud data centers are susceptible to single point failures, and more. Therefore, they suggested by adopting the multi-cloud strategy these challenges can be overcome. However, due to the heterogeneous nature of multiple cloud providers, adopting the multi-cloud strategy can be challenging because of problems like different APIs, data formats, networks, and storage architectures across providers. It eventually prevents clouds from becoming interoperable, from exchanging data to migrating applications from one cloud to another. Hence, cloud interoperability in multi-cloud platforms is a critical issue to be handled.

C. Cloud Interoperability

According to IEEE international standard vocabulary, interoperability is referring to the ability of two or more systems, products, or components to communicate information and utilize that information [4]. Therefore, in general, cloud interoperability is the ability of the systems to interoperate across different cloud platforms. Nogueira et al. [20] suggested that the term “cloud interoperability” describes the capacity to create applications that integrate resources from different cloud providers to capitalize the unique features offered by each cloud provider.

Achieving cloud interoperability across multiple platforms is a challenge to overcome due to the distinct offerings, technologies, and interfaces by different cloud providers. Thus, complicates the process of merging or shifting resources and services between these different cloud platforms. The general issue with cloud interoperability is that different providers do not utilize common APIs, which makes it difficult for users and applications to interact with the cloud [6, 7, 8, 9]. Additionally, Varghese and Buyya [6] have listed other common issues like diverse network and storage architectures across different providers, significant programming effort is needed to develop a multi-cloud application due to the format differences of multiple providers, and manual management of tasks due to the lack of common interfaces. On top of that, Birje et al. [9] added that it is hard to detect the fault in data transmission across applications and clouds. As a result of these issues, consumer’s acceptance and adoption of multi-cloud strategy is hampered [8].



Organizational Interoperability
Semantic Interoperability
Syntactic Interoperability
Technical Interoperability
Highest level
Lowest level

Fig. 3. Levels of interoperability and their correlations.

In general, most interoperability solutions are considered in four levels, with each level signifying a varying degree of compatibility and integration across cloud systems [10, 21, 22] (see Fig. 3). By having these interoperability levels, organizations can evaluate their ability to collaborate with various cloud providers and systems.

Based on Fig. 3, the interoperability levels and their correlations are described as the following:

1) Technical interoperability: This level is considered the lowest level of interoperability because it focuses on the technological facets of interoperability. For example, enabling the exchange of data and communication between multiple cloud systems across different platforms and infrastructures [10]. It covers technical aspects like interface specifications, data integration services, secure communication protocols, and data presentation [21].

2) Syntactic interoperability: In this interoperability level, it is often paired with the implementation of technical interoperability. This level is concerned with standardization of data formats to allow data to be exchanged among cloud systems [22]. It can be done by specifying the exact syntax and format of the data to be exchanged.

3) Semantic interoperability: This level is essential in interoperability between different systems as it tries to ensure that the meaning of the exchanged data can be understood and interpreted correctly [10]. In this level, users must share a common understanding of the data, metadata, and procedures used by various cloud platforms. To make data exchange and processing easier, standardized data models, ontologies, and metadata standards are frequently needed [22].

4) Organizational interoperability: This level addresses interoperability at a higher level of abstraction where it includes coordinating business processes, workflows, and automation across multiple cloud environments [21]. The interoperability at this level is dependent on the successful implementation of the previous interoperability levels: technical, syntactical, and semantic interoperability [22].

This study will be focusing on the semantic interoperability level in multi-cloud platforms. Multi-cloud strategy has developed as a strategic solution in the changing landscape of modern Information Technology (IT) infrastructure, enabling organizations to optimize performance, resilience, and cost-effectiveness by distributing their workloads over several cloud service providers. This paradigm shift reduces the risk of vendor lock-in and increases overall flexibility by allowing businesses to leverage the strengths of multiple cloud platforms. Thus, enabling semantic interoperability in a multi-cloud context is critical because semantic interoperability can improve application and data portability [23].

The term “semantic” is about understanding and making sense of words [24]. Semantic interoperability can be defined as the ability to exchange data in a meaningful way between two or more systems [25]. Semantic interoperability in multi-cloud platforms refers to the ability of disparate cloud systems and services to communicate seamlessly by having a mutual understanding of exchanged data and thus being able to use the data in a meaningful way. In a scenario where organizations opted for multiple cloud providers and services to meet their computing and storage needs, data exchange and processing can be a challenge due to unique data formats, structures, and policies offered by these providers and services. Semantic interoperability can address this challenge by guaranteeing that data and information can be exchanged effortlessly and understood across diverse cloud platforms without ambiguity and loss of meaning.

However, establishing semantic interoperability in the context of multi-cloud platforms has various challenges and limitations. At present, there are no industry-wide standards for semantic representation among various cloud providers [26]. But rather, most research activities and existing standard-setting entities produce various standardization efforts by resolving semantic interoperability problems from multiple perspectives. Another challenge of semantic interoperability is ensuring that performance, scalability, security, and other metrics are not compromised as these metrics are considered the quality attributes of any cloud systems [27]. For example, as the size and complexity of multi-cloud environments increase, ensuring semantic interoperability at scale becomes increasingly important because cloud computing services are scalable to meet the needs of the consumers. On top of that, implementing semantic interoperability is a complex task due to potential data model and ontology mismatches that can only be discovered during runtime [28]. It is due to the wide range of data models and ontologies utilized by various cloud services. Nonetheless, despite the challenges and limitations, research initiatives in semantic interoperability in multi-cloud platforms should continue for a variety of compelling reasons, including meeting evolving business needs, enhancing cross-cloud collaboration, mitigating vendor lock-in, optimizing resource utilization, and others.

III. Extended Cloud Computing Interoperability Taxonomy

A well-defined taxonomy for semantic cloud interoperability is necessary to provide a better understanding of the topic and address the relationships between different elements of a multi-cloud ecosystem. The extended taxonomy is built upon an existing cloud computing interoperability (CCI) taxonomy by Ayachi et al. [10]. There are three main axes in Ayachi et al.’s taxonomy:

- CCI factors: It is comprised of five principal factors of CCI solutions, which are CCI deployment level, CCI interaction patterns, CCI consumer-centric, CCI approach, and CCI time-line perspective.

- CCI scenarios: It refers to the scenarios match with the use cases that have been studied previously, which includes provider-side scenarios and client-side scenarios.

- CCI solutions: It presents existing research efforts on proposed solutions to enable cloud interoperability.

To extend the existing CCI taxonomy, this study explores four types of approaches for semantic interoperability based on the work in [29, 30], and they are:

1) Semantic approach: The semantic approach primarily focuses on the semantic or meaning of data. In the cloud landscape, the implementation of semantic approach is through semantic web technologies, which includes defining shared ontologies, vocabularies, and semantic models to enable uniform data interpretation across cloud platforms [31]. One of the challenges of this approach is due to distinctive ontologies, it is difficult to align them and ensuring effective semantic mappings between them [32].

2) Standard-based approach: In order to facilitate semantic interoperability when exchanging data, the standard-based approach places a strong emphasis on the establishment of common standards, protocols, and data formats. Several standardization efforts have been made by standardization bodies and organizations that cover standards concerning development, security, management, deployment, and other matters related to the cloud platforms. In the work by Kaur et al. [29], the authors provided a complete list of organizations with their standardization projects. However, the main issue with this approach is no standard has been accepted universally to solve the semantic interoperability problems [26].

3) Model-based approach: The model-based approach centers around developing and deploying shared models that represent data structure and semantics. These models are developed using common modeling languages such as Unified Modeling Language (UML) or domain specific languages. This approach, however, is limited by the ability to transition between models and actual solution implementations [33]. Cloud Modelling Framework (CloudMF), which uses model-driven engineering to facilitate provisioning and deploying multi-cloud applications, is an example of a model-based approach [34].

4) Open libraries and open services: This approach relies on the use of abstraction layers and adapters, which support interoperability in the context of multi-cloud platforms. Some of the well-known open libraries are Apache jclouds and Apache Libcloud. For open services, some examples include RightScale, enStratius, and Kaavo [29].

This study will further investigate the semantic approach to fulfil the study's goal. Recent existing literature was studied with an aim to identify the best semantic approach for facilitating semantic interoperable clouds. In a survey by Adhoni [23], the author studies three popular approaches for building semantic interoperability solutions: semantics, frameworks, and standards. He claims that common APIs and data models are key solutions in semantic approach. DiMartino et al. [35] provide three categories of cloud portability and interoperability solutions: framework and model-based approaches, adapting methodologies, and standardization efforts. They stated that using semantic modeling can be beneficial in three aspects of cloud computing: to define the functionalities of applications and quality-of-service details regardless of the platforms, creating models for representing metadata, and enhancing service descriptions between different platforms. Additionally, semantic web technologies like Web Ontology Language (OWL), Web Ontology Language for Service (OWL-S), Resource Description Framework (RDF), SPARQL Protocol and RDF Query Language (SPARQL), and The Semantic Web Rule Language (SWRL) can be used to address these three aspects. According to Kaur et al. [29], the two approaches that are typically recommended for achieving semantic interoperability are standardized APIs and data models. In addition to the two approaches already stated, the authors noted from existing research that using a broker can help ease semantic interoperability by making it easier for users to match their needs with those of cloud vendors. In a systematic review by Tomarchio et al. [30], the authors have concluded their review with four interoperability approaches: open standards, semantics, model-driven engineering (MDE), and open libraries and services. Under the semantics approach, the authors claimed that employing semantic technologies (e.g.: OWL, SPARQL, and SWRL) for achieving semantic interoperability is a proven solution. Bouzerzour et al. [36] discovers that the most adopted approach for achieving cloud service interoperability is the use of semantic technologies, which is from the client's perspective. They have identified existing works that use APIs, ontology, semantic engine, inference rules, and semantic annotation to achieve semantic interoperability. As per Ramalingam and Mohan [26], the semantic level for portability and interoperability of cloud services can be addressed with semantic cloud ontology (e.g.: OWL and OWL-S) and frameworks. The authors have reviewed existing efforts on interoperable and portable frameworks based on three semantic technologies (i.e.: OWL, WSDL, and RDF) and discovered that the representation of semantic cloud services and resources lacks a common or uniform approach.

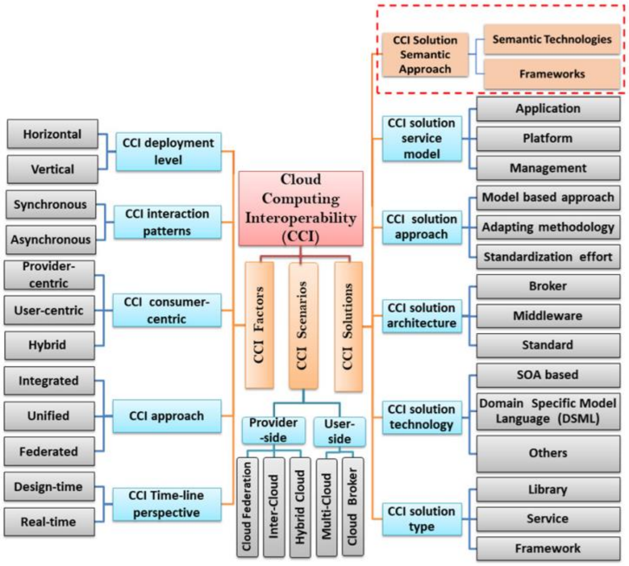


Fig. 4. Extended taxonomy for cloud computing interoperability.

As a result, considering the discussions in the preceding paragraph, this study suggests extending the existing cloud computing interoperability taxonomy by Ayachi et al. [10] by adding a sixth CCI Solution, namely CCI Solution Semantic Approach, with its two approaches which are Semantic Technologies and Frameworks. As shown in Fig. 4, they are depicted within a dashed rectangle. The details of CCI Solution Semantic Approach are discussed in the next subsections.

B. Semantic Technologies

In recent years, semantic technologies were frequently used to accomplish semantic cloud interoperability by providing a common platform for understanding and representing data and services in the cloud. Semantic technologies or sometimes called semantic web technologies comprised of a set of methods, tools, and standards that specifically deals with the meaning and interpretation of data to be understood by machines and applications [36]. Once data is interpreted correctly, these machines and applications can process the data more intelligently.

Current literature agrees that ontologies are the core element of semantic solutions [36, 26, 37, 38]. An ontology reflects domain knowledge, where the ontology classes are typically depicted using graphical models, as models are considered to have explicit semantics [39]. Ontologies are often expressed in a formal language that can be interpreted by both humans and machines, like RDF and OWL. Applications such as information retrieval, semantic web, natural language processing, data integration, and knowledge management all heavily rely on ontologies. They provide a shared understanding among various systems and users by offering an organized and standardized means of representing and exchanging knowledge. Al-Sayed et al. [40] stated that three fundamental components build up an ontology: classes (or concepts), objects (or instances), and properties (or relations). The class is used to describe a collection of instances with comparable characteristics. Properties are used to indicate relationships between instances (i.e.: object property) or between instances and data (i.e.: data-type property). Besides ontologies, other semantic technologies that have been employed for semantic cloud interoperability are semantic APIs, semantic engine, inference rules, and semantic annotations [36].

One of the recent works on ontologies for semantic interoperability is MIDAS-OWL, which is an ontology built on OWL to formally represent the interactions between SaaS and Data as a Service (DaaS) [41]. The proposed ontology connects data among DaaS by rewriting queries with semantically identical properties. PaaSport semantic model is another OWL-based ontology to best support an algorithm for semantic matchmaking and ranking, which suggests the most appropriate PaaS offerings to the application developer [42].

C. Frameworks

According to Partelow [43], the term "framework" has multiple definitions and purposes depending on the field in which it is used. Hence, the author provides several notable definitions of the term “framework” in different contexts and fields of study. It can be concluded that a framework is a methodical and well-structured collection of ideas, procedures, and tools that serves as a basis for creating and addressing complex problems. In software development, for example, a framework provides scaffolding for guiding the overall design and implementation of a system or a project. In addition to providing a pre-established structure and design patterns, frameworks frequently come with tools and libraries that facilitate the development process. Therefore, it offers several benefits to software development by helping to speed up the development process, ensure consistency across projects, promotes flexibility and easy to reuse the components.

Due to businesses’ growing interest in multi-cloud strategy and the need to ensure that the clouds are semantically interoperable, the solutions for semantically interoperable clouds demand an efficient framework. Frameworks that support semantic cloud interoperability, either through standardized interfaces or protocols, can be useful when implementing solutions within the context of a reference architecture. This is because reference architecture acts as a blueprint or template for the design and development of concrete architectures in IT domains. It is considered as a one-to-many relationship between a particular implementation and concrete architectures, and thus, it is an abstract representation of that architecture [44]. It outlines the recommended components, interfaces, and protocols to enable seamless interaction and integration between cloud platforms. It also includes guidelines and best practices for security, scalability, performance, portability, interoperability, and management [45]. Furthermore, Valle et al. [46] revealed that existing works did not explicitly propose techniques (e.g.: models, procedures, or other terminology) to characterize interoperability in reference architectures. As such, the authors emphasized the need to suggest novel approaches for modelling interoperability in reference architecture and for addressing interoperability during architecture instantiation. Therefore, this study suggests that building a cloud solution using a reference architecture is seen as a fitting approach that can contribute to a uniform representation of semantic-based solutions.

Existing prominent organizations and interest groups have produced their own reference architectures or open frameworks and made them freely available for generating further innovative solutions. These architectures or frameworks are offered as open standards that acknowledge the various needs for heterogeneous ecosystems and have been set as a rule for cloud interoperability. Bakshi and Beser [47] review eleven existing reference architectures from standards bodies, consortiums, and forums. In their review, they emphasized that the NIST Cloud Computing Reference Architecture (CCRA) has generic cloud computing architectural building blocks with five major actors (i.e.: Cloud Consumer, Cloud Provider, Cloud Carrier, Cloud Auditor, and Cloud Broker). Each actor has its own roles that are important for managing and providing cloud services in the cloud [45]. Other reference architectures are concerned more on the compliance towards standards, networking and communication services, security, cloud infrastructure, cloud management systems, and cloud interoperability.

Sana et al. [48] review nine existing reference architectures by NIST, Oracle, Distributed Management Task Force

(DMTF), International Business Machines Corporation (IBM), Hewlett-Packard (HP), Cisco, Cloud Security Alliance (CSA), Storage Networking Industry Association (SNIA), and Elastra. The authors concluded with three categories of reference architectures in cloud computing, and they are:

1) Role-based: In this form of reference architecture, the services and activities are matched to roles like cloud service providers and cloud consumers. The architectures of this kind of categories are NIST, Oracle, and DMTF.

2) Layer-based: This form of reference architecture maps services and activities to various architectural layers, including resource layers, application layers, service management layers, and security layers. The architectures of this kind of categories are IBM, HP, and Cisco.

3) Context-based: Reference architectures of this kind offer specific configurations to suit customer needs and make their adoption easier. The architectures of this kind of categories are CSA, SNIA, and Elastra.

Therefore, based on the review by Bakshi & Beser [47] and Sana et al. [48], out of all the reference architectures, the NIST CCRA and IBM CCRA can easily be adapted to this study. These two CCRAs can be a good reference and guideline as they systematically represent the reference architecture using role-based and layer-based architectures. Hence, a semantic interoperability layer can be added as part of the proposed reference architecture for semantic multi-cloud interoperability.

IV. Related Works and Discussion

Even though several cloud computing reference architectures have been produced by notable organizations and interest groups (e.g.: NIST, IBM, AWS, and Google Cloud), the main purpose of these reference architectures is to establish common frameworks and guidelines for industry-wide adoption. Typically, standard-based architectures are more stringent and directive to guarantee uniformity and compliance amongst implementations [49]. As a result, reference architectures have been produced by research initiatives to broaden the possibilities available to other researchers and industries. Research-driven reference architectures are often developed to explore new and test ideas, concepts, or technologies. They may not necessarily aim for immediate standardization.

Therefore, this study aims at reviewing recent (2018-2023) research-driven reference architectures for achieving semantic multi-cloud interoperability. Thirteen recent related works on semantic interoperability in multi-cloud platforms are selected, while the works in other domains such as the Internet-of-Things (IoT), Artificial Intelligence (AI), Blockchain, and big data are excluded. The review focuses on the authors' contributions and summarizes the findings based on the six CCI Solutions (as depicted in the extended cloud computing interoperability taxonomy in Fig. 4). The findings are reported in Table I.

As shown in Table I, it is found that most of the semantic approaches are using ontologies, like OWL, OWL-S, and RDF. This indicates that ontologies are proven solutions for semantic interoperability. Other than ontologies, APIs are among the popular solutions as they can serve as common interfaces between different platforms. The solutions are implemented as models, common architectures, and even toolkits. For the models, most works proposed semantic models that can be employed as part of a framework, stored as libraries, and adopted in semantic engine or semantic layer. For the common architectures, they are represented using layer-based, role-based, and hybrid of both. Apart from that, not every proposed solution aims to address interoperability across the three cloud service models (i.e.: IaaS, PaaS, and SaaS). Most solutions address interoperability independently for each of the three cloud service models. Existing works also prefer providing solutions based on broker and middleware architecture. Standards are the least preferred in developing research-driven architectures. SOA based are seen as the most favorable implementation of the solutions. It might be because broker and middleware architectures can effectively complement the SOA based implementation. The type of solutions produced is mostly frameworks and libraries. Finally, the limitations of each reviewed work are presented in the last column of Table I.

TABLE I. Review of Recent Related Works

Related Works (2018-2023)	**CCI Solutions**						**Limitations**
	CCI Solution Semantic Approach	***CCI Solution Service Model***	***CCI Solution Approach***	***CCI Solution Architecture***	***CCI Solution Technology***	***CCI Solution Type***	
FCLOUDS framework to achieve semantic interoperability in multi-clouds [50]	API, Open Cloud Computing Interface (OCCI)	Application	Model based approach	Middleware	DSML	Framework	Limited to the OCCI standard.
A common interoperable model for cloud computing [48]	API, Architecture is a hybrid of role-based & layer-based	Application, Platform, Management	Adapting methodology	Standard	SOA based	Framework	API is insufficient for semantic understanding.
PaaSport semantic model: An ontology for a platform-as-a-service semantically interoperable marketplace [42]	OWL, RDF, API, Service Level Agreement (SLA), Semantic model (layer-based)	Platform	Model based approach	Broker	SOA based	Service	The solution is specific to PaaS offerings.
CloudLightning Ontology (CL-	OWL, Semantic engine	Platform, Management	Model based approach	Middleware	SOA based	Library	Currently, the system cannot evaluate

Related Works (2018-2023)	**CCI Solutions**						**Limitations**
	CCI Solution Semantic Approach	***CCI Solution Service Model***	***CCI Solution Approach***	***CCI Solution Architecture***	***CCI Solution Technology***	***CCI Solution Type***	
Ontology): An ontology for heterogeneous resources management interoperability and HPC in the cloud [51]							performance, resource utilization, and energy consumption.
PacificClouds: A flexible microservices based architecture for interoperability in multi-cloud environments [52]	API, SLA, Microservice	Management	Adapting methodology	Broker	SOA based	Service	API is insufficient for semantic understanding. The implementation of semantic SLA is not clearly stated.
EasyCloud: A rule-based toolkit for multi-platform Cloud/Edge service management [53]	API, toolkit	Application	Adapting methodology	Broker	SOA based	Library	API is insufficient for semantic understanding. The solution is specific to SaaS offerings.
Cloud interoperability based on a generic cloud service description: Mapping OWL-S to GCSD [54]	Mapping rules (OWL-S), Pivot model (mediator for transforming different cloud service description languages to the GCSD).	Application.	Model-based approach.	Middleware.	DSML	Library	The solution is specific to SaaS offerings.
EasyCloud toolkit to effectively support the creation and usage of Multi-cloud Systems (MSs) [55]	API, toolkit	Application	Adapting methodology	Broke	SOA based	Library	API is insufficient for semantic understanding. The solution is specific to SaaS offerings.
Semantic Interoperability Framework for IAAS Resources in Multi-Cloud Environment [56]	RDF, OWL, SPARQL, Ontology mapping	Management	Model-based approach	Broker	SOA based	Framework	The solution is specific to IaaS resource management.
MIDAS: A domain specific language to provide middleware for interoperability among SaaS and DaaS/ DBaaS through a metamodel approach [57]	API, Semantic mapping, Structured Query Language (SQL) or Not Only SQL (NoSQL), Metamodel (Eclipse Modeling Framework (EMF)	Application	Model-based approach	Middleware	DSML	Framework	Limited to Middleware for DaaS/DBaaS and SaaS (MIDAS) architecture.
Cloud Enterprise Resource Planning (ERP) API Ontology [58]	OWL	Application, Platform, Management	Model-based approach	Middleware, Broker	SOA based	Framework	No ontology evaluation in a practical application for business data migration between cloud ERP providers.
PaaS and IaaS Resource Semantic Interoperability Framework (extended from their previous work) [59]	RDF, OWL, SPARQL, Ontology mapping	Platform, Management	Model-based approach	Broker	SOA based	Framework	The solution is specific to PaaS and IaaS resource management.
Cloud Interoperability Pivot Model (CIPiMo) for cloud service interoperability [60]	Mapping rules (WSDL and OWL-S), Pivot model (mediator for transforming different cloud service description languages to the GCSD)	Application	Model-based approach	Middleware	DSML	Library	The solution is specific to SaaS offerings.

Even though several research efforts have been done related to the topic of this study, it is found that existing works on reference architectures for semantic multi-cloud interoperability are still not in a mature stage and prompting for future works. Some research gaps that can be identified from the review are as the following:

- The integration of semantic-based solutions (e.g.: semantic model) within a framework (e.g.: reference architectures) is not explicitly and uniformly represented. This is an essential consideration in current research given the growing interest in multi-cloud strategy and the fact that multi-cloud platforms are inherently diverse.
- Cloud interoperability solutions are not inclusive of three cloud service models (i.e.: IaaS, PaaS, and SaaS). Most of the works address interoperability independently across the three cloud service models. It is important to consider cloud interoperability vertically and horizontally across the three cloud service models.

By identifying the research gaps in recent related works, this study aims to propose future works that attempts to solve these problems. Therefore, the following are suggested for future works of this study:

- To identify necessary requirements for developing ontologies and reference architectures.
- To develop a semantic model utilizing ontologies and other semantic technologies in order to facilitate semantic interoperability in data exchange across various cloud platforms.
- To develop a reference architecture for semantic multi-cloud interoperability by adapting a hybrid of role-based and layer-based architectures with an extended semantic interoperability layer. In addition to that, there is a need to identify the required roles (actors) and layers for the proposed reference architecture.
- To implement the proposed semantic model and reference architecture against use cases in multi-cloud platforms.

V. Conclusion

Semantic interoperability in multi-cloud platforms enables uniform interaction and interpretation of data and applications across diverse platforms. However, achieving semantic interoperability remains a challenge, and research efforts in this area are ongoing. Although professional groups or organizations have developed standard solutions for semantically interoperable clouds, research-driven initiatives are still required to enhance semantic interoperability by delivering uniform blueprints.

This study explores the significance of multi-cloud computing in today’s dynamic and complex IT landscape. As organizations increasingly rely on cloud services for their diverse computing needs, understanding the implications and benefits of adopting a multi-cloud strategy becomes paramount. The study investigates how multi-cloud environments can address the evolving requirements of scalability, flexibility, and other requirements while navigating interoperability concerns. By examining the recent related works on two main areas, which are semantic interoperability and reference architecture, this study aims to provide a strategic solution in the form of a reference architecture for semantic interoperability in multi-cloud platforms. Furthermore, the review on recent related works reveals that the lack of widely accepted semantic models and frameworks indicates that the field of study is still in its infancy and needs further development.

Therefore, two contributions have been proposed in this study, and they are:

- An extended CCI taxonomy by adding the semantic approach which consists of semantic technologies and frameworks that are considered crucial approach to enable an effective semantic interoperability in multi-cloud platforms. This taxonomy can serve as a knowledge base for future researchers and promote consistency across different research studies.
- A review of recent related works on semantic interoperability in multi-cloud platforms, highlighting the current CCI solutions employed by the authors in their proposed work. The review includes the limitations of each work, and thus prompting for future work. The result of this review is not only important for studying the current technologies used for semantic interoperability, but also for identifying the research gaps that may present in current research.

Pancreatic Cancer Detection Through Hyperparameter Tuning and Ensemble Methods

Koteswaramma Dodda, Dr. G. Muneeswari
School of Computer Science and Engineering, VIT-AP University, Amaravati 522237, India

Abstract—**Computing techniques have brought about a significant transformation in the field of medical research. Machine learning techniques have facilitated the analysis of vast amounts of data, modeling of complex scenarios, and the ability to make well-informed decisions. This presents an opportunity to develop reliable and effective medical system implementations, which may include the automatic recognition of uncertain issues related to health. Currently, significant research efforts to be directed towards the prediction of cancer, particularly focusing on addressing the various health complications caused by this disease, which can adversely impact multiple organs within the body. Pancreatic Cancer (PC) stands out as a highly lethal form of tumor, with a rather discouraging global five-year survival rate of approximately 5%. The truth behind the early detection increases the survival rate and it also helps the radiologists to give better treatment to those who are affected at early stages. Creatinine, LYVE1, REG1B, and TFF1 are urine proteomic biomarkers that offer a promising non-invasive and affordable diagnostic technique for detecting pancreatic cancer. In this study, a novel model that combines gridsearchCV technique to search and find the optimal combination of hyperparameters for a random forest classifier. In this research a new ensemble method to enhance the performance for classification of pancreatic cancer and non-cancer by using urinary biomarkers which is collected from Kaggle. The implemented model achieved better results of Accuracy 99.98%, F-1 score 99.98, Precision 99.98, and Recall 99.98.**

Keywords*—Pancreatic cancer; Machine learning (ML); urinary biomarkers; grid search hyper parameter tuning; Random Forest (RF)*

I. Introduction

According to cancer statistics, Pancreatic Cancer (PC) is predicted to overtake all other causes of death globally in 2022 [1]. The pancreas is positioned posterior to the stomach and anterior to the spine, with the liver, spleen, and gallbladder encircling it. Pancreas releases hormones into the digestive tract to regulate blood sugar levels. The pancreas, positioned behind the lower stomach, is responsible for both regulating blood sugar levels through hormone production and releasing digestive enzymes. When cancer forms in the tissue of the pancreas, it is known as pancreatic cancer. This is due to its location in stomach which is becoming a difficult task for clinicians (researchers) to find PC. Most instances of Pancreatic Cancer occur in those over 45 like additional risk condition, specific genetic mutations, chronic pancreatitis, diabetes, and advancing age.

Now-a-days, PC has become more prevalent [2]. At initial stages Pancreatic cancer often remains asymptomatic. Symptoms including icterus back or bellyache pain, decreased appetite, unexplained weight loss, and digestive issues may appear as the condition worsens [3]. Hence, there exist significant variations in the structure and presentation of the pancreas among different individuals. Among the various types of PC, Pancreatic Ductal Adenocarcinoma (PDAC) is leads to dead. Pancreatic Cancer, which currently lacks a cure, ranks is among the most severe diseases with one of the poorest survival rates. PC stands out for having the lowest survival rate nearly five years of any cancer, primarily due to its late-stage diagnosis, which stands at 11% [1]. Because early indicators are rare, pancreatic cancer (PC) is infrequently detected in its early stages [4], [5]. As a result, both surgical interventions and treatments involving chemotherapy and radiation are generally ineffective in combating PC [6]. To enhance knowledge about the risk of pancreatic cancer, medical professionals advise patients to undergo additional diagnostic measures, such as biomarker testing and medical imaging scans [7]. There are number of difficulties are reported for imaging early pancreatic cancer. The expense associated with radiological image screening is considerable, making it an improbable choice for widespread pancreatic cancer (PC) screening.

Consequently, researchers are turning their attention towards the utilization of biomarkers as an initial approach to early PC detection. The rapid advancements in genomic sequencing and its diverse techniques, including proteomics, epigenomics, and transcriptomics, generate vast amounts of multi-omics data. Biomarkers in PC serve critical roles in early identification, prognosis, treatment decision-making, and research, resulting in more effective and customized care for patients suffering from this difficult disease. The essential biomarkers that play a pivotal role in the early identification of PC can be found in bodily fluids, which encompass cyst fluid, pancreatic juice, and bile. However, gathering these fluids necessitates invasive methods like surgery or endoscopy. In contrast, blood stands out as a low-risk, cost-effective, and easily repeatable source of tumor biomarkers [8]. Blood contains a wealth of proteomic biomarkers, including Carbohydrate Antigen 19-9 (CA19-9), and transcriptomic biomarkers like Circulating Micro RNAs (miRNAs), which can be detected through RNA sequencing. [9].

Historically, blood has served as the principal reservoir for these biomarkers, although urine presents itself as a viable alternative biological fluid. It makes it simple to collect a non-invasive sample in large quantities and do repeated measurements. As of right now, there is no reliable biomarker for detecting PDAC at early stage. The single biomarker used in clinical practice, serum CA19-9, is used largely as a prognostic indicator and to track therapy effectiveness because it is neither specific nor sensitive enough for screening [10]. Urine stands as a hopeful substitute body fluid for the exploration of biomarkers. It proves to be an excellent option for broad diagnostic screening due to its non-invasive and cost-effective nature, as patients can readily provide ample samples [11]. Urine includes proteome indicators much like blood does.

A three-protein biomarker panel that was presented by Radon et al. in 2015 [12] suggests that urine samples can be utilized to diagnose people with early-stage PC. LYVE-1, TFF1, and REG1A were investigated putative proteomic biological markers. In a smaller study, scientists investigated that the miRNA in urine is also used for diagnosis of pancreatic ductal adenocarcinoma at early stage. By substituting REG1B for REG1A in 2020, Debernardi et al. [13] discover an additional protein biomarker panel. Furthermore, because of the comparable symptoms in early-stage PDAC cases, they can differentiate between cases of PDAC and benign hepatobiliary disease, which can be challenging. This analysis takes into account four important urine biomarkers: TFF1, LYVE1, REG1B, and creatinine. Creatinine is likely employed to assess function of kidney. Moreover, Lymphatic Vessel Endothelial Hyaluronan Receptor 1 has associations with tumor metastasis, REG1B with pancreatic regeneration, and Trefoil Factor 1 with the regeneration and urinary tract repair. The analysis of computer-aided diagnosis (CAD) systems has seen the emergence of ML and DL techniques, which serve as the foundation for handling a wide range of information about patients, including radiology, pharmacogenetics, and biological markers.

In the healthcare sector, machine learning (ML) has become a game-changing technology that is revolutionizing the way medical data is analyzed, diagnoses are made, and treatments are given. Random forest serves as a widely employed ML algorithm for addressing both Regression and Classification tasks. GridsearchCV, on the other hand, is the method used for fine-tuning hyperparameters to identify the most effective settings for a given model. AdaBoost, as a potent ensemble learning algorithm, harnesses the collective strength of multiple weak learners to construct a resilient predictive model.

The following is the paper organizational structure. In Section II, a number of related works are addressed. The proposed system methodology is examined in Section III. In Section IV the experimental results are discussed. Finally, Section V concludes the proposed research paper.

II. Literature Review

In the study, Lee et al. [14] detected miRNA indicators released into the bloodstream. The developed diagnostic system for PC by choosing 39 miRNA markers using a penalized support vector machine (SVM) is uses a smoothly trimmed absolute deviation. The model's accuracy was 93%, and AUC of 0.98.

Long et al. [15] identified and validated oncogenic indicators of pancreatic cancer at the genome level using data mining and multi-omics data. Random forest (RF) technique was used to build their prediction system because it is a simple methodology. After effectively uncovering the unseen biological information from multi-omics data, Scientists have pinpointed dependable biomarkers for the early observation, prediction, and diagnosis of PC. The suggested Random Forest (RF) model achieved an impressive 96% of efficiency.

Debernardi and colleagues [16] identified diagnostic miRNAs for detecting pancreatic ductal adenocarcinoma (PDAC) based on urine samples at early stage. The discriminatory potential miRNA biomarkers were identified using LR algorithms. The suggested models yielded the most favorable outcomes, demonstrating 83.3% sensitivity, 96.2% specificity, with AUC 0.92.

Exosomes were used by Ko et al. [17] to diagnose PC utilizing machine learning and nanofluidic technologies. In order to assess unrefined clinical samples, they created a multichannel nanofluidic device. Tenth, to aid in the definitive diagnosis of cancer patients, these exosomes are subjected to the linear discriminant analysis (LDA) technique. The AUC for this prediction model's classification of pancreatic tumours against healthy samples was 0.81.

Lee et al. [18] reported the construction of a prediction model for the people who are in advanced stage from population-based research to find at early stage. The diagnostic methodology acknowledged that will aid in educating the medical community about the risk of pancreatic cancer. NHIRD, Taiwan's health insurance database, served as the foundation for this study. Combination of four models is used to create predictive model: voting ensemble, ensemble learning, deep neural networks, and logistic regression (LR). The model’s AUC ranged from 0.71 to 0.76, and its accuracy was between 73 and 75%.

To identify PC at the localized stage, D Agarwal et al. [19] proposed highly sensitive nano biosensors for protease/arginine detection. The hard hierarchical decision structure (HDS) and soft hierarchical decision structure (SDS) beat traditional multi-class classification methods, achieving an accuracy score of 92%.

Thanya et al. [20] employs color conversion and anis lateral filters on pancreatic cancer CT images from a PCCD database. FK-NNE segmentation and features based on histograms are extracted. A DCNN combined with a DBN classifier classifies pancreatic cell tumors as benign or malignant. The accuracy climbed to 99.6%, with a sensitivity of 100% and a specificity of 99.47%.

1D CNN-LSTM model accurately categorizes patients with pancreatic cancer, outperforming competing models in assessment measures by 97%, Karar et al. [21] based on urine biological markers. The study evaluates several risk prediction algorithms in order to create PancRISK, a biomarker-based risk score. Out of 379 patients were categorized into training and testing sets using urine biomarkers. When a number of machine learning algorithms were compared, none of them performed noticeably better than the others. The PancRISK score was derived using the logistic regression model; however, it could be enhanced by include the PDAC biomarker CA19-9. Currently, Blyuss et al. [22] are investigating the utility of PancRISK for non-invasive patient risk assessment in pancreatic cancer.

In a separate investigation, Jiao et al. [23] delved into the connection between ITGA3 expression in the pancreas and the observations and unhealthy features of patients with pancreatic cancer. Their methodology encompassed data mining and the application of Chi-squared tests to evaluate associations. Their findings unveiled a notable elevation in ITGA3 expression in pancreatic cancer patients, showcasing correlations with microanatomy, stage, and recurrence. Most notably, heightened ITGA3 expressions analogous with diminished persistence rate are especially to find cancer at earlier stage.

In their study, Liu and colleagues [24] investigated 11 long non-coding RNAs (lncRNAs) associated with pancreatic cancer and identified plasma ABHD11-AS1 as a probable biomarker for the detection of pancreatic cancer. They observed that combining ABHD11-AS1 with CA199 improved the efficiency of pancreatic cancer diagnosis compared to using ABHD11-AS1 by itself, especially for early tumor detection. These findings play a potentially important role in lncRNAs for the diagnosis of cancer.

Iwano et al. [25] proposed to develop a PDAC-symptomatic model using serum anabolism from Japanese patients. Utilized liquid chromatography/electrospray ionization mass spectrometry, Researchers developed a diagnostic algorithm based on machine learning. By combining primary metabolites and phospholipids, they enhanced the accuracy of cancer diagnosis and the area under the receiver operating characteristic curve. The incorporation of 36 statistically significant metabolites as a combined biomarker led to a significant 97.4% improvement in results. This system offers an efficient screening approach for pancreatic ductal adenocarcinoma (PDAC).

Discovered by Takahashi et al. [26] Long noncoding RNAs (lncRNAs) play a role in the epithelial-mesenchymal transition (EMT) in pancreatic ductal adenocarcinoma (PDAC). A lncRNA, known as HULC, has been identified as a future biomarker for PDAC. HULC was observed to have elevated expression levels, induced by transforming growth factor-β, in both PDAC cells and their extracellular vesicles (EVs). Suppression of HULC led to reduced invasion and migration of PDAC cells by inhibiting the process of epithelial-mesenchymal transition (EMT). The encapsulation of HULC in EVs may hold promise for aiding in the diagnosis of human PDAC. PDAC poses a significant threat as it is corelated with mortality. Current diagnostic tests and prognostic tests are limited due to the lack of reliable biomarkers. The analysis of methylation in cell-free DNA (cfDNA) holds great promise as a non-invasive method for detecting specific patterns related to disease in pre-neoplastic lesions and chronic pancreatitis.

Brancaccio et al. [27] present a review that delves into the benefits and challenges of cfDNA methylation studies, as well as the latest developments in identifying early diagnostic or prognostic biomarkers for Pancreatic Cancer. In the provision of patient care with invasive malignancies, biomarkers are crucial. Pancreatic Cancer with a dismal prognosis is because of its advanced stage and lack of available treatments. The lack of predictive biomarkers and proven screening tools for early diagnosis and targeted therapy exacerbates this. In the last two decades, there has been a growing body of information on biomarkers related to pancreatic cancer. The limited sensitivity and specificity of CA 19-9 have hindered its exclusive approval as the sole biomarker for diagnosis and evaluating treatment response up to this point.

Hasan et al. [28] cover emerging and existing biomarkers in this article that may be vital for early diagnosis, prognostic, and predictive indications of pancreatic cancer. CD73, a protein that attenuates tumor immunity, has been studied for its role in PC.

Chen et al. [29] found that patients with higher CD73 expression had poorer overall survival and disease-free survival. CD73 was also associated with reduced methylation and higher PD-L1 expression. This suggests that CD73 may be a biomarker for response to anti-PD-1/PD-L1 treatment in PC. Blockade of CD73 could be a promising therapeutic strategy for PC.

The results that we have seen in the literature indicate that different biomarkers are employed to identify PC. Numerous publications present systems for PC categorizations and early detections is done by using noncoding RNSs and the biomarker CA 19-9 as input. Th3dese systems are based on various machine learning and deep learning techniques. Urine proteome indicators are the main focus of this proposed system.

III. Methodology

PC is a devasting disease with a high risk rete, predicting at early is very crucial for patient.Accurate diagnosis is improve the chances to give perfect treament,recently ML techniquies have gained prominence in the health sector. By consider the publicly available dataset urinary biomarkers related to PC from Kaggle repository. To create any model frist step is the collection and preprocessing of data. After preprocessing step, data is splitted as training data and testing data(80% & 20%) .The parameters which influences the performance of the model are tuned by the hyperparameter tuning method gridsearchCV, these parameters are pass to the model as input data.GridsearchCV helps to fine-tune the parameters and optimizing its performance.A hybrid model is developed for classification of PC, with random forest and Ada Boost giving a promising approach to enhance the accuracy of diagnosis.

The created hybrid model demonstrates the major influence on early PC detection and, in the end, enhances patient outcomes in the PC battle. Fig. 1 shows the symbolic representation for the suggested pancreatic cancer classification system.

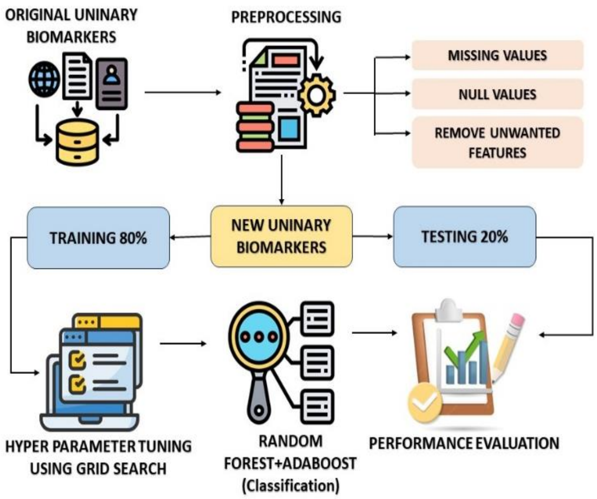

Fig. 1. Proposed pancreatic cancer classification system.

A. Dataset Description

The urinary biomarkers related to PC dataset are collected from the publicly available data repository Kaggle. Table I shows the urinary biomarkers dataset attributes and information. The data collection, supported by the biomarker panel, involved 590 urine samples gathered from various sources, including the University College London, the Barts Pancreas Tissue Bank, the University of Liverpool, Cambridge University Hospital, and the University of Belgrade, the Spanish National Cancer Research Centre. These samples comprised control samples 183, from individuals with 108 benign hepatobiliary conditions (including 119 from chronic pancreatitis patients), and 199 from individuals managed with pancreatic ductal adenocarcinoma (PDAC). The dataset has total 14 columns and 509 rows. The columns reflect numerous cancer risk factors, whereas the rows represent the study samples. The sixteen variables used in this data collection are as follows: the sample's ID. A cohort, which is a distinctive string used to identify each participant. Samples from cohort 1 have been utilized before. Samples from Cohort 2 have been added, and they are from the same above-mentioned sources. Sample_ Origin from where the sources are collected. Age, Sex, Diagnosis, Stage, Benign_Sample_Diagnosis, Blood plasma levels of the monoclonal antibody CA 19-9 are typically high in people with pancreatic cancer. There were just 350 subjects examined. Creatinine serves as an indicator of renal function in urine. Moreover, the presence of Lymphatic Vascular Endothelial Hyaluronan Receptor 1 (LYVE1) protein was identified in urine, indicating a potential significance in tumor metastasis. Additionally, the study quantified the urinary levels of proteins appended to pancreatic regeneration, specifically REG1A and REG1B. Furthermore, the urinary levels of Trefoil Factor 1 (TFF1), which might be related to the urinary tract, were assessed in a cohort of 306 patients.

Pancreatic cancer is categorized into stages such as IA, IB, IIA, IIB, III, and IV. However, in the dataset some input variables can be designated as irrelevant. Specifically, "sample id," automatically generated by Neural Designer, "Sample origin" signifies the source of patient samples, having no bearing on the ultimate diagnosis. "Stage" is a parameter exclusive to cancer patients. "Patient cohort" doesn't show any influence on the Sample Diagnosis, and "benign sample diagnosis" is an unrelated feature to the final sample diagnosis.

TABLE I. URINARY BIOMARKERS DATASET ATTRIBUTES AND INFORMATION

S. No	Feature	Specifies
1	Sample_id	Patient's id
2	Patient_cohort	To identify each participant
3	Sample_Origin	Where the patient samples came from
4	age	Patient's age, in years
5	sex	F-female M-male
6	diagnosis	Patient is having cancer
7	stage	Cancer stages IA, IB, IIA, IIIB, III, and IV
8	Benign_Sample_Diagnosis	Patient's not having cancer
9	plasma_CA19_9	Blood plasma levels of antibody CA_19-9
10	creatinine	Urine indicator of renal function
11	LYVE1	A protein in urine
12	REG1B	Pancreatic regeneration associated protein
13	TFF1	Urinary Trefoil Factor 1

The dataset consists of urine samples (590), classified into three variant groups of patients. These groups include healthy stage with 183 samples, and individuals with Stage of Benign and Stage of PDAC cases, 208 and 199 samples, respectively. Table II is a visual representation of this breakdown.

TABLE II. CHARACTERISTICS OF THE CLINICAL DATASET COMPRISING SAMPLES OF URINE FROM INDIVIDUALS WITH PANCREATIC CONDITIONS IN PROPOSED STUDY

Health Condition	Number of Sample	Gender	Range of age (median value)
Healthy stage	183	F (115) M (68)	26 – 89 (58) 30 – 87 (55)
Stage Benign	208	F (101) M (107)	26 – 82 (53) 29 – 82 (55)
Stage PDAC	199	F (83) M (116)	42 – 88 (68) 29 – 87 (67)

Fig. 2 shows the gender distribution of patients in different stages whereas Fig. 3 shows PC stage gender distribution on dataset.

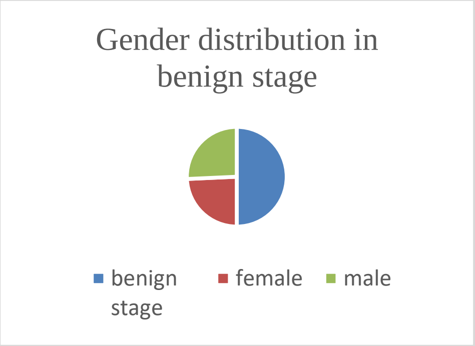

Fig. 2. Benign stage gender distribution on dataset.

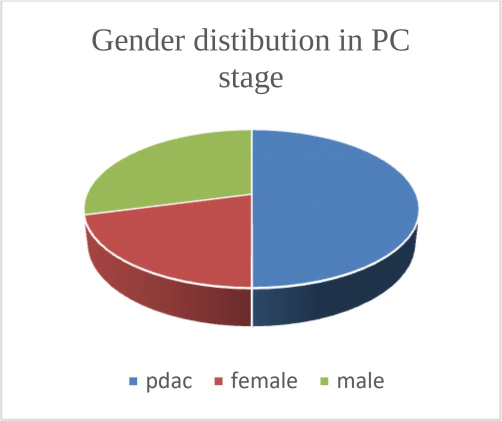

Fig. 3. PC stage gender distribution on dataset.

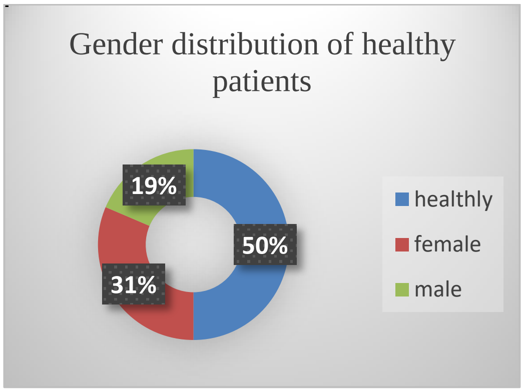

Fig. 4. Healthy patients gender distribution on dataset.

B. Preprocessing

Preprocessing is a crucial preliminary stage in data analysis. The situations where the dataset contains irrelevant, incomplete (missing), or inconsistent data, preprocessing becomes necessary. The preprocessing stage typically includes the following steps:

1) Data cleaning: This involves addressing missing values, which can be done by either omitting the entire data entry, replacing the missing value with a specific value, or employing strategies to manage null values. Inconsistencies in the dataset may also be resolved manually.

2) Data transformation: Converting data from one format to another format is called data transformation. When required, numerical data may undergo transformations for categorical variables, one-hot encoding is often employed to convert them into a suitable format for analysis.

In this study at data cleaning step the number of unwanted data, null data and missed data were cleaned. At transformation step one-hot encoding is used to covert char data into integer data.

Fig. 5 displays the graph that illustrates the correlation between each feature in the dataset and shows the degree of dependence between a variable to other variable used in the study. According to the color scale, the correlation relationship between the columns close to white is high, while the correlation relationship decreases gradually in the colors towards red.

C. Random Forest (RF)

RF is one of the best classification algorithms in Machine-learning. Instead of relying solely on output of a one decision tree, the random forest algorithm aggregates predictions from multiple decision trees then ultimately makes predictions based on the majority vote among these individual tree predictions. Fig. 6 shows random Forest classification. RF is a classification method that consists of a collection of decision trees, each built on different subsets of the dataset. By aggregating the results from these trees, often by taking their average, it enhances the predictive accuracy for the given dataset. But, the classification of random forest shows the low accuracy for the given dataset.

In RF classification Gini index is decide how nodes are distributed on a decision tree branch. It determines the branches is more likely to occur and find the class and probability of a node in each branch.

$$\text{Gini} \ = 1 - \sum_{i=1}^{j} f(i)^2 \qquad (1)$$

f is the class of frequency in the dataset.

c is the number of classes.

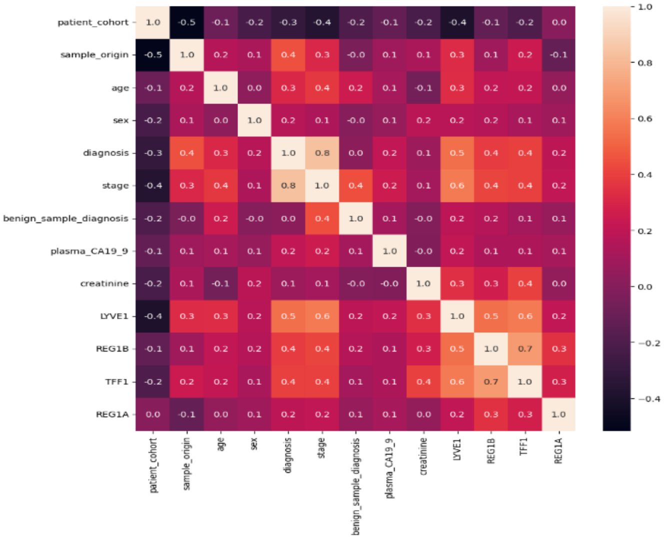

Fig. 5. Matrix of correlation.

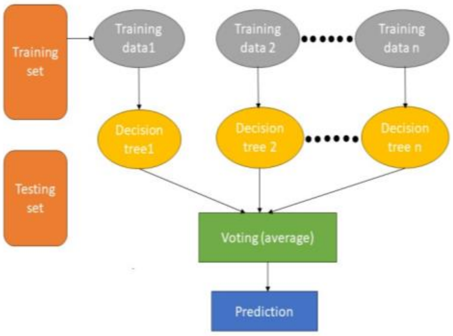

Fig. 6. Random forest classification.

There is another way to determine how nodes branch in a decision tree are determined is entropy. Entropy determines which branch the node should follow by analyzing the probability of a specific outcome. Its calculation involves the use of a logarithmic function, making it more mathematically sophisticated than the Gini index.

$$\text{Entropy } = \sum_{i=1}^{c} -p_i \log(p_i) \tag{2}$$

where, the p_i is the probability of randomly selecting a node in class i.

Information gain is a metric used to identify the most informative features in a dataset, and it is depended on the entropy value. It quantifies the difference in entropy before and after a data split and, in doing so, measures the impurity or disorder within class elements. Essentially, information gain helps determine which feature, when used to split the data, leads to the greatest reduction in uncertainty or entropy, making it a valuable criterion for feature selection in decision tree-based algorithms.

Information Gain= Entropy before splitting- Entropy after splitting

Consider the following pseudo code for RF classification.

Pseudo code of random forest classification.

Step 1: F features are select from the feature set randomly.

Step 2: In F each of x.

- Find the Gain.

$$\text{Gain } (s,x) = E(s) - E(s,x)$$

$$E(s) = \sum_{i=1}^{c} -f_i \log(f_i)$$

$$E(s,x) = \sum_{c \in X} P(c)E(c)$$

where E(s) two classes entropy, E(s,x) is the entropy of feature x..

- Choose the node with the highest information gain, denoted as y.
- Divide the node into sub-nodes.
- To build the tree, iterate through steps a, b, and c until the minimum required number of samples for splitting is reached.

Step 3: To create a forest consisting of n trees, replicate steps 1 and 2 n times.

The performance of RF model with all selected features is 83%. To improve the classification accuracy hyper parameter tuning is applied to evaluate the optimal parameters of the model. To find the best hyper parameters to build a single model which is suitable to improve the RF classification Grid search CV is one of the suitable hyper parameter techniques for the RF classification.

D. Hyperparameter Tuning

Hyperparameter tuning may be automated with the use of GridSearchCV, which also improves model performance and does away with manual trial-and-error. Fig. 7 shows grid search across two parameters. Grid Search combines each of the supplied hyperparameters and their values in a different way, calculates the performance of each combination, and then chooses the hyperparameters with the best value.

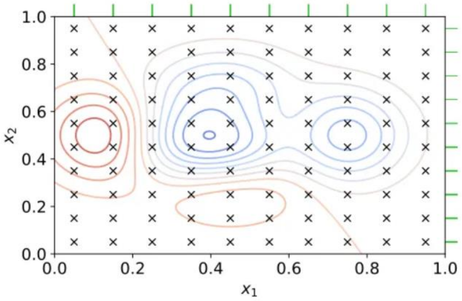

Fig. 7. Grid search across the two parameters.

Within the scikit-learn library's model_selection module, you can find a function known as GridSearchCV ().

Initiating the execution can be done by creating a GridSearchCV () object. In the scikit-learn model_selection class, there exists a function known as GridSearchCV (). The process begin can be begin by creating a GridSerachCV () object.

Clf=GridSearchCV (estimator, param_grid, cv, scoring).

The necessary four inputs are estimator, param_grid, cv, scoring.

These arguments are explained as follows:

1) estimator: A scikit-learn model

2) param_grid: A dictionary associating parameter names with lists of parameter values.

3) cv: A numeric value that specifies the number of folds in K-fold cross-validation.

4) scoring: Performance measure.

By using the GridSearchCV () prepare a best random model for predicting the pancreatic cancer efficiently. To obtain the better performance develop a hybrid model with the grid search cv random model with the help of Boosting algorithms. Ada Boost is one of the best boosting algorithms to improve the classification performance.

E. Boosting Algorithm

Ada Boost is one of the boosting algorithm in this one common estimator is used to learn for the decision trees in every split. By using with the splits, it builds a model with same weights in all levels if there are any high weights are assigned then those are called wrongly classified. In this context give the importance for high weights training with another model until reaches the minimum error. The argument is that while AdaBoost can be used independently of decision trees, it is frequently combined with them in reality because of the advantages that stumps have over other weak learners.

The mathematical summary of Ada Boost algorithm as follows:

1. Initializing Weights

   Dataset with samples of N, give each data point weight with $w_i = 1/N_s$.

   For each m=1 to M:

   Dataset sampled by the weight $w_i^{(m)}$ to attain training samples T_s

For each datapoint, AdaBoost initializes a weight of $1/N_s$. Once more, the weight of a datapoint indicates the likelihood that it will be chosen during sampling.

2. Training Weak Classifiers

   For all the training samples T_s , fit a classifier X_m

   X_m is a weak classifier then trained using the training dataset.

3. Here the AdaBoost algorithm is begins. The weights are updated as follows

$$\epsilon = \frac{\sum_{yi \neq K_m(x_i)} w_i^{(m)}}{\sum_{yi} w_i^{(m)}} \tag{3}$$

y_i is target variable ground truth value

w_i^m is the sample weight i at m^{th} iteration

the weight is updated at certain iteration m

$$\alpha_m = \frac{1}{2} \ln \frac{1-\epsilon}{\epsilon} \tag{4}$$

$$w_i^{(m+1)} = w_i^{(m)} e^{-\alpha_m y X_m(T_s)} \tag{5}$$

y represents the true values of the targent feature

$X_m(T_s)$ prediction made by the stump at iteration m

α_m predictive power of stump m

4. Making new overall Predictions

$$K(x) = \text{sign}[\sum_{m=1}^{M} \alpha_m X_m(x)] \tag{6}$$

The proposed hybrid classification model using a combination of a Random Forest classifier and an AdaBoost classifier developed. The Random Forest classifier is first tuned using gridsearchCV, and then the AdaBoost classifier is used to enhance the accuracy of RF. Finally, the working manner of the combined model is evaluated using metrics like accuracy, a classification report, and a confusion matrix.

IV. Results and Discussions

There are several researches are going on urinary biomarkers to determine whether they belonged to the pancreatic cancer or healthy patients (see Fig. 4). The publicly available dataset is used for the implementation of the proposed approach. The proposed system uses the hyperparameter tuning technique gridsearchCV to select the hyperparameters from the dataset, then perform the classification with RF and use AdaBoost to improve the classification accuracy. Training data make up 80% of the dataset, whereas testing data make up 20%. There are three subsections within the section: evaluation metrics, results, and comparison with other results of other approaches. This study employs classification algorithms and assesses their performance using metrics such as Accuracy, Recall, Precision, and the F-1 score.

Let TP (True Positive) represent the outcome in which the model correctly predicts the positive class, TN (True Negative) represents the outcome in which the model correctly predicts the negative class, FP (False Positive) represent the outcome in which the model incorrectly predicts the positive class, and FN represent the outcome in which the model incorrectly predicts the negative class. The above-mentioned performance measurements may thus be described as follows:

1) Accuracy: Accuracy, one of the most straightforward classification metrics, is computed as the ratio of correct predictions to all predictions made.

For calculation:

$$\text{Accuracy} = \frac{TP+TN}{TP+TN+FP+FN}$$

2) Recall: True Positives represent predictions that correctly match the total number of positive cases, whether they were accurately predicted as positive or incorrectly predicted as negative (True Positives and False Negatives). The following is the calculation method for recall:

$$\text{Recall}= \frac{TP}{TP+FN}$$

3) Precision: Precision measures the proportion of positive predictions that were accurate. It can be expressed as the ratio of all correctly predicted positive instances (True Positives and False Positives) to the total number of positive predictions.

$$\text{Precision}= \frac{TP}{TP+FP} \times 100$$

4) F1-Score: Calculating the F1 Score involves taking the harmonic mean of Precision and Recall, giving equal weight to both metrics. The formula for computing the F1 score is as follows:

$$\text{F1- score}=2*\frac{precision*recall}{precision+recall}$$

5) ROC Curve: The classification accuracy also computed by the Receiver-Operating-Characteristic curve. It's constructed using True-Positive (TP) and False-Positive (FP) at different target levels. TP is determined by recall, while FP is established using fallout. This illustrates how a ROC curve plots the fallout and sensitivity of the classifier. Fig. 8 shows ROC analysis of the proposed system.

6) Confusion matrix: A confusion matrix is a common tool used in machine learning and statistics to evaluate the performance of a classification algorithm, particularly in the context of binary classification. It provides a clear and detailed breakdown of how a classifier's predictions align with the actual class labels in a dataset. A confusion matrix (see Fig. 9) is typically represented as a 2x2 matrix, and it contains four key metrics: TP, TN, FP, FN.

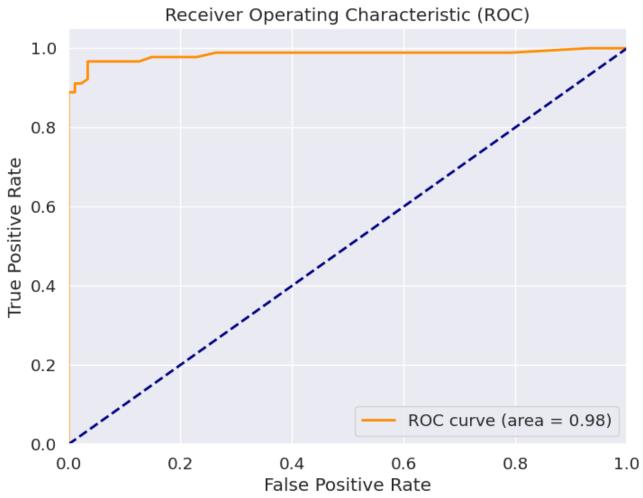

Fig. 8. ROC analysis of the proposed system.

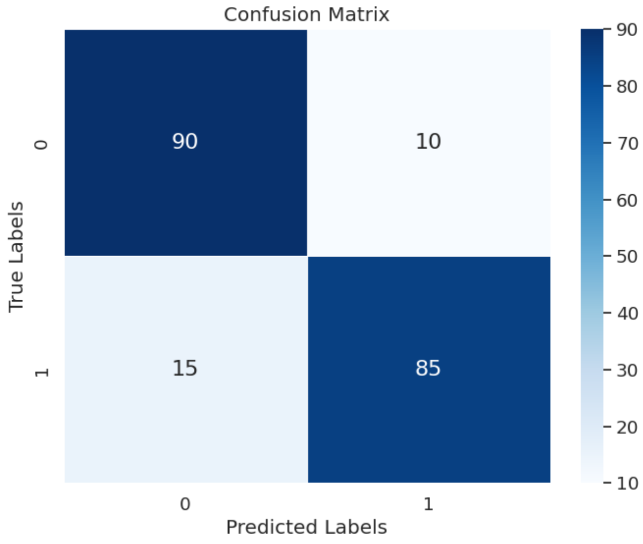

Fig. 9. Confusion matrix of proposed system.

Lately, machine learning techniques have seen substantial adoption in healthcare, particularly in the realm of cancer diagnosis. Utilizing hybrid ensembled classifiers, creatinine, LYVE1, REG1B, and TFF1 urine biomarkers have been effectively analyzed to detect pancreatic cancer. The proposed hybrid ensembled model surpasses other basic models with the maximum accuracy score of 97% in prior studies, as shown in Table III's assessment findings. Conventional ML models, such as LR, RF, and SVM, performed inadequately to correctly detect conditions related to pancreatic cancer. Therefore, hybrid ensembled classification model has been developed to predict pancreatic cancer based on urine biomarkers. As described above, the advantageous of gridsearchCV have the capability to ignore unnecessary feature and tune the feature which are very efficient to detect pancreatic cancer from the urine biomarkers.

7) Comparative analysis: The Table III offers an extensive comparison of the proposed model with established methods, conducting a thorough analysis of classification outcomes. Utilizing state-of-the-art classifiers, the proposed system is comprehensively evaluated in terms of accuracy, recall, precision, and the F1 score. Fig. 10 shows the comparative analysis of proposed system upon different classifiers based on urinary biomarkers.

TABLE III. A COMPARATIVE EVALUATION OF THE PROPOSED APPROACH WITH DIFFERENT CLASSIFIERS FOR PANCREATIC CANCER CLASSIFICATION USING URINARY BIOMARKERS

Classifier	Recall	Precision	F1-score	Accuracy
Random Forest	87	79	82	75
LR	76	64	89	74
KNN	64	65	-	64
GBC	77	73	-	72
1D CNN	100	90	95	93
LSTM-1D CNN	100	96	98	97
GridsearchCV+ RF+Ada Boost	**99.98**	**99.98**	**99.98**	**99.98**

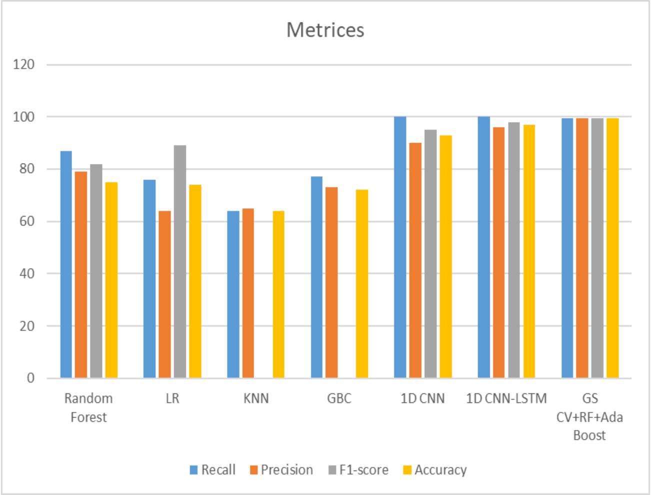

Fig. 10. Comparative analysis of proposed system upon different classifiers based on urinary biomarkers.

V. CONCLUSION

The scarcity of publicly available medical datasets is a significant challenge to the training of supervised learning models, particularly with regard to pancreatic cancer, as a result of which the only available training model performs poorly in terms of classification accuracy. A new ensemble strategy that uses urinary biomarkers gathered from Kaggle, all efficient features from dataset are tuning based on gridsearchCV then to classifies the pancreatic cancer and non-pancreatic cancer uses random forest, to improve performance of classification boosting algorithm Ada Boost was proposed. Metrics used to gauge the proposed model's performance Precision, F-1 score, Accuracy, and Recall all scored 99.98.

In future the machine learning models obtained optimum performances to detect pancreatic cancer at early stages automatically which are helpful for both clinicians and patients to save their life. This type of systems may assure prominent results in real time medical scenarios.

An Efficient Honeycomb Lung Segmentation Network Combining Multi-Paradigms Representation and Cascade Attention

Bingqian Yang, Xiufang Feng, Yunyun Dong*
School of Software, Taiyuan University of Technology, Taiyuan Shanxi 030024, China

***Abstract*—Honeycomb lung is a pulmonary manifestation that occurs in the terminal stage of various lung diseases, which greatly threatens patients. Due to the different locations and irregular shapes of lesions, the accurate segmentation of the honeycomb region is an essential and challenging problem. However, most deep learning methods struggle to effectively utilize both global and local information from lesion images, resulting in cannot to accurately segment the lesion. In addition, these methods often ignore some semantic information that is necessary for the segmentation of lesion location and shape in the decoding stage. To alleviate these challenges, in this paper, we propose a dual-branch encoder and cascaded decoder network (DECDNet) for segmenting honeycombs lesions. First, we design a dual-branch encoder consisting of ResNet34 and Swin-Transformer with different paradigm representations to extract local features and long-range dependencies respectively. Next, to further combine the different paradigm features, we develop the feature fusion module to obtain richer representation information. Finally, considering the problem of information loss during the decoder, a cascaded attention decoder is constructed to aggregate the multi-stage encoder information to get the final segmentation result. Experimental results demonstrate that our method outperforms other methods on the in-house honeycomb lung dataset. Notably, compared with the other nine universal methods, the proposed DECDNet obtains the highest IoU (86.34%), Dice (92.66%), Precision (93.21%), Recall (92.13%), F1-Score (92.66%), and achieves the lowest HD95 (7.33) and ASD (2.30). In particular, our method enables precisely segmenting lesions under different clinical scenarios as well. Our code and dataset are available at https://github.com/ybq17/DECDNet.**

***Keywords*—Honeycomb lung; attention; convolutional neural network; transformer; image segmentation**

I. INTRODUCTION

Honeycomb lung, also called interstitial pulmonary fibrosis, is a disease where the lung tissue is destroyed and fibrosed. It exhibits distinctive honeycomb-like features, that seriously threaten patient's life [1-2]. Based on published literature, the annual incidence of honeycomb lung is estimated to be between 0.9 and 13 cases per 100,000 individuals [3]. The survival time from initial diagnosis to death is short, ranging from three to five years, with a poor prognosis and high mortality rate [4-5]. Early diagnosis is vital for improving patient prognosis and prolonging their survival [6]. With the development of radiological technology, computed tomography (CT) has become the gold standard for diagnosing honeycomb lung [7]. Information such as the size and location of lesions in CT images can help doctors identify honeycomb regions and make subsequent treatment plans.

In clinical practice, the contours of lesions are usually delineated by physicians. However, the unique characteristics of honeycomb lung make the delineation of lesions a challenging task for physicians. Honeycomb lesions usually have the following properties: (1) the location of the lesion is not fixed and the contour is complex. (2) The lesions are blended with surrounding normal tissue, resulting in blurred boundaries. (3) The size and shape of lesions often vary from person to person. The above properties make it very time-consuming for doctors to contour lesions manually. In addition, due to the differences in doctor experience, the quality of delineation of diseased regions is inequality. To alleviate the burden on doctors and aid in diagnosis, many studies pay attention to computer-aided automatic diagnosis of lesions [8-12]. However, due to the inherent properties of these methods, it is challenging to achieve an accurate diagnosis of the lesion tissue.

With the development of deep learning, convolutional neural networks (CNN) have achieved significant success in the field of medical imaging due to their powerful feature extraction capabilities [13]. Many CNN methods have been applied to medical image segmentation, such as U-Net [14], V-Net [15], and ResUnet [16] which have obtained excellent results. The above methods all adopt an encoder-decoder structure, where the encoder is used to extract feature information at different scales of the image, and the decoder restores the image according to the encoder information. Since the superiority of this architecture, a few variants based on it have a dominant position in segmentation tasks [17-18]. Despite these models having achieved significant performance, their performance is still restricted due to their inherent receptive field [19]. To overcome the limitations, some works try to integrate attention mechanisms and expand the receptive field to improve segmentation accuracy [20-22]. Although the above works improve the segmentation performance of the network, they still suffer from capturing insufficient long-range dependencies.

Recently, transformer has achieved promising results in the field of natural language processing [23]. Due to its ability to capture long-distance dependencies, it has attracted the attention of researchers, and more and more works attempts to apply it to the field of computer vision. Dosovioskiy [24] was the first to introduce the transformer into the image recognition task; he divided an image into non-overlapping patches instead of tokens and fed them into transformer. In order to further improve the performance of image tasks, multi-scale transformer has emerged. For instance, Swin-Transformer [25] and PVT [26] used sliding windows and pyramid architectures respectively to reduce computational cost. Inspired by these studies, we apply the transformer to the honeycomb lung image segmentation task, but the results are not satisfactory due to the limitations of only using self-attention, which restricts the acquisition of local information.

CNN and transformer focus on two aspects of image information. On the one hand, due to the use of convolutional operations with inductive bias, CNN has locality and translation invariance [27]. This property allows CNN to preferably extract local information, but it also limits the receptive field, resulting in cannot to extract global features. Many solutions have been proposed to solve this problem, such as dilated convolution [28], large kernel convolution [29], and pyramid pooling [30]. However, these approaches can only alleviate this problem and cannot completely solve it. On the other hand, transformer utilizes the self-attention mechanism to capture long-range dependencies, but it neglects local information, resulting in the loss of detailed features.

According to the above analysis, we believe that CNN and transformer can be combined to compensate for their weaknesses and obtain higher performance. Several methods have tried to combine CNN and transformer to get local information and long-range dependencies to segment specific medical images, such as TransUNet [31], Tfcns [32], and HiFormer [33]. However, these architectures have some drawbacks that limit their ability to achieve better performance: 1) They cannot effectively combine local and global information from CNN and transformer respectively. 2) They cannot properly aggregate multi-stage information during the decoding stage. Considering these problems, we propose a novel network named DECDNet that combines different paradigms representation to segment the honeycomb region. Concretely, we first design two encoder branches, one is CNN to extract local information, and the other is transformer to get long-range dependencies. Second, we develop a feature fusion module to efficiently combine features from different branches. Lastly, to better aggregate multi-stage information, we construct an attention cascade decoder called ACD. Our contribution can be summarized as five-fold:

- We innovatively segment large-scale honeycomb lung CT images and plan to open this dataset. Our dataset will be available at https://github.com/ybq17/DECDNet.
- In order to extract the local information and global information of the image, a dual-branch encoder composed of ResNet34 and Swin-Transformer is designed to obtain the multi-paradigms representation of the image.
- Considering the problem of insufficient feature fusion, we develop a feature fusion module for efficiently combining information from different branches.
- To track the information loss in the decoding stage, a novel attention-based cascade decoder is constructed to aggregate multi-stage encoder information.
- Experimental results demonstrate that our proposed DECDNet surpasses other segmentation models as well as adaptable to different clinical scenarios.
- The rest of this paper is organized as follows. We first review related work in Section II and describe the overall architecture in Section III. In Section IV, we evaluate the performance of DECDNet on the honeycomb lung dataset. In Section V we discuss the experimental results. We conclude the paper in Section VI.

II. Related Works

A. Honeycomb CT Image Segmentation

CT imaging is a common technology used in clinical practice to diagnose honeycomb lung [34]. Different from pulmonary function tests (PFTs) and composite physiologic index (CPI) assessment in judging the patient's condition [35-36], CT imaging quantifies the degree of fibrosis in the lung and helps physicians diagnose the disease more intuitively [37]. Currently, many related studies focus on automatically segmenting honeycomb regions in CT images to quantify the degree of lesions.

For automatic segmentation methods of honeycomb lung can be divided into the following two categories: traditional computer-based CT analysis and deep learning-based models. The first category uses pulmonary fibrosis disease programs such as CALIPER to perform quantitative analysis of lesions. For instance, Jacob et al., [38] extracted characteristic manifestations in CT images, such as honeycomb lesions, reticular patterns, and ground-glass opacity. Then they used an automated procedure to quantify the severity. Nakagawa et al., [39] deployed a computer-assisted method to quantify fibrosis based on the estimated area of the lesions. However, such methods heavily rely on subjective experience that may lead to suboptimal results. Compared with traditional auxiliary approaches, deep learning-based methods achieve end-to-end automatic segmentation, not only reducing dependence on feature selection but also achieving promising results. Handa et al., [40] developed new deep-learning software that can automatically identify and quantify subdivided parenchymal honeycomb lesions. Su et al., [41] proposed a network called RDNet that accurately segmented the honeycomb regions, and the corresponding Dice index was 0.747. Considering more noise and lower contrast honeycomb images, Wei et al.,[42] introduced the popular transformer to quantify the lesions and achieved remarkable performance. Motivated by these studies, our work emphasizes the use of deep learning-based methods to reduce the role of feature selection and perform end-to-end lesions segmentation.

B. Convolutional Neural Network

With the development of deep learning, convolutional neural networks (CNN) have achieved remarkable success in a variety of computer vision tasks. In the segmentation task, Long et al., [43] proposed a fully convolutional neural network that achieves pixel-level classification. Inspired by the success of FCN, several approaches were introduced to improve segmentation performance, such as dilated convolution [28] and context modeling [30]. Later, an encoder-decoder network called UNet [14] was proposed by Ronneberger for medical image segmentation. With the popularity of UNet, a series of U-shaped architectures have been developed to better segment medical images, such as UNet++ [44], ResUnet [16], etc. In order to further improve segmentation performance, attention mechanisms were introduced into UNet by Ozan [21]. Attention mechanisms can selectively balance the importance of different spatial locations in the feature maps, allowing the network to focus on relevant objective regions. This approach has shown great potential in improving segmentation performance.

C. Vision Transformer

Transformer was designed originally for Natural Language Processing (NLP) and has achieved remarkable progress in the field [23]. Instead of using convolutional operations, transformer uses self-attention to capture long-range dependencies. Inspired by the success of transformer in the NLP field, Dosovitskiy et al., [24] proposed the vision transformer (ViT) model, which applied transformer to visual tasks for the first time. ViT split the image into patches, similar to words, and fed them into the transformer. Experimental results demonstrated that ViT surpasses many CNN models and has become the backbone for vision tasks. However, ViT requires a large amount of data and high computational complexity. To address this issue, several methods try to reduce the computational cost of ViT. Wang et al., [25] proposed the Pyramid Vision Transformer (PVT), which is inspired by the CNN pyramid structure and reduced the computational cost by using a hierarchical feature extraction strategy. Liu et al., [26] proposed the Swin Transformer, which only focuses on each local window to reduce the computational cost to linear. Recently, massive work has applied transformer to medical image segmentation tasks. Chen et al., [31] proposed TransUnet, which was the first to apply transformer to medical image segmentation. It used a multi-layer CNN-transformer encoder to extract both local and global information and a CNN decoder to restore the size of the output. Swin-UNet [45] and DS-TransUnet [46] used a pure transformer encoder-decoder architecture for 2D segmentation but did not achieve significant performance improvements. UNETR [47] adopted a transformer encoder to extract information and a CNN decoder to obtain 3D segmentation results.

III. Methodology

In this section, we describe our proposed method. Firstly, we illustrate a dual-branch encoder composed of ResNet34 and Swin-Transformer to extract complementary local information and long-distance dependencies of the image respectively. In the ResNet34 branch, the texture and structural information of lesions are fully utilized. In the Swin-Transformer branch, more attention is paid to the global features of lesions in images such as location and size. Then, we describe a feature fusion module that can fuse information from different branches at different scales. Finally, we present an ACD decoder that alleviates information loss during the decoding stage. As shown in Fig. 1, the input CT image size is 224×224×3, and the output result is a binary lesion segmentation result. To learn different paradigms representation, the input image is extracted by ResNet34 and multi-level Swin-Transformer respectively to extract multi-scale features of the image. Then, multi-scale features from different branches are fused by four feature fusion modules to obtain richer information. Lastly, to further reduce the information loss during the decoding stage, the ACD decoder receives fusion features to get the final segmentation result. More details are described in the following subsection.

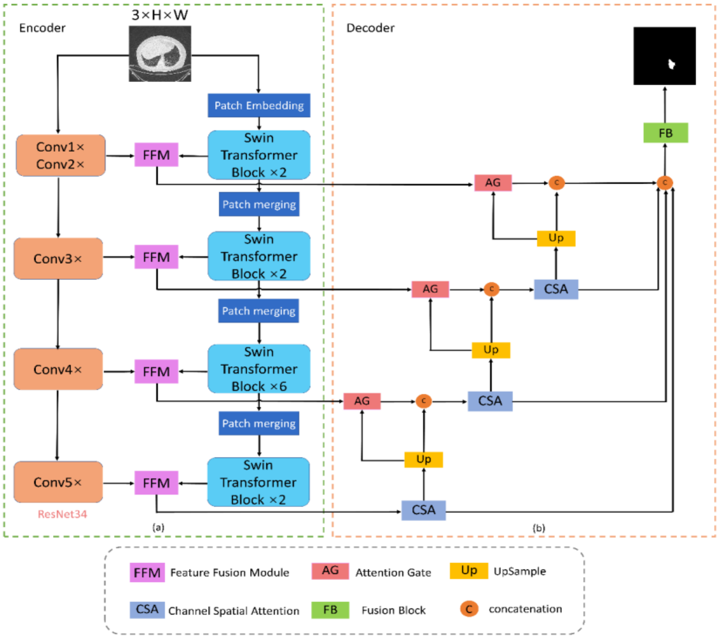

Fig. 1. The architecture of the proposed honeycomb lung segmentation network (DECDNet).

A. Encoder

Our proposed encoder consists of two multi-scale branches Resnet34, Swin-Transformer, and four feature fusion modules (FFM). Specifically, ResNet34 and Swin-Transformer respectively extract local and global information of images at different scales, such as texture, position, and structure. Here, ResNet34 and Swin-Transformer have four distinct layers each. To produce features with different scales, the patch merging operation will be performed before the feature map is inputted into the next Swin-Transformer layer. Then, the obtained multi-scale features through the above two parallel hierarchical branches contain different levels of semantic information. The FFM fuses each layer's information from different branches to enrich the features and feed them to the decoder.

1) CNN branch: As shown in Fig. 1(a), we use ResNet34 to construct the first encoder branch to obtain spatial detail and contextual information in the honeycomb lung images. In this branch, ResNet34 is divided into five blocks, noted as conv1, conv2, conv3, conv4, and conv5. When a feature map goes through a block, its width and height are reduced by a factor of 2. Taking a honeycomb lung CT image of size H×W×3 goes through conv1 and conv2 layers, which will yield a 3D feature c_1 of size H/4×W/4×C, where we set C to 48 to ensure feature consistency. Next, by passing through conv3, conv4, and conv5 layers, three features c_2, c_3, and c_4 are obtained, with sizes of H/8×W/8×2C, H/16×W/16×4C, and H/32×W/32×8C, respectively. These feature maps contain multi-scale semantic information and will be used as inputs for the feature fusion module.

2) Transformer branch: Recently, Alexely [24] proposed ViT, the first application of the transformer model to visual tasks. ViT has achieved outstanding progress in visual tasks due to its ability to capture long-range dependencies. It mainly consists of two parts: multi-head self-attention (MSA) and multi-layer perception (MLP). However, it has a major issue that its exponential computational complexity makes it difficult for downstream tasks such as image segmentation. To address this problem, Swin-Transformer [25] is developed that only focuses on local regions, greatly reducing the computational complexity. Inspired by the success of Swin-Transformer, we stack 12 Swin-Transformer blocks and patch operations to build the second encoder branch. In this branch, the focus is more on capturing the location and size information of the honeycomb lesions. Each Swin-Transformer is composed of two modules. The first module consists of W-MSA, LN, MLP, and residual connections. The second module introduces a sliding window mechanism to improve W-MSA and enhance information interaction. This process is defined as follows.

$$\hat{z}^l = W - MSA\left(LN(z^{l-1})\right) + z^{l-1},$$

$$z^l = MLP(LN(\hat{z}^l) + \hat{z}^l,$$

$$\hat{z}^{l+1} = SW - MSA(LN(z^l)) + z^l,$$

$$z^{l+1} = MLP(LN(\hat{z}^{l+1})) + \hat{z}^{l+1} \qquad (1)$$

The encoder branch is divided into four layers, as shown in Fig. 1(a). The first layer consists of two Swin-Transformer blocks and a patch embedding operation that splits the image into patches. The remaining three layers use patch merging to reduce the size of the image. And the number of Swin-Transformer blocks is set to 2, 6, and 2 for these layers, respectively. In this branch, the input image has the same dimensions as the CNN branch, which is H×W×3. The outputs of each layer are denoted as t_1, t_2, t_3, and t_4, with sizes of ((H/4, W/4), C), ((H/8, W/8), 2C), ((H/16, W/16), 4C) and ((H/32, W/32), 8C) respectively. They have the same pixel points as the outputs of the corresponding level CNN branch. We set the patch size to 4, so the feature dimension C is equal to 4×4×3=48.

3) Feature fusion module: In order to fuse different branches of features, we design the feature fusion module called FFM. It can efficiently and flexibly fuse features from CNN and transformer branches with different resolutions and different channels, and its structure is illustrated in Fig. 2. In this module, we first adjust the shape of the transformer features by reshaping operation. Then the CNN features and transformer features (called f and g) from each encoder branch are adjusted for dimensions by 1*1 convolution. Next, the f and g are merged by concatenation operation. The merged features are fed into the 1×1 convolution, and then the normalization operation and activation function are executed. Finally, the two encoder branch features are completely fused by a 1×1 convolution layer. In the encoder, we deploy four feature fusion modules to fuse the multi-scale features of CNN and Transformer under different branches. The fused feature balances multi-scale global information and local features, enriching the representation information.

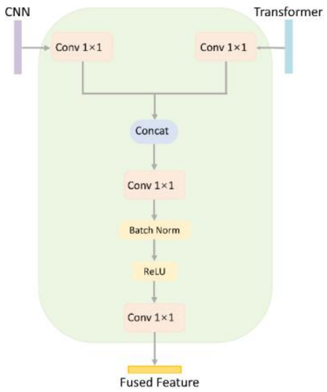

Fig. 2. The structure of the proposed Feature-Fusion Module (FFM).

B. Decoder

As illustrated in Fig. 1(b), we propose a novel decoder called ACD that can efficiently aggregate multi-stage information from the encoder. It consists of four components: Up, AG, CSA, and FB. Up is used for upsample operation, AG is used for cascaded feature fusion, CSA can refine features, and FB is used to fuse multi-level features. Specifically, we set up three CSA to enhance feature information at different scales and three AG corresponding to the output of FFB. In addition, AG is employed to integrate the fusion information from the FFB and the upsampled features from the lower level. Next, we use a concatenation operation to merge the features of AG and the lower layer. Then, CSA is executed to refine the merged features. Finally, we use FB to integrate the output of different layers to obtain the final prediction. More details are described in the following subsection.

1) Up: Up is used to restore the current feature size to match the dimension of the upper layer's feature. Each Up consists of a ReLU activation function, batch normalization operation, a 3*3 convolution operation, and a linear upsampling. Upsample () with an upsampling factor of 2. The Up operation can be formulated as follows:

$$Up(x) = (ReLu(BN(Conv(Upsample(x))))) \quad (2)$$

2) Fusion block: To enhance feature representation, we design the Fusion Block (FB) to efficiently utilize multi-level features. As shown in Fig. 3(a), FB consists of two parts: residual connection and Convblock. The Convblock consists of Convolution (Conv), Batch Normalization (BN), and Rectified Linear Unit (ReLu). On the one hand, the convolutional block assists the network in enhancing features. On the other hand, the residual connection avoids gradient explosion. Then, the results of the two parts are added together to obtain the final prediction result.

3) Channel spatial attention: The Channel Spatial Attention (CSA) module can refine the feature map, as shown in Fig. 3(b). It consists of spatial attention, channel attention, and a 1×1 convolution. When the input features enter this module, parallel channel attention and spatial attention are used to enhance the spatial and channel features of the image, respectively. Then, these features are fused through concatenation and the dimension is reduced through convolution. The fusion feature retains important spatial and channel information, which assists the decoder in better-recovering information.

4) Attention gate: Motivated by the success of the attention mechanism, we introduce the attention gate (AG), which can combine multi-stage features, extract areas of interest, and ignore irrelevant parts using spatial attention. As shown in Fig. 3(c), each AG consists of two 1x1 convolutions to change dimensions, two batch normalizations, and two activation functions: ReLu and Sigmoid. Specifically, the FFB features denoted f is first added point-wise with the features from the lower-level denoted d. Then, convolution and activation operations are performed to obtain the spatial attention map. Finally, the attention map is element-wise multiplied by f using the Hadamard product.

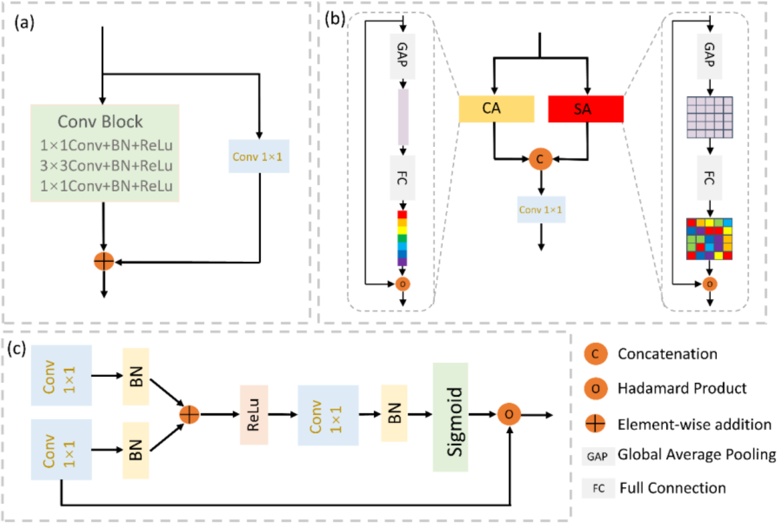

Fig. 3. Structure of (a) FB, (b) CSA, and (c) AG.

IV. Experimental Results

A. Datasets

We use CT images of honeycomb lungs provided by Shanxi Provincial People's Hospital for the experiment. A total of 7170 honeycomb images with size 512 × 512 pixels were collected from chest CT scans of 121 patients as our dataset. These scans were conducted using specific scan parameters, including an X-ray voltage of approximately 120 kVp, a current of 200-500 mA, and a gantry rotation speed of 0.5 seconds per rotation. And the slice images were acquired with a uniform slice thickness of 5 mm. The dataset includes images with lesion sizes ranging from small focal areas of a few millimeters to extensive lesions spanning large lung areas. Lesion appearances also vary, from early-stage subtle honeycombing with fine reticular patterns to advanced-stage prominent cystic changes as illustrated in Fig. 4. All of these images are labeled by experienced radiologists. After annotation, we resize the images to 224×224 and apply normalization to accelerate model convergence. We divide the dataset into training/validation/testing sets at a ratio of 6:2:2, with 4302 images used for training and 1434 images used for validation and testing.

B. Evaluation Metrics

We adopt five common metrics to evaluate segmentation performance: Dice coefficient (Dice), Jaccard index (IoU), Precision, Recall, and F1-score. These metrics are calculated using true positives (TP), false positives (FP), true negatives (TN) and false negatives (FN):

$$Dice = \frac{2TP}{2TP+FP+FN} \tag{3}$$

$$IoU = \frac{TP}{TP+FP+FN} \tag{4}$$

$$Precision = \frac{TP}{TP+FP} \tag{5}$$

$$Recall = \frac{TP}{TP+FN} \tag{6}$$

$$F1-score = \frac{2\times Recall\times Precision}{Recall+Precision} \tag{7}$$

In addition, Hausdorff distance (HD) 95% and average surface distance (ASD) are used to measure the performance of the model in segmenting the boundaries of honeycomb regions.

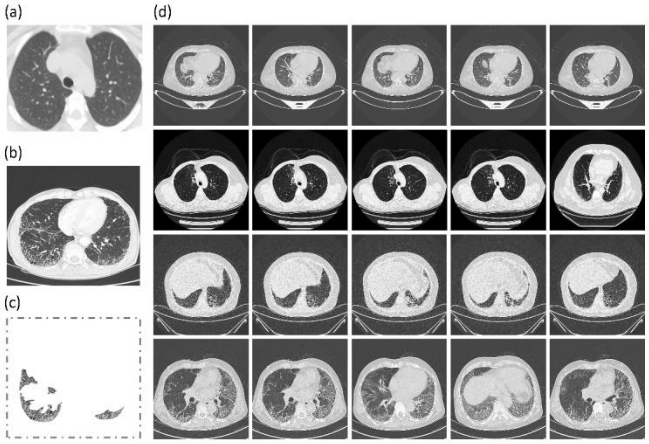

Fig. 4. (a) A normal lung image, (b) A honeycomb lung image, (c) Honeycomb lung lesions, and (d) Some honeycomb lung images in the datasets.

C. Implementation Details

Our architecture is implemented using PyTorch and trained on an RTX Nvidia 3090 GPU. And we use the SGD as the optimizer with a momentum of 0.9 and weight decay of 0.0001. The learning rate and batch size are set to 0.0001 and 24, respectively. Further, aiming to improve the generalization and robustness of the model, we use data augmentation technology such as flipping and rotation to diversify the data.

The loss function is composed of commonly used cross-entropy loss and dice loss, defined as follows:

$$= \alpha l_1 + (1-\alpha) l_2 \tag{8}$$

where, l_1 denotes the cross-entropy loss and l_2 denotes the dice loss. The weight ratio α is a balancing factor, set to 0.4 based on experimental testing.

D. Evaluation Results

To demonstrate the effectiveness of our proposed DECDNet, we conducted comparative experiments with nine methods. All methods are evaluated both quantitatively and qualitatively. These competing methods include the following: U-Net [12], Att-UNet [19], UNet++ [42], FPN [28], DABNet [46], ViT [22], CGNet [47], TransUNet [29], SwinUNet [43]. The above methods cover three types: traditional CNN architecture, pure transformer architecture, and the combined architecture of CNN and transformer. And we evaluated our method on seven evaluation metrics mentioned earlier. The smaller the ASD and HD95 value is, the better the performance is; the larger the other index values are, the better the performance is. Table I shows the qualitative evaluation results of all methods on the honeycomb lung dataset. The experimental results demonstrate that our proposed network has higher IoU, Dice, Precision, Recall, and F1-score, as well as smaller HD95 and ASD. Compared with the second-ranked SwinUNet, our method increases IoU and Dice by 2.13% and 1.23%, respectively, reaching 86.34% and 92.66% Precision, Recall, and F1-Score also improved by 1.68%, 0.81%, and 1.24%, respectively. HD95 and ASD decreased by 2.08 and 0.51 compared to Swin-UNet, reaching 7.33 and 2.30, respectively. These results indicate that our proposed DECDNet can accurately segment the honeycomb lesions. Moreover, our method outperforms traditional CNN methods, ViT, and TransUnet in terms of FLOPs or Params, not only achieving the best segmentation results but also balancing the accuracy and computational complexity.

Meanwhile, to quantify segmentation performance, we conducted visual comparisons of the segmentation with different methods on the honeycomb lung dataset. As shown in Fig. 5, we visually compared the segmentation results of UNet, FPN, TransUNet, SwinUNet, and our model with the ground truth. Within these results, the red box draws attention to significant differences compared with the mask. Obviously, the transformer method is more accurate than the traditional CNN method for segmenting honeycomb lung lesions However, due to the transformer ignores the local features of the image, the segmentation of the lesion boundary is smoother compared with the mask. In contrast, our proposed architecture efficiently utilizes different paradigms representation and alleviates the information loss during the decoding stage. The boundary delineation and region segmentation of the honeycomb lung are more similar to the ground truth. In the above quantitative and qualitative analyses, DECDNet achieves the best performance on the honeycomb lung dataset, demonstrating that our proposed method can accurately segment the contours and regions of honeycomb lung.

Additionally, to evaluate the adaptability of this model in clinical practice, we performed experiments to evaluate our method under various conditions considering the patient positioning, lesion size, and the presence of adjacent organs that commonly occur in clinical applications. We conducted the visual analysis of CT images of different lesion sizes, different slices, and different angles. As shown in Fig. 6 and Fig. 7, regardless of the size, axis, or slice of the lesion, DECDNet can accurately segment and outline the lesions. Table II shows the quantitative results for Dice and Hd95 in various conditions, further proving the adaptability of our method for lesion area segmentation in different clinical scenarios.

TABLE I. COMPARING OUR METHOD WITH OTHER METHODS ON THE HONEYCOMB LUNG DATASET

Methods	IoU (%)	Dice (%)	Precision (%)	Recall (%)	F1-Score (%)	HD	ASD	FLOPs(G)	Params(M)

E. Ablation Studies

1) Evaluation of encoder: Our encoder is composed of CNN and transformer with different paradigms. Since the transformer can capture long-range dependencies, it tends to ignore local feature information. To address this issue, we introduced CNN as an auxiliary branch to compensate for the loss of spatial detail information. To further verify the importance of the CNN branch, we employed variants of pure transformer and CNN-combined transformer as two encoder structures. As shown in Fig. 8, the encoder that combines CNN with the transformer outperforms the pure transformer encoder. The results presented in Table III suggest that the integration of the CNN branch also enhances boundary segmentation performance. Thus, the introduction of CNN as an auxiliary branch is necessary to improve segmentation performance.

TABLE III. ABLATION EXPERIMENTS ON BOUNDARY EVALUATION FOR CNN BRANCH

Methods	HD	ASD
No-CNN	8.40	3.01
Ours	7.33	2.30

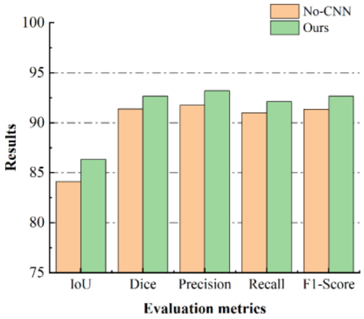

Fig. 8. Ablation study on the influence of CNN branch.

2) Evaluation of FFM: To verify the effectiveness of FFM in segmentation performance, we removed FFM and used Conv2d to adjust the feature dimensions, then adopted the add operation to fuse feature. In this way, we denote the variable as Conv2d+add to verify the importance of FFM. The segmentation performance shown in Fig. 9 reveals the effect of FFM in feature fusion. Specifically, the model with FFM achieved higher IoU, Dice, Precision, Recall, and F1-score compared to using only the add operation. In addition, the employment of FFM can improve boundary segmentation performance. As shown in Table IV, our method achieved lower HD95 and ASD. These results demonstrate that simply using add cannot fully utilize the features from CNN and transformer, while FFM can better help the network utilize different branches feature.

3) Evaluation of decoder: The decoder is an important factor that affects segmentation performance, and its main role is to restore feature maps to obtain the final prediction. The classic decoder does not use attention mechanisms but restores image resolution by fusing multi-stage skip connections and upsampling features to achieve the final prediction. While, Atten-UNet uses attention in skip connections during the decoding stage to focus on the lesions, denoted as the attention decoder. Different from the above decoder, we proposed a new attention-based cascaded decoder called ACD to efficiently combine multi-stage features from the encoder, enabling the network to better focus on the honeycomb regions. The results shown in Fig. 10 demonstrate that compared to the classic decoder and attention decoder, the architecture using ACD achieves improvements in IoU, Dice, Precision, Recall, and F1-score. Our decoder also obtains the smallest HD95 and ASD, as shown in Table V. The presented results provide evidence that our decoder can better focus on the lesions and efficiently integrate multi-stage features to get segmentation results.

4) Evaluation of combination FFM and cascade: To verify the effectiveness of the FFM and Cascade decoder combination for model performance, we conducted four sets of experiments to explore the influence of each component on honeycomb lung segmentation. Firstly, setting a model that only uses pointwise additive fusion and classical encoder for segmentation as the baseline model. To ensure fairness, all experiments adopt the same environment settings.

TABLE IV. ABLATION EXPERIMENTS ON BOUNDARY EVALUATION FOR FFM

Methods	HD	ASD
Conv2d+add	8.27	3.09
Ours	7.33	2.30

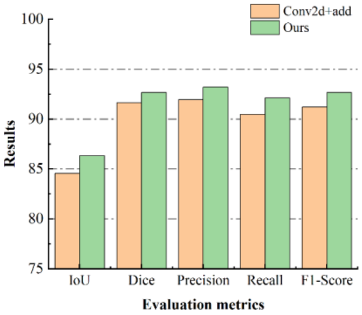

Fig. 9. Ablation study on the influence of FFM.

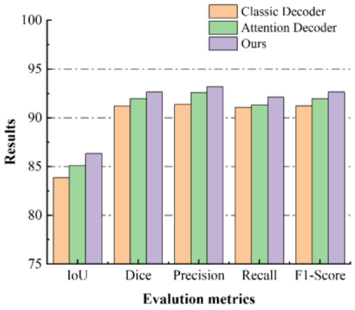

Fig. 10. Ablation study on the influence of different decoders.

TABLE V. ABLATION EXPERIMENTS ON BOUNDARY EVALUATION FOR DIFFERENT DECODERS

Methods	HD	ASD
Classic decoder	11.30	3.38
Attention decoder	8.19	2.88
Ours	7.33	2.30

As shown in Fig. 11, the combination of FFM and Cascade decoder achieved the best segmentation performance of honeycomb lesions. For boundary outline, the combination method also obtains the lowest HD and ASD as illustrated in Table VI, which is more similar to the groundtruth. Therefore, FFM and Cascade are necessary to improve the accuracy of segmentation.

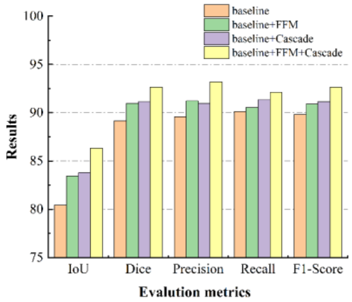

Fig. 11. Ablation study on the influence of the combination FFM and Cascade.

TABLE VI. ABLATION EXPERIMENTS ON BOUNDARY EVALUATION FOR THE COMBINATION FFM AND CASCADE

Methods	HD	ASD
baseline	12.78	4.05
baseline+FFM	10.60	3.29
baseline+Cascade	9.82	3.11
baseline+FFM+Cascade	7.33	2.30

V. DISCUSSION

Honeycomb lung is a terminal manifestation of lung disease, which greatly threatens patients. In clinical applications, the segmentation of lesions is essential. It aids in evaluating lesions, identifying the distribution of lesions, and assisting doctors in making accurate diagnoses. Moreover, segmenting honeycomb lung is a challenging task due to their ambiguous and irregular characteristics. Therefore, it is crucial to design a network that achieves higher segmentation accuracy for the precise localization of honeycomb lung lesions. Our proposed DECDNet architecture integrates global and local information from different paradigms to alleviate the limitations of CNN and transformer. In addition, the specially designed ACD decoder can effectively recover image information from the encoder. We conducted experiments on our method and nine universal segmentation algorithms, and our method achieved the highest IoU (86.34%), Dice (91.87%), Recall (92.13%), Precision (93.21%), F1-score (92.66%), and the smallest HD95 (7.33) and ASD (2.30). To quantify the results, we show the visual segmentation results of different methods, as shown in Fig. 5. Compared with other methods, our method can not only focus on the major lesions but also pay more attention to the boundaries of the honeycomb lung. Next, we visualized the segmentation performance in different clinical situations, as shown in Fig. 6 and Fig. 7, indicating that the proposed model is adaptable to diverse clinical scenarios. Additionally, to verify the effectiveness of each part of our architecture, we conducted three groups of ablation experiments to explore the effects of the dual-branch encoder, FFM, and ACD decoder. The results show that all three parts are effective and can improve the segmentation performance of the network. Therefore, our proposed method can precisely segment the honeycomb lung lesions, alleviate the burden on doctors, and assist in diagnosis.

Although our method has shown outstanding performance on the honeycomb lung dataset, it still has some defects that need to be addressed. On one hand, our model did not achieve promising performance in cases where the lesion size is small and the background is complex. On the other hand, as we have only tested on data from a single center, the generalizability of our model remains to be considered. In the future, we will expand and improve our method by adjusting multi-scale inputs and collecting data from multiple centers to address these issues.

VI. CONCLUSION

In this paper, we propose a novel network called DECDNet for the segmentation of honeycomb lung CT images. Specifically, we first design a dual-branch encoder to efficiently capture global and local information from different paradigms. Next, the feature fusion module is developed to fuse CNN and transformer features. Finally, we develop an attention-based cascade decoder to aggregate multi-stage encoder information. Our method demonstrated its effectiveness in extensive experiments through the effective extraction, fusion, and restoration of local information (such as the texture and structure of lesions) and global information (such as location and size). And our model achieves state-of-the-art performance on the honeycomb lung dataset. In addition, our model also accurately segments lesions under various conditions, making it a valuable method for assisting doctors in locating and tracking lesions, as well as making diagnoses. In the future, we will focus on further automatic diagnosis of honeycomb lung, such as by adopting multi-scale inputs to avoid noise and collecting multi-center data to enhance the model's generalizability.

***Abstract*—This study presents a novel and workable approach to solving the critical issue of improving energy management in smart buildings. Using a large dataset from a seven-story office building in Bangkok, Thailand, our work introduces a novel approach that combines Deep Q-network (DQN) algorithms with energy storage models and cost optimization strategies. The suggested approach is intended to reduce operational expenses, improve the energy economic performance, and efficiently control peak demand. The energy storage model used in this research incorporates the use of the capabilities of advanced storage models in smart buildings, particularly lithium-ion batteries and supercapacitors. When the cost optimization approach is applied using linear programming, energy consumption costs are significantly reduced. Notably, our method outperforms current algorithms, specifically outperforming them, to show its effectiveness in smart building energy management by outperforming current algorithms, especially Genetic and Fuzzy Algorithms. In comparison to traditional methods, the DQN algorithm exhibits an impressive 8.6% reduction in Mean Square Error (MSE) and a 6.4% drop in Mean Absolute Error (MAE), making it a standout performer in the research through Python software. The results highlight the significance of optimizing DQN algorithm parameters for best outcomes, with a focus on adaptability to various properties of smart buildings. This investigation is novel because it integrates cost optimization, reinforcement learning, and energy storage. This results in a flexible and all-inclusive framework that can be used for effective and sustainable energy management in smart buildings.**

I. INTRODUCTION

Reinforcement learning integration with smart energy management is an attainable approach to improving energy system efficiency and optimizing consumption of energy. A subfield of machine learning called reinforcement learning (RL) trains agents to make decisions through interaction with their surroundings and feedback in the form of rewards or punishments. Applying reinforcement learning (RL) to smart energy management can help with complicated and dynamic decision-making problems [1]. RL algorithms perform well in settings where making decisions is dynamic and necessitates flexibility in response to shifting circumstances. With smart energy management, control techniques could be dynamically adjusted by RL for optimal energy utilization, taking into account variable elements such as weather patterns, user behaviors, and energy costs [2]. The algorithms have the potential to be utilized for precise load forecasting, energy demand pattern prediction, and energy-consuming device scheduling [3]. This lowers peak demand and maximizes the usage of energy resources. It may be used to enhance techniques for demand response. To take part in demand-side management programmes and gain incentives, agents can be trained to react to signals from utilities or energy suppliers and modify their patterns of energy usage [4]. The energy system can more easily incorporate renewable energy sources like wind and solar electricity thanks to these learning algorithms [5]. RL agents are able to optimize the use of renewable resources, balance supply and demand, and manage energy storage systems. It can maximize the control of distributed energy resources (DERs), such as solar panels, batteries, and electric cars, in microgrid settings [6]. Within the microgrid, agents can learn to balance the production and consumption of energy, increasing overall efficiency. RL is ideal for managing energy storage systems in an optimal way. Agents are able to acquire the best battery charging and discharging techniques, accounting for user preferences, grid circumstances, and power pricing [7]. Additionally, algorithms can assist energy management systems in adhering to legal and policy requirements [8]. Agents can be trained to make choices that adhere to regulatory requirements, energy efficiency standards, and other environmental considerations. Because these models can learn and adapt continuously, intelligent energy management systems can get better over time as they interact with their surroundings and gather input [9].

The implementation of machine learning techniques has led to significant improvements in energy management in smart buildings. Machine learning algorithms, especially those that employ supervised and unsupervised learning, provide insightful information and prediction powers that improve energy efficiency. To optimize lighting, other energy-consuming devices, HVAC systems, and occupancy trends, predictive models may be trained to examine historical data, weather patterns, and other pertinent variables [10]. Furthermore, anomaly detection algorithms can spot anomalous patterns in energy use, which allows for early intervention in the event of possible inefficiencies. Real-time adaptability is provided via reinforcement learning approaches, which dynamically modify control strategies in response to changing situations. The necessity for sizable labeled datasets, the interpretability of intricate ML models, and the possibility of biases in training data remain obstacles in spite of recent developments [11]. In order to protect against possible vulnerabilities, the deployment of ML models necessitates comprehensive consideration of cyber security measures [12]. Despite the encouraging outcomes of ML integration in smart buildings, these issues must be resolved to guarantee the stability and dependability of these systems in practical settings. Ongoing research and development initiatives are crucial to overcoming these obstacles and realizing the full potential of machine learning in smart building energy management as the field develops [13]. The capability of managing the intricate, nonlinear interactions present in energy systems is one of DRL's main advantages in smart buildings. Through constant environmental interaction and feedback in the form of incentives or penalties, DRL algorithms can acquire the best control rules for energy-intensive equipment such as lighting, HVAC systems, and other gadgets. Because of their adaptable nature, smart buildings can react quickly to changes in the weather, occupancy patterns, and energy prices, resulting in effective energy management. Deep learning integration makes it easier to uncover complex patterns from data, which leads to more precise forecasts and well-informed decision-making. Achieving a feasible deployment requires balancing the interpretability of the model with computing performance. The promise for significant gains in energy efficiency, cost savings, and sustainability continues to be a driving factor behind the development of intelligent building management systems as research into efficient DRL for smart buildings advances.

In the modern energy landscape, integrating energy storage technologies with sophisticated energy management methods is a critical first step towards improving efficiency, dependability, and sustainability. Because it may be used to store extra energy during times of surplus and release it during times of low generation or high demand, energy storage is essential for mitigating the intermittent nature of renewable energy sources. Advanced energy management strategies use complex algorithms, which frequently include machine learning and optimization approaches, to automatically regulate the cycles of energy storage systems' charging and discharging. These solutions optimize energy storage use by analyzing weather forecasts, historical data, and real-time demand patterns. This ensures that stored energy is strategically deployed to balance peak demand, minimize grid stress, and improve overall system resilience. Moreover, grid stability is enhanced and the integration of decentralized renewable energy resources is supported by the incorporation of energy storage into the energy management system. Despite these benefits, broad use will need to address issues including high upfront costs, the current generation of storage technologies' low energy density, and regulatory barriers. The secret to opening the door to a more robust and sustainable energy future lies in the smooth integration of energy storage systems through sophisticated energy management tactics, which will be made possible by ongoing technological and scientific developments. The following are the research study's main contributions,

- For the purpose of improving energy management in smart buildings, the study presents and uses Deep Reinforcement Learning algorithms. The study improves the system's capacity to make wise choices in a dynamic environment by utilizing DRL and taking into account variables like cost savings, peak demand reduction, and occupant comfort.

- The research provides a contribution by integrating a sophisticated energy storage model into the infrastructure of smart buildings. Modern technologies like lithium-ion batteries and supercapacitors are integrated into this concept and are arranged to store and harvest extra energy from renewable sources, improving sustainability and the economy.

- With the objective of minimizing overall energy consumption costs, the study presents a linear programming-based cost optimization model. This model offers a comprehensive approach to effective energy management by taking into account factors including electricity tariffs, operational costs, and potential fines for exceeding energy thresholds.

- A number of quantitative parameters are used in the study to evaluate the degree to which the suggested technique performs. These measures include the accuracy of the reinforcement learning model, cost savings, and percentage reductions in peak demand.

- The study emphasizes that the suggested tactics affect the lowering of peak demand. The results show that demand charges are significantly lower during peak hours, proving that the DRL strategy is effective in optimizing and modifying energy usage patterns.

- A comparative examination of the suggested DRL technique and a Genetic Algorithm (GA) approach is included in the paper. This comparison analysis shows that the DRL technique performs better in terms of peak load control and cost savings.

The paper's summary is given in Section I. Reviewing previous research, Section II highlights the gaps in the field's understanding of energy storage and management. The primary research question about the intricacies of smart building management is defined in Section III. Section IV presents the suggested technique. By comparing classifier performance, presenting empirical data in Section V, and examining conclusions and future research goals, Section VI demonstrates the importance of this research for smart building energy management.

II. Related Works

Elsisi et al. [14] presents a fresh and creative solution to the major problems associated with reducing energy usage and utilization in smart buildings, especially in the residential and commercial sectors. An impressive endeavor that places deep learning and the Internet of Things at the center of Industry 4.0 is the combination of these two technologies. A forward-thinking approach to effective energy management is demonstrated by the use of artificial intelligence tools in conjunction with the Internet of Things to share signals across machines and equipment. The paper's main contribution is the introduction of a people identification method based on deep learning that uses the YOLOv3 algorithm to maximize air conditioner performance and thereby cut energy usage. This method, which is based on precisely counting the people in a given space, allows for creative choices to be made for real-time air conditioner operational management in the context of smart buildings. The incorporation of the suggested system with an Internet of Things platform is also highlighted in the research. A dashboard receives internet-based updates on the number of people spotted and the condition of the air conditioners. This integration improves energy-related decision-making by offering insightful data on utilization trends and air conditioning usage. The simulation results that are reported in the research offer strong proof of the suggested approach's usefulness and effectiveness. The capacity of the deep learning-based identification algorithm to model extremely non-linear connections in data is demonstrated by its effective and accurate detection of the number of people in the designated region. The smooth broadcast of identification status on the dashboard of the IoT platform validates the system's usefulness. In conclusion, by utilizing deep learning and Internet of Things technology, the article significantly advances the subject of smart building power management. In addition to addressing the issues associated with energy consumption, the suggested method has potential uses in the remote control of a variety of controllable equipment. This study is positioned as a useful and innovative addition to the convergence of artificial intelligence, IoT, and energy conservation in smart buildings due to its integration of state-of-the-art technology and its encouraging simulation findings.

Shivam, Tzou, and Wu [15] presents a thorough machine learning-based multi-objective forecasting energy management plan for home grid-connected PV-battery hybrid systems. The hybrid approach under discussion combines an electric load in the form of a residential building, a bank of batteries for storing electricity, and a solar array. The suggested approach makes use of a three-tiered control framework: a dual forecasting framework based on residual causal dilation convolutional networks for generating electricity and electric load; a logical level for managing computational load and accuracy; and a multi-objective optimization for effective energy trade with the utility grid by means of battery charge scheduling. The prediction model exhibits precise one-step forward estimates for solar energy output and load, having been developed via a sliding window approach. The suggested energy management strategy is to minimize energy acquired through the utility grid, maximize the state of charge of the battery bank, and lower carbon dioxide emissions. Limits are placed on the highest amount of carbon dioxide that can be produced and the state of charge of battery banks. Using hourly power and load data, the approach is assessed under static as well as dynamic electricity pricing scenarios. The suggested dual prediction model has a high coefficient of predictability (93.08% for energy output and 97.25% for electrical load) according to simulation findings. The suggested prediction model shows substantial advances in accuracy when compared to naïve estimation, support vector machine, and artificial neural network (ANN) models. When combined with the sophisticated prediction model, the all-encompassing approach effectively controls more than half of the annual load demand, leading to notable decreases in carbon dioxide emissions and electricity costs when compared to residential structures with no hybrid energy systems or hybrid energy systems without an energy management plan. The research presents an organized and meticulous methodology, supported by comprehensive simulations, demonstrating its usefulness in incorporating machine learning into the predictive management of energy for home grid-connected PV-battery hybrid power systems.

Lan et al. [16] outlines a novel machine learning-based strategy for renewable microgrid energy management, with a special emphasis on a changeable structure made possible by remote tie and sectionalizing switches. The study notably uses sophisticated support vector machines (SVM) to model and estimate the hybrid electric vehicle (HEV) charging needs within the micro grid. To tackle the possible effects of HEV charge on the network, the study presents two discrete scenarios: intelligent and coordinated charging. A revolutionary modified optimization approach based on dragonflies addresses the complex nature of the issue formulation and provides a customized solution to the complicated problem. Also, a self-adaptive modification is suggested, which enables solutions to choose the modification strategy that best fits their particular situation. The effectiveness and suitability of the suggested strategy are shown by simulation findings on an IEEE microgrid evaluation system in both synchronized and autonomous charging scenarios. A high degree of precision is indicated by the mean absolute % inaccuracy of 0.978 for the anticipated total charge demand of HEVs. Moreover, the outcomes demonstrate a significant 2.5% decrease in the micro grid’s overall operating expenses when using the intelligent charging strategy in contrast to the coordinated method. The study advances the area by providing a thorough solution to the complex problems associated with controlling energy in renewable microgrids taking into account the needs of HEV charging. The relevance of the research is highlighted by the revolutionary reconfigurable structure, the personalized optimization strategy, and the use of modern machine learning techniques. The simulation findings validate the suggested approach's realistic deployment in renewable microgrid networks and offer compelling proof of its efficacy.

Syed et al. [17] focuses on the crucial component of dynamism estimating at the home level in smart constructions inside the larger framework of smart grid management of energy. Precise forecasts of energy usage in smart constructions are required for effective power generation and administration. The two primary phases of the suggested hybrid deep learning approach are model construction and data cleansing. Pre-processing techniques, such as adding lag values as extra features, are applied to raw data during the data-cleaning step. A hybrid deep learning architecture, comprising fully linked layers, unidirectional long-term short-term memory, and bidirectional LSTMs, is employed throughout the model-building stage. The objective of the model is to efficiently capture temporal relationships while maintaining high forecasting accuracy, low training time, and computing economy. The suggested model performs better than popular hybrid models like Convolutional Neural Networks, ConvLSTM, LSTM encoder-decoder frameworks, and stacking models, according to the evaluation of two benchmark energy consumption datasets. The suggested model achieves a mean percentage error in absolute terms of 2.00% for Case Study 1 and 3.71% for Case Study 2, indicating significant improvements. On the other hand, for the corresponding datasets, LSTM-based models produced greater MAPE readings of 7.80% and 5.099%. Furthermore, for the used energy consumption datasets, the suggested model shows promise in multi-step week-ahead everyday projections, exhibiting improvements in MAPE of 8.368% and 20.99% when compared to LSTM-based models. By presenting a unique hybrid deep learning model designed for household-level energy forecasts in Smart Buildings, the research makes a substantial contribution to the area. The thorough testing of the suggested method against well-known models and the documented increases in predicting accuracy highlight its possible applicability. This study offers useful insights for researchers and practitioners working in the fields of Smart Grid management of energy and Smart Buildings, especially about improving accuracy in forecasting household-level energy usage.

Han et al. [18] focuses on the potential of edge intelligence in the Internet of Things for green energy management, filling a major gap in the literature. The main goal is to provide a system based on deep learning for intelligent management of energy that can meet the needs of modern homes, businesses, and smart grids. The system attempts to forecast future short-term energy convention and enable effective statement among customers and energy providers. The paper's main contributions are the following: an innovative sequences learning-based energy forecasting mechanism, optimum normalization technique selection, and real-time energy management via devices at the edge interacting with a shared cloud-based data supervisory server. The lowest mistake rates and less temporal complexity are features of this forecasting system. According to the suggested architecture, edge devices connect in real time to a shared cloud server inside an IoT network, enabling efficient interactions across related smart grids and energy demand and response. To address the heterogeneous nature of electrical data, the study employs a number of preprocessing approaches. Next, an effective algorithm for decision-making is implemented for forecasting the immediate future on devices with limited resources. The efficiency of the suggested framework is demonstrated by extensive tests, which indicate a considerable decrease of 3.77 units for root MSE (RMSE) and 0.15 units for mean-square error (MSE) for commercial and residential datasets, respectively. The paper provides a significant addition to green energy conservation in the Internet of Things networks, especially when discussing edge intelligence. The suggested framework is a notable development in the field because of its useful applications in forecasting energy usage, improving communication, and lowering forecasting mistakes.

The reviewed studies collectively advance the field of energy management across diverse domains. According to one study, a novel solution to smart building energy management combines deep learning and IoT to maximize air conditioner efficiency by identifying individuals. A multi-objective forecasting strategy for residential grid-connected PV-battery hybrid systems is presented in another research. It uses a three-tiered control framework and achieves significant savings in power prices and carbon emissions. Within the field of renewable microgrid energy management, a study employing a modified optimization technique with support vector machines demonstrates efficacy in lowering total operating costs. Another study presents a hybrid deep learning approach with improved accuracy over conventional models, focusing on home-level energy forecasting in smart buildings. Finally, a study highlights the potential of edge intelligence in green energy management by putting forth a deep learning-based system that significantly lowers predicting errors and intelligently manages energy in Internet of Things networks. When taken as a whole, these research help to bridge the gap between cutting edge technologies such as IoT, machine learning, and deep learning by providing more effective and sustainable energy management techniques for a variety of applications.

III. Problem Statement

The effective management of energy in smart buildings is the issue that the literature addresses, with a special emphasis on the integration of energy storage systems using sophisticated energy management techniques. One of the current issues is making decisions effectively in a changing environment in order to maximize the utilization of energy, cut expenses, and improve overall operational efficiency. The research highlights the importance of using the Deep Q-Networks algorithm—a type of deep reinforcement learning (DRL)—as a solution to these problems. Emphasis is placed on the DQN algorithm's capacity to estimate and optimize the action-value function in a network of deep neural networks, demonstrating its efficacy in teaching appropriate energy management tactics. The suggested approach is to use DQN to help smart building managers make defensible choices about lighting, HVAC, and energy storage. Reducing peak demand, occupant discomfort, and costs significantly depends on the DQN algorithm's ability to manage intricate and dynamic interactions in the smart building environment. According to the literature, combining DQN with cost optimization methods and complex energy storage models results in a more effective and sophisticated method of managing energy in smart buildings [19].

IV. Proposed EMDQN Framework for Energy Management in Smart Building

The proposed energy management methodology for smart buildings follows a systematic sequence, beginning with the collection of a diverse dataset. Through Min-Max normalization, the dataset is pre-processed to ensure consistent scaling. The application of reinforcement learning evaluates the effects of centralized and decentralized model predictive controllers on peak demand and operational expenses. Simultaneously, an advanced energy storage model is introduced, utilizing lithium-ion batteries and supercapacitors to strategically capture and use excess energy. A cost optimization model, employing linear programming, aims to minimize overall energy consumption costs. The results and discussion section then analyzes the methodology's performance, focusing on metrics like peak demand reduction and cost-effectiveness. Deep Q-Networks (DQN) play a pivotal role in optimizing energy management, aligning decisions with objectives such as cost reduction, peak demand reduction, and occupant comfort. The entire process is illustrated through a flowchart, providing a comprehensive overview of the methodology's implementation from preprocessing to performance assessment. The entire methodology process is represented in Fig. 1.

Fig. 1. Proposed framework for energy management in smart building.

A. Data Collection

The valuable tool for study and advancement in the area of smart building energy management is the dataset gathered from Kaggle. This comprehensive dataset, which comes from a seven-story office building in Bangkok, Thailand, includes one-minute interval records of power usage and interior environmental measures. It covers the period from July 1, 2018, to December 31, 2019. The data on power use covers each of the building's 33 zones for plug loads, lights, and air conditioning systems. The collection is further enhanced by complementary interior environmental sensor data, which includes ambient light, relative humidity, and temperature readings for the same zones. The CU-BEMS dataset is distinct because it provides a thorough analysis of the electricity consumption at the building level, broken down by zone and floor, and it captures the functioning of important loads in commercial buildings. Numerous applications benefit greatly from such a dataset, such as multiple-level load forecasting, the development of indoor thermal models, the validation of building simulation models, the creation of demand response algorithms based on load types, and the application of reinforcement learning algorithms for multiple AC unit control. This dataset provides a solid foundation for optimizing energy consumption and storage techniques in smart buildings, which is in line with the goals of our planned study on smart buildings [20].

B. Data Pre-processing using Min-Max Normalization

The distributional properties of the original data are maintained by using Min-Max normalization. It provides a normalized representation that keeps the crucial data for training the model while scaling the values and preserving the connections and trends within the feature. All of the data points inside a feature are guaranteed to be scaled to a common range between 0 and 1 as a consequence of the normalization procedure. Outliers, which are data points significantly deviating from the majority, can distort the effectiveness of the subsequent analysis and modeling. Outliers can distort the uniform scaling intended by Min-Max normalization, leading to suboptimal model performance. By addressing outliers effectively during pre-processing, the dataset's integrity is preserved, ensuring that the subsequent energy management model is robust and reflective of the true underlying patterns in the smart building data. This uniform scaling is essential for preventing certain features from dominating the learning process due to their larger magnitudes is represented in Eq. (1).

$$X_i^m = \frac{X_i^m - X_{Min}^m}{X_{Max}^m - X_{Min}^n} \tag{1}$$

where, x_i^m is any value of a variable m; $X_{Max}^m$and X_{Min}^n are the maximum and the minimum values of that variable; $x_{i,scaled}^m$ is the value after scaling. By utilizing the Min-Max Scaler to normalize the input data, it is possible to prevent the issue where one characteristic overwhelms the others because of its larger range of values. If features are not normalized, the model could overweight the characteristics with higher values, thereby resulting in less than-ideal model performance. By scaling all characteristics to the same range, the Min-Max Scaler ensures that every feature has an equal impact on the model predictions.

C. Utilization of Reinforcement Learning in Dynamic Environment

The objective of Reinforcement Learning (RL), a machine learning technique, is to maximize a numerical reward while solving certain challenges in a predetermined environment. Numerous common and specialized engineering problems may be solved with this technology. Within the reinforcement learning paradigm, an agent engages in iterative interactions with its surroundings, picking up and applying certain behaviors based on the state of the environment. After that, the environment offers a reward in addition to its most recent condition, and so on, until the agent maximizes the total rewards obtained. The policy is often defined as the method by which an agent operates from a specific state. Finding the best course of action for the agent to maximize cumulative rewards in the given environment is the main objective. The reinforcement learning structure in Smart building is represented in Fig. 2.

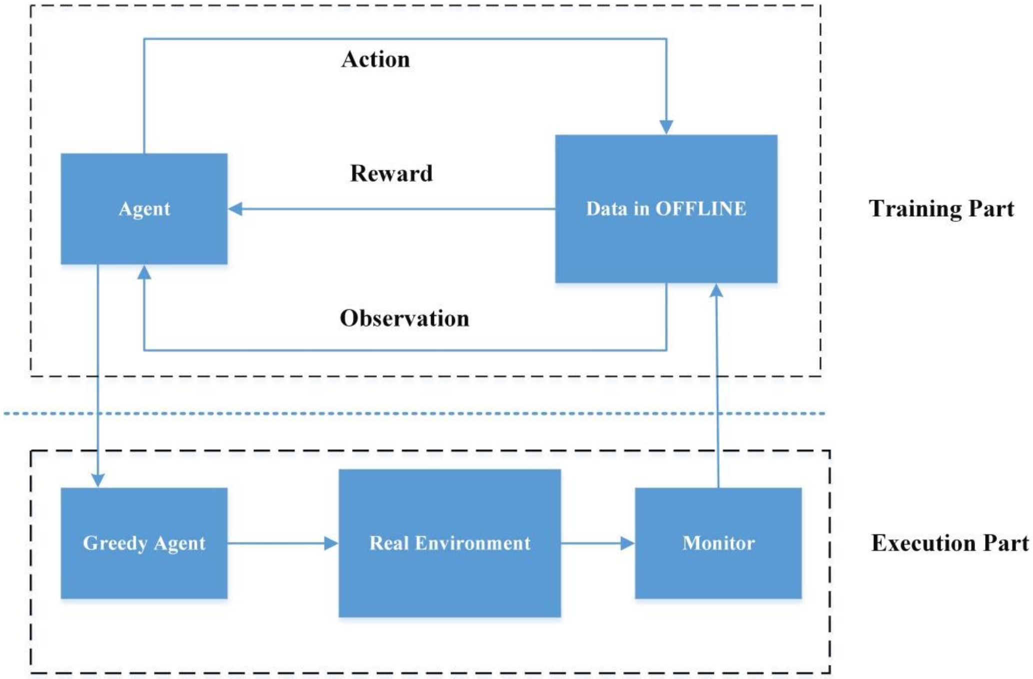

Fig. 2. Decision and control framework for reinforcement learning in smart energy management.

The environment in our research is assumed to be a Markov decision procedure, in which the agent's next state is determined only by its present state and the action it has selected, ignoring all other states and actions. The chosen value function for the inquiry is the Q-value, which is represented as$Q_p(a_x, b_x)$. The pairing of a state a_x and an action b_x at discrete time x is represented by this Q-value. The main goal of the agent is to maximize the Q-value at each time step. To find the best policy p in scenarios involving decision-making, Q-learning, a basic RL technique, is utilized. The Bellman equation is used in the Q-learning procedure to calculate and update the Q-value(a_x, b_x) is depicted in Eq. (2):

$$Q_p(a_x, b_x) = r(a_x, b_x) + \gamma max Q(a_x + 1, b_x + 1) \qquad (2)$$

In this case, the maximum discount future reward $\gamma max Q(a_x + 1, b_x + 1)$and the current reward $r(a_x, b_x)$add up to the ideal Q-value$Q_p(a_x, b_x)$. The relative relevance of present and future benefits is usually ascertained using a discounting factor $\gamma \in [0, 1]$. a smaller γ results in a more shortsighted agent that prioritizes immediate gains, whereas a bigger γ supports a more forward-looking strategy. To balance incentives for now and the future, the system operator can change the value of γ.

D. Deep Q-Networks (DQN) Algorithm for Energy Management Strategy

Deep Q-Networks is a reinforcement learning algorithm that combines deep learning with Q-learning to approximate and optimize the action-value function in a deep neural network. To determine the best practices for energy management in smart buildings, DQN is employed. In order to accomplish certain goals like cost reduction, peak demand reduction, and occupant comfort, it assists the system in making decisions about HVAC settings, lighting control, and energy storage measures. The Q-value represents the expected cumulative reward of taking a particular action in a given state is represented in Eq. (3)

$$Q_p(a_x, b_x) \leftarrow (1 - \alpha) \cdot Q_p(a_x, b_x) + \alpha \cdot (r + \gamma \cdot maxa' Q(a_x', b_x')) \qquad (3)$$

$Q_p(a_x, b_x)$ is the Q-value for state a_x and actionb_x. α is the learning rate, r is the immediate reward after taking action b_x in state a_x, γ is the discount factor, a_x' is the next state, b_x' is the next action. With parameters θ, a deep neural network approximates the Q-value. The Mean Squared Error between the goal Q-value and the predicted Q-value is the loss function used to train the network is presented in Eq. (4):

$$Loss(\theta) = E[(Q(a_x, b_x; \theta) - (r + \gamma \cdot maxa' Q(a_x', b_x'; \theta-)))^2] \qquad (4)$$

In this case, θ− stands for the parameters of a target network, which are updated with the online network's parameters, θ, on a regular basis. The input of deep neural network architecture is usually the state representation, and the architecture consists of fully linked layers. Each unit in the output layer represents the expected Q-value for a particular action, and there are as many units as there are potential actions. DQN frequently employs an epsilon-greedy strategy, in which the agent chooses an action (exploration) at probability ϵ and an action (exploitation) at probability 1−ϵ based on the maximum projected Q-value.

E. Energy Storage Model in Smart Building

For the purpose of maximizing cost-effectiveness, sustainability, and energy efficiency, an improved energy storage model is essential. In order to effectively store and manage energy and meet the changing demands of the building and its occupants, the model incorporates Super capacitors, lithium-ion batteries, when it comes to smart building energy management, this combination delivers clear benefits. Supercapacitors perform very well in cycles of fast charge and discharge, offering brief bursts of energy at times of peak demand and well balancing the intermittent nature of renewable energy sources. However, over longer periods of time, sustained and effective energy storage is guaranteed by lithium-ion batteries, which are renowned for their high energy density and dependability. Super capacitors, lithium-ion batteries, are the cutting-edge energy storage technologies are cleverly positioned to harvest extra energy produced from solar panels or other renewable energy sources during times of low demand. In order to ensure a steady and dependable power supply, this stored energy may subsequently be effectively used during periods of high demand or when renewable sources are insufficient. Predictive analytics and clever algorithms improve the system's responsiveness, allowing it to adjust to changing grid circumstances and energy needs. Smart building infrastructure is represented in Fig. 3.

The process for generating equations that represent the dynamics of energy storage, including the charging and discharging processes, is necessary to develop an energy storage model for a smart building. There is a single basic equation that determines the charge state (S_c) of the energy storage system over time can be expressed in Eq. (5):

$$S_c(x+1) = S_c\,(x) + c_x \frac{\gamma^{ch}\Delta\mathrm{x}}{Q_{storage}} p_{storage}^{charge}(x) + d_x \frac{\Delta\mathrm{x}}{\gamma^{disch} Q_{storage}} p_{storage}^{discharge}(x) \quad (5)$$

where, $p_{storage}^{charge}(x)$ and $p_{storage}^{discharge}(x)$ indicates the charging power and discharging power, $p_{storage}^{charge}(x) + d_x \geq 0$ and $p_{storage}^{discharge}(x) \leq 0$; γ^{ch} and γ^{disch}represents the discharging and charging effectiveness of the energy storage model ; The energy storage capacity and the time step duration are denoted by Δx. This formula is an example of a simplistic model; more intricate models may be developed by adding variables like round-trip efficiency, ageing effects, and temperature's effect on battery performance. These formulas enable the effective use of energy storage supplies while taking the dynamic nature of energy needs and external factors into account. They are crucial parts of a larger smart building energy management system.

F. Cost Optimization Model

The utilization of cost optimization models in smart building energy management often entails minimizing the total cost of energy consumption, taking into account variables such as power rates, operating expenses, and possible fines for over-energy thresholds. The following is an example of a popular formulation for this kind of model that uses linear programming is represented in Eq. (6):

$$C_x = \left(\frac{m_x - n_x}{2}|P_x| + \frac{m_x + n_x}{2}P_x\right),\ \forall\, x, \quad (6)$$

where, the energy purchasing and selling prices are represented by m_x and n_x. It is commonly recognised that the ESS's lifespan would be harmed by repeated charging or discharging. The Energy Storage System depreciation cost at time interval x is defined as follows to observe in Eq. (7),

$$C_x = \varphi(|c_x| + |d_x|) \quad (7)$$

where, c_x and d_x are charging and discharging power, and φ indicates the depreciation coefficient.

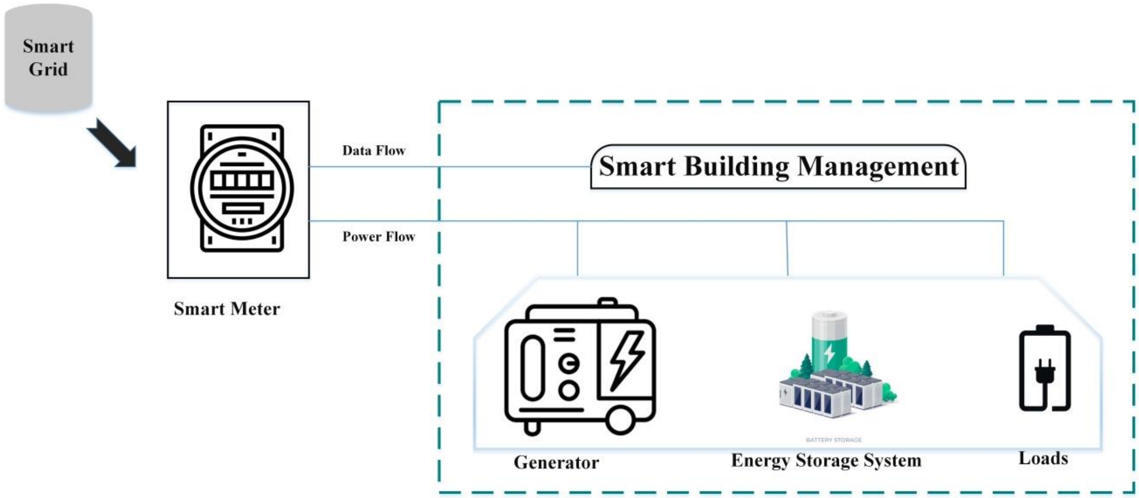

Fig. 3. Energy management system.

G. Reward

The reward function in a reinforcement learning setting typically represents the immediate benefit or cost associated with taking a particular action in a given state. In the context of energy management in smart buildings, the reward function can be designed to reflect the system's objectives. For instance, it might consider factors such as energy cost reduction, peak demand reduction, and occupant comfort. Here is a general form of the reward function, denoted as R in Eq. (8),

$$R(a_x, b_x) = r(a_x, b_x) + \gamma \cdot maxa'Q(a_x + 1, b_x + 1) \quad (8)$$

a_x and b_x represent the state and action at discrete time x. $r(a_x, b_x)$ is the immediate reward after taking action b_x in state ax. γ is the discount factor, determining the relative importance of present and future rewards. It is typically in the range [0, 1], where a smaller γ makes the agent more shortsighted, prioritizing immediate gains, while a larger γ supports a more forward-looking strategy.

V. Results and Discussion

The results section of the study focuses on evaluating the effectiveness and performance of the proposed methodology for efficient deep reinforcement learning in smart buildings, particularly concerning the integration of energy storage systems through advanced energy management strategies. Key metrics are employed to assess various aspects of the system's functionality, including cost optimization, peak demand reduction, occupant comfort, and overall energy efficiency. Quantitative measures, such as cost savings, peak demand reduction percentages, and the accuracy of the reinforcement learning model, will be reported. The results and discussion section receives inputs from the reinforcement learning model, energy storage model, and cost optimization model. The grid peak demand reduction performance and cost reduction performance analyses are part of the Results and Discussion section, providing insights into the effectiveness of the proposed methodology.

A. Cost Reduction Performance Analysis

Fig. 4 illustrates the breakdown of summertime electrical demand charges for the scenarios Without DQN, DQN-Temperature, DQN-Battery, and With DQN. It highlights interesting trends in peak demand management. August demand charges for the typical technique Without DQN are 1897 units; however, when the entire DQN strategy is integrated, these demand charges are significantly reduced to 1234 units, which is an outstanding decrease of almost 35.01%. Reductions are also achieved via the DQN-Battery and DQN-Temperature techniques, which have demand charges of 1698 and 1687 units, respectively. June and July reveal that DQN tactics work as well, with demand charges reduced by around 33.13% and 30.82%, respectively. On the other hand, September offers a special case with an unanticipated rise in demand fees for all DQN methods in contrast to the conventional model.

In Fig. 5, the DQN method produces the largest energy charge decrease in the winter, totaling 3897 units as opposed to 6785 units in the conventional Without DQN scenario, or a significant reduction of almost 42.61%. With a decrease in demand charges from 4587 units to 3298 units, or around 28.16% less, the reduction in demand charges is likewise noteworthy. The drop in cost is similarly notable in the summer. Compared to the conventional method, the With DQN technique helps to save around 16.99% in demand charges and 6.07% in energy charges.

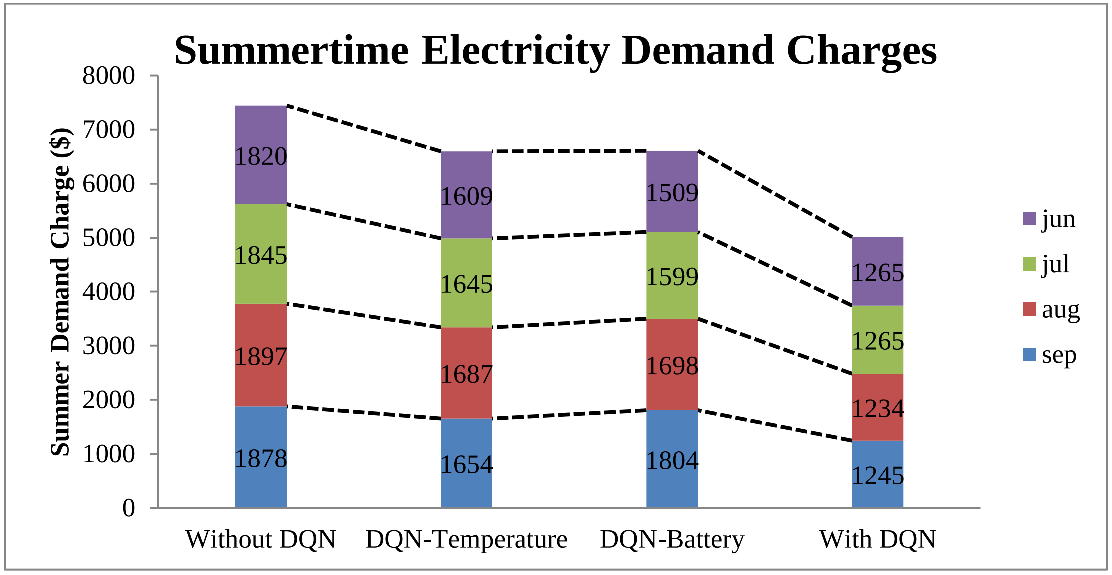

Fig. 4. Analysis of summertime electricity demand charges.

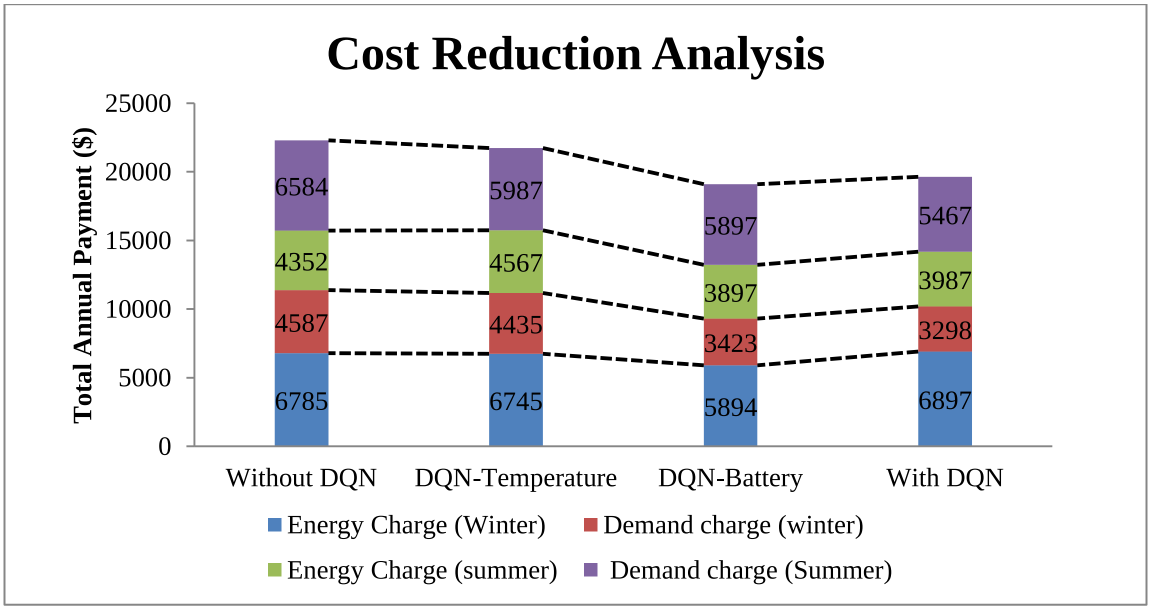

Fig. 5. Total annual cost reduction analysis.

The DQN techniques, especially the all-inclusive With DQN model, demonstrate how well they work to maximize energy use, tactically control peak demand, and eventually lower total operating expenses. This report highlights the potential financial benefits of using advanced energy management strategies and highlights DQN's contribution to the facility's large summer and winter cost savings.

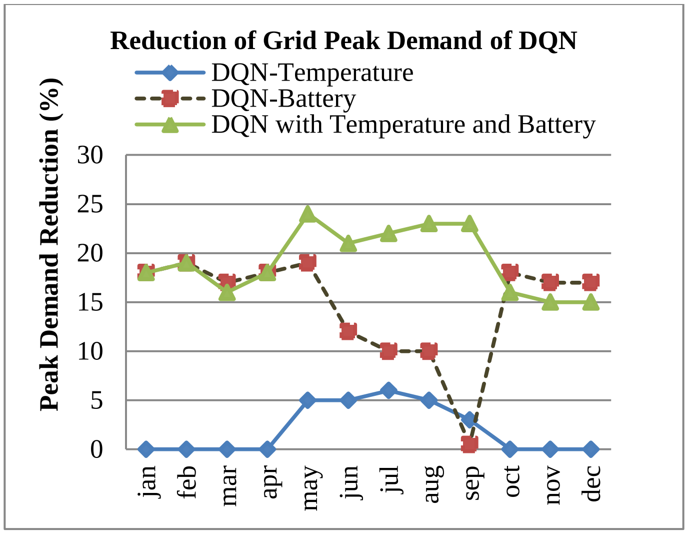

Fig. 6. Peak demand reduction evaluation.

Fig. 6 describes the observed peak demand reduction of 26.32% in May indicates a noteworthy beneficial impact of the adopted techniques, namely the DQN strategy, in the context of smart buildings. This significant decrease indicates that energy consumption habits were successfully adjusted and optimized during a month when demand is usually higher. The DQN strategy's ability to strategically manage and reallocate energy resources is demonstrated by its efficacy in May, which greatly enhances the building's total energy efficiency.

In Fig. 7, the rewards are received at various times when a reinforcement learning model is being trained or assessed. The rewards corresponding to each episode's progressive numbering show how well the model performed at each level. In this particular case, the incentives exhibit an increasing tendency as the number of episodes rises, going from an initial reward of -7.1 to -5 at episode 12,000 in this particular situation. The objective is to train the model to maximize its cumulative reward over episodes; the negative values indicate that the model is penalized for specific states or behaviors.

Table I compares the performance metrics of a proposed Deep Q-Network strategy with a Genetic Algorithm method for various situations of home energy management strategies. The peak load, power added to the grid, and power taken out of the grid are all represented by the Power figures.

The overall energy consumption and revenue/cost throughout time are tracked by cumulative energy and cumulative revenue/cost. The daily net cost is shown by the Net Cost. Comparing the Proposed DQN method to the GA approach, the percentage changes show that there is a reduction in peak load of 0.8918%, a fall in cumulative income of 3.4972%, a reduction in daily cost of 0.7647%, and an overall decrease in net cost of 6.7887%. These findings demonstrate the potential of the Proposed DQN method as an efficient home energy management strategy by indicating that it performs well in terms of peak load control and cost reduction.

B. Error Rate Evaluation

The mean square error (MSE) is a non-negative quantity, and its units are often the squared units of the original data. In regression analysis and other modeling tasks, it is commonly employed as an unbiased measure to assess how well a model with predictions or estimator is working. It is expressed in Eq. (9).

$$MSE = \frac{1}{m}\sum_{i=1}^{m}\left(X_i - \widehat{X}_\iota\right)^2 \quad (9)$$

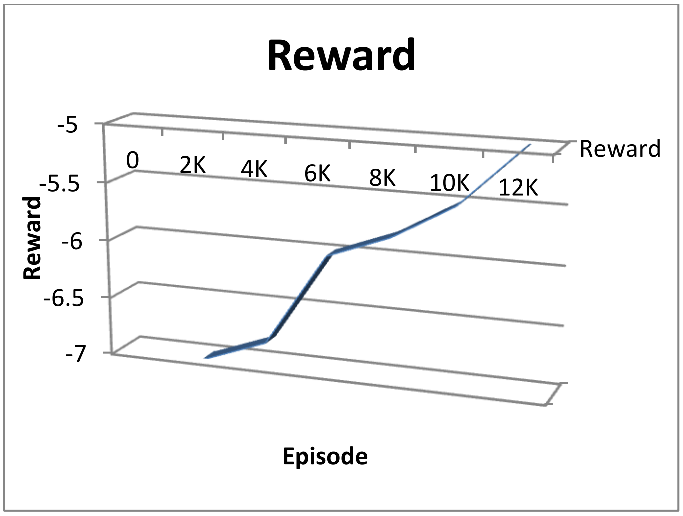

Fig. 7. Reward for proposed DQN algorithm.

TABLE I. COMPARISON OF THE RESULTS BETWEEN USING STRATEGIES GA AND PROPOSED DQN

Algorithm for Home Energy Management Strategy	Power (kW)	Cumulative Energy (kWh)		Cumulative Revenue/Cost (USD)		Net Cost (USD)
	Peak Load	Injected to Grid	Drawn from Grid	Revenue	Cost	Daily Cost
GA [21]	6.7894	53.0567	58.3765	2.7863	3.1243	0.3987
Proposed DQN	5.8976	53.0567	54.8793	2.7863	3.0596	0.3100
Increment (%)	-	-	-	-	-	-
Reduction (%)	0.8918	-	3.4972	-	0.7647	6.7887

where, m is the total amount of data points, X_i is the actual values and $\widehat{X_\iota}$ is the estimated values. MAE is used to indicate the quality of a prediction approach or estimator and is frequently given in the same units as the original data. It is expressed in Eq. (10).

$$MAE = \frac{1}{n}\sum_{i=1}^{m}\left|X_i - \widehat{X_\iota}\right| \tag{10}$$

where, m is the total amount of data points, X_i is the actual values and $\widehat{X_\iota}$ is the estimated values.

TABLE II. COMPARISON OF ERROR RATE

Energy Management Strategic Methods	Mean Square Error (%)	Mean Absolute Error (%)
Fuzzy Algorithm	14.5	15.87
Genetic Algorithm	12.6	14.43
Proposed DQN	8.6	6.4

The performance evaluation of three distinct energy management strategy methods—the Genetic Algorithm, the Proposed Deep Q-Network, and the Fuzzy Algorithm—is shown in Table II. Mean Absolute Error and Mean Square Error, both expressed in percentage terms, are the metrics used for evaluation. With a Mean Square Error of 14.5% and a Mean Absolute Error of 15.87%, the Fuzzy Algorithm exhibits a comparatively elevated degree of prediction mistakes. With a Mean Absolute Error of 14.43% and a Mean Square Error of 12.6%, the Genetic Algorithm performs more effectively. The proposed DQN performs much more effectively than both algorithms, with a Mean Square Error of 8.6% and a significantly lower Mean Absolute Error of 6.4%. Based on these findings, it appears that the Proposed DQN is a more promising method for optimizing energy systems than the Fuzzy and Genetic Algorithms in terms of prediction accuracy in energy management.

C. Discussion

The study's findings center on assessing the effectiveness and performance of the suggested approach for effective deep reinforcement learning in smart buildings, with a special emphasis on how improved energy management techniques integrate energy storage systems. Key performance indicators that are included in the evaluation include overall energy efficiency, peak demand reduction, cost optimization, and occupant comfort. Quantitative metrics are presented, including cost savings, percentages of peak demand decrease, and the accuracy of the reinforcement learning model. The results present the cost reduction study, which shows notable decreases in demand charges, energy charges, and overall operating expenditures in the summer and winter. The peak demand reduction evaluation shows a significant improvement in May due to the implemented approaches, with a decrease of 26.32%.

Furthermore, Methodology illustrates the incentives attained at various episodes throughout the model's training or assessment, exhibiting a progressive upward trend over time. The Proposed Deep Q-Network (DQN) method and the Genetic Algorithm [21] technique are thoroughly compared in Table I, which also highlights the benefits of the DQN strategy, which include a decrease in peak load, cumulative income, and total net cost. Taken as a whole, these measures highlight how well the suggested technique works to maximize energy consumption, cut expenses, and improve the overall performance of smart buildings. The study demonstrates the effectiveness of a systematic DRL framework for energy management in smart buildings. The proposed methodology integrates Min-Max normalization, reinforcement learning, and Deep Q-Networks to optimize decision-making processes. The integration of supercapacitors and lithium-ion batteries in the energy storage model is highlighted. This model aims to maximize cost-effectiveness, sustainability, and energy efficiency by strategically capturing and utilizing excess energy, addressing the intermittent nature of renewable energy sources.The study employs linear programming to develop a cost optimization model, aiming to minimize overall energy consumption costs. This model considers variables such as power rates, operating expenses, and potential fines for exceeding energy thresholds, providing a holistic approach to cost-effective energy management.

VI. CONCLUSION AND FUTURE WORKS

The energy management approach for smart buildings that is being presented demonstrates promise in terms of improving energy efficiency, cutting expenses, and efficiently controlling peak demand. It incorporates energy storage models, a Deep Q-network algorithm, and cost optimization techniques. Reinforcement learning is integrated into the system to enable dynamic adaptation to changing environmental circumstances and occupant demands. This optimizes decision-making processes related to energy storage measures, lighting management, and HVAC settings. When compared to conventional algorithms like fuzzy and genetic algorithms, the suggested DQN algorithm demonstrated notable improvements in cost reduction, peak demand management, and overall energy efficiency. The algorithm was developed on an extensive dataset from a seven-story office building in Bangkok, Thailand. Furthermore, the energy storage model improves the smart building's capacity for effective energy management and storage by cleverly using cutting-edge technology like lithium-ion batteries and supercapacitors. The linear programming-based cost optimization methodology helps to further reduce the overall cost of energy consumption. The effectiveness of the DRL technique may also be sensitive to the quality and representativeness of the dataset. Furthermore, the proposed energy storage model, while incorporating advanced technologies, simplifies the dynamics by using a basic equation, omitting factors such as round-trip efficiency and aging effects.

There are a number of directions to pursue in order to expand and enhance the suggested technique in future research. Initially, the flexibility and performance of the DQN algorithm might be improved by fine-tuning its hyperparameters and architecture to better fit the unique features of various smart buildings. Further optimizing the sustainability of the system might involve investigating the integration of renewable energy sources and implementing more sophisticated energy storage technology. Furthermore, given the dynamic nature of smart buildings, examining how online learning methods may be used to continually adjust to shifting circumstances and occupant behavior may help develop more adaptable and responsive energy management strategies. Moreover, broadening the scope of the cost optimization model to incorporate other variables like weather predictions, grid conditions, and dynamic pricing models may offer a more thorough method of reducing energy expenditures. All things considered, the approach that has been described provides a strong basis for smart building energy management. Research projects in the future can build on this foundation to tackle new problems and possibilities that arise in the quickly developing field of sustainable and energy-efficient building technology.

Abstract—**Parkinson's disease (PD) is a neurodegenerative condition that impacts a significant global population. The timely and precise identification of PD plays a pivotal role in facilitating early intervention and the efficient management of the condition. Recently, speech analysis has emerged as a promising non-invasive technique for the detection of PD due to its accessibility and ability to reveal subtle vocal biomarkers associated with the disease. This research introduces an innovative approach utilizing Short-Time Fourier Transform (STFT) to generate spectrograms, specifically Bark Spectrogram Cepstral Coefficients (BSCC) and Mel Spectrogram Cepstral Coefficients (MSCC). These coefficients are compared with traditional and well-known coefficients, namely Mel-Frequency Cepstral Coefficients (MFCC) and Bark Frequency Cepstral Coefficients (BFCC). To extract the most effective coefficients for Parkinson's disease detection, three robust classification techniques—Long Short-Term Memory neural networks (LSTM), Convolutional Neural Networks (CNN), and Artificial Neural Networks (ANN)—are employed. As a result, the BSCC and MSCC algorithms achieve a maximum accuracy rate of 90%, surpassing the accuracy of the traditional MFCC and BFCC coefficients. Therefore, these newly proposed coefficients prove to be more precise in diagnosing Parkinson's disease compared to the conventional MFCC and BFCC coefficients.**

Keywords—Parkinson's Disease (PD); Bark Spectrogram Cepstral Coefficients (BSCC); Mel Spectrogram Cepstral Coefficients (MSCC); Long-Term Memory Neural Networks (LSTM); Convolutional Neural Networks (CNN); Artificial Neural Networks (ANN)

I. INTRODUCTION

Parkinson's disease (PD) ranks among the most widespread and incapacitating neurodegenerative conditions, impacting millions of individuals across the globe. Named after the pioneering work of British physician James Parkinson, who first documented its clinical manifestations in 1817, Parkinson's disease has emerged as a profound challenge in modern medicine. Characterized by its progressive deterioration of motor function, PD also presents an intricate array of non-motor symptoms, encompassing sleep disturbances, cognitive impairments, emotional alterations, and autonomic dysfunctions.

This neurological condition is mainly characterized by the deterioration of dopaminergic neurons located in the substantia nigra part of the brain, resulting in a significant reduction in dopamine production. The repercussions of this disruption within the central nervous system manifest through a range of distinctive clinical symptoms, including muscle rigidity, resting tremors, bradykinesia (slowness of voluntary movements), and postural instability.

The timely and precise detection of PD is of paramount importance in providing timely and effective medical interventions. While current diagnostic methods primarily rely on clinical evaluation and specialized imaging techniques, an expanding body of research suggests that significant insights into the early detection of Parkinson's disease may be gleaned from analyzing the human voice. This hypothesis is rooted in the notion that subtle vocal changes, often imperceptible to the human ear, may serve as early indicators of the disease. Leveraging the advancements in machine learning and voice analysis technologies, researchers are increasingly exploring the potential of voice-based biomarkers for PD diagnosis.

In the academic literature, there is increasing attention to the application of speech-based techniques using both machine learning and deep learning for the detection of Parkinson's disease. Numerous research papers have investigated the application of machine learning methodologies, including SVM [1] – [4], KNN [5], [6] , DT [7] , and genetic algorithms [26] in this context. Simultaneously, the PD identification has been addressed through the employment of established convolutional neural network (CNN) architectures such as AlexNet, DenseNet, LSTM, SqueezeNet, VGG19, and others, as well as custom-designed CNN architectures developed by researchers for deep learning investigations [8], [9]. Notably, CNN architectures have demonstrated enhanced performance in the domain of feature extraction [8].

Moreover, CNN techniques have exhibited success in various research domains, encompassing tasks like ocean noise detection [10], COVID-19 detection via X-ray images [11]–[13], mammography image segmentation and classification [14], classification of environmental sounds [15], Alzheimer's disease detection [16], skin cancer diagnosis [17], identification of cartilage lesions [18], fatigue diagnosis based on heart sounds [19], diagnosis of joint disorders [20], premature retinopathy assessment [21], and even the diagnosis of idiopathic Parkinson's disease [22].

In this research, we explore the use of spectrogram-based techniques, specifically BSCC (Bark Spectral Cepstral Coefficients) and MSCC (Mel Spectral Cepstral Coefficients), to extract pertinent vocal features for disease classification. Our dataset, sourced from the SAKAR database, comprises 38 audio recordings, encompassing 18 patients diagnosed with PD and 20 healthy individuals. The stratification of the dataset allows for a comprehensive examination of the proposed methodologies in distinguishing between healthy and affected individuals.

This paper is structured as follows: Section I presents an extensive review of the background, contextualizing the significance of voice analysis in Parkinson's disease diagnosis. Section II delves into related work. Section III is about database. Section IV outlines the proposed methodology, elucidating the intricacies of the BSCC and MSCC techniques and their application in our study. Section V and Section VI encompasses the discussion of results, presenting findings, and insights derived from our experiments. Lastly, we summarize our main findings and their implications for further research and clinical applications in Section VII.

II. Related Work

The study of Mehmet Bilal et al. outlines a new approach for detecting PD based on voice signals using LSTM and pre-trained deep networks. The process involves four steps: noise reduction, mel-spectrogram extraction, deep feature extraction using pre-trained ResNet models, and classification with an LSTM model. Experiments conducted with the PC-GITA dataset, a widely used dataset, demonstrate superior classification performance compared to existing methods, emphasizing the importance of early diagnosis for speech-related Parkinson's symptoms, an accuracy of 98.61% was attained [23], for Gaffari selik et al. In their study, the research leverages advanced deep learning and machine learning techniques to diagnose PD using voice signal datasets from both PD patients and healthy individuals (PDO_Dataset and PD_Dataset). The study examines existing machine learning and CNN algorithms for PD diagnosis, conducting a comparative performance analysis. Furthermore, a novel approach named SkipConNet + RF, combining RF and CNN, is introduced for PD detection. SkipConNet extracts crucial features from voice signals and then employs the RF algorithm for estimation. This approach significantly enhances RF algorithm performance, achieving an improvement ranging from 3% to 17.19%. Remarkably, the SkipConNet + RF method achieves remarkable accuracy, with a 98.30% on the PDO_Dataset dataset and 99.11% success rate on the PD_Dataset dataset, showcasing its potential as a highly effective tool for PD diagnosis [24] .

The article of Quan et al. presents a novel deep learning approach for detecting PD through voice signals. The approach utilizes time-distributed 2D-CNNs to extract dynamic time series features and employs a 1D-CNN to capture dependencies between these features. The model's performance was evaluated on two databases. On Database-1, it outperformed traditional machine learning models, achieving accuracies of 81.6% for sustained vowel /a/ and 75.3% for a short Chinese sentence. On Database-2, the model attained up to 92% accuracy across various speech tasks, including reading sentences in Spanish. The model's learned time series features effectively captured variability and the reduced frequency range in PD sounds, crucial for diagnosis. Furthermore, the study highlights the significance of the low-frequency region in Mel-spectrograms for PD recognition from voice, surpassing the influence of the high-frequency region [25], For Karan et al. Their study addresses the use of speech as an early marker for PD detection, given its impact on several speech components. To overcome challenges related to non-stationarity and discontinuity in speech signals, the researchers introduce a novel feature called IMFCC based on empirical mode decomposition. The performance of these proposed IMFCC features is evaluated using two datasets, each comprising 25 Parkinson-affected individuals and 20 normal. The findings demonstrate that IMFCC features offer significantly improved classification accuracy in both datasets, with an impressive increase of 10–20% compared to MFCC features. This suggests the potential of IMFCC as a highly effective tool for PD identification through voice analysis [26]. Chen et al. employed an architecture that utilized the HHT and KNN algorithms. They extracted a total of 21 characteristics, consisting of 12 from each sound sample using the HHT algorithm and nine using the LPCC algorithm. Subsequently, these extracted characteristics were individually classified using KNN, DT and RF algorithms. The authors reported the best performance using the KNN, achieving an accuracy of 93.3% [27].

The study of Tasnas et al. Investigate the connection between speech dysfunction and PD, particularly focusing on novel dysphonia measures aimed at predicting PD symptom severity through speech signals. A sum of 132 dysphonia metrics was calculated based on sustained vowel sounds. These measures were then reduced to four parsimonious subsets using feature selection algorithms. These subsets were utilized for binary classification, employing both RF and SVM as statistical classifiers. The research leveraged a database with 263 samples from 43 subjects and demonstrated that these novel dysphonia measures can achieve remarkable results, with an overall classification accuracy of nearly 99% using only ten dysphonia features. The study highlights the complementarity of these newly proposed measures with existing algorithms, enhancing the classifiers' ability to distinguish PD subjects from healthy controls. These findings represent a significant advancement towards non-invasive diagnostic decision support for PD [28]. Yaman et al. utilized a freely accessible dataset from the UCI dataset platform, comprising 240 speech samples, with 40 from PD patients and 40 from healthy ones. Their approach involved augmenting the dataset's attributes through the application of a statistical pooling method. Subsequently, they derived weighted features employing the ReliefF technique. These weighted feature vectors were then subjected to classification using both SVM and KNN techniques, yielding a commendable 91.25% success rate with the SVM algorithm and 91.23% with the KNN method [29]. The paper of Kavita Bhatt et al. Highlights the significance of early PD detection in the elderly, emphasizing common symptoms such as dysarthria, tremors, cognitive changes, and muscle stiffness. The study proposes a Deep Neural Network algorithm using spectrograms generated by the Superlet Transform for PD detection from speech signals. The method achieved an impressive 96% on the ItalianPVS dataset and 92% overall accuracy on the PC-GITA dataset, outperforming state-of-the-art methods in PD detection from diverse speech data sources [30].

The research conducted by Mahboobeh and colleagues focuses on the demanding task of diagnosing PD earlier, particularly focusing on gender-specific differences in speech characteristics. A hybrid method is proposed, leveraging features' scores based on a two-dimensional projection. After removing gender-specific features, the approach employs Classification-Based Feature Score (CBFS) and Statistical-Based Feature Score (SBFS) to rank the remaining features. Resampling enhances feature selection stability. Various classifiers (KNN, NSVM, LSVM, RF, and NB) are applied, achieving 84% and 86% accuracy rates for women and men, respectively, with fewer selected features compared to prior studies. The results highlight feature commonalities despite gender differences and validate using an independent dataset for added robustness [31]. The proposed model comprises three key stages. Firstly, noise is eliminated from the signals using the DWT-EMD and EMD-DWT methods. Secondly, MFCC and GTCC features are extracted from the enhanced audio signals. The final step involves classification, where these features are input into CNN and LSTM models designed to capture sequential information from the extracted features. In the experimental phase, the study employs the PC-GITA and Sakar datasets, applying a ten-fold cross-validation method. Impressively, the highest classification accuracy for the PC-GITA dataset, the accuracy reaches 100% for EMD-DWT-GTCC-CNN and 96.55% for DWT-EMD-GTCC-CNN. For the Sakar dataset reaches 100% for both the EMD-DWT-GTCC-CNN and DWT-EMD-GTCC-CNN combinations. These findings underscore the effectiveness of GTCC features over MFCC in Parkinson's disease assessment. This research showcases a promising avenue for accurate and timely detection of PD through speech analysis, potentially improving the effectiveness of telemedicine-based diagnosis and monitoring systems [32].

III. Database

The study utilizes a dataset from a prior investigation, comprising 38 voice recordings. This dataset includes 20 individuals diagnosed with Parkinson's disease (PD) and 18 individuals classified as healthy controls. During these recording sessions, participants were specifically instructed to articulate the vowel 'a' using a standard microphone with a sampling frequency of 44,100 Hz, and the recordings were conducted on a desktop computer equipped with a 16-bit sound card. These voice recordings form the foundation of our analysis [33].

The proposed methodology involves the utilization of advanced feature extraction techniques as shown Fig. 1, including MFCC, MSCC, and BSCC, BFCC which will be detailed subsequently. These extracted acoustic features are then fed into powerful classification models, such as ANN, CNN and LSTM. The integration of these cutting-edge feature extraction methods and state-of-the-art classification algorithms forms the core of our approach, ultimately facilitating the accurate differentiation between individuals affected by PD and those in a healthy control group. The subsequent sections will provide a comprehensive explanation of each method and its role in our classification framework.

IV. Proposed method

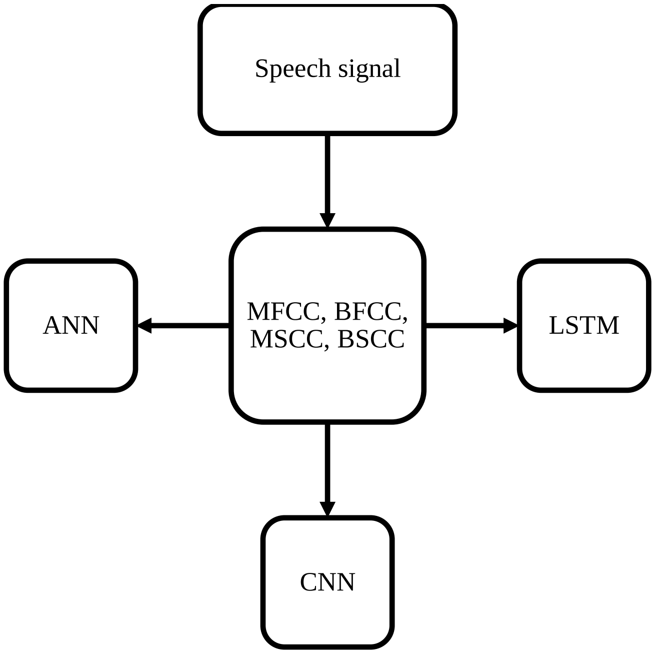

Fig. 1. The schematic for the proposed method.

A. MFCC

MFCC stands as a commonly employed method for extracting features in the realm of speech and audio signal processing, Fig. 2 depicts the different steps to follow in order to obtain the MFCC coefficients.

Pre-emphasis: The audio signal is pre-emphasized by applying a high-pass filter to amplify high-frequency components, as described this equation with k = 0.97.

$$\mathrm{H(z) = 1 - kz^{-1}} \tag{1}$$

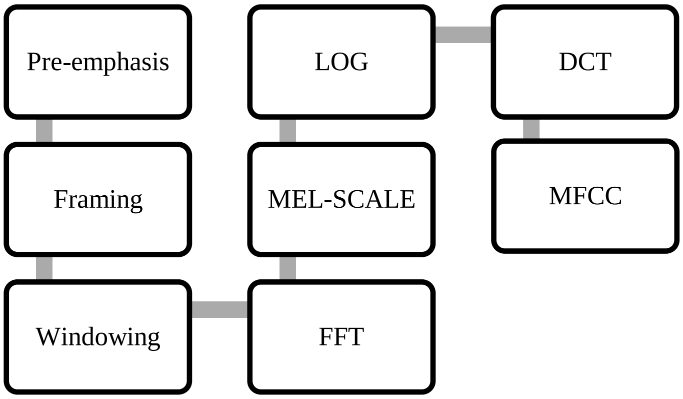

Fig. 2. The steps for calculating MFCC coefficients.

Framing: The signal with pre-emphasis undergoes segmentation into short, overlapping frames to capture temporal attributes.

Windowing: Each frame is windowed using the Hamming window function to prepare it for Fourier analysis.

$$w(n) = 0{,}54 - 0{,}46\cos\left(\frac{2\pi n}{N-1}\right) \qquad (2)$$

FFT (Fast Fourier Transform): The FFT is applied to each frame to convert it into the frequency domain.

$$S_n = \sum_{k=0}^{N-1} S_k e^{-j2\pi\frac{kn}{N}} \qquad (3)$$

Mel Scale: The resulting spectrum is transformed onto the Mel scale, which simulates human auditory perception.

$$\text{Mel} = 2595\log_{10}\left(1 + \frac{f}{700}\right) \qquad (4)$$

Discrete Cosine Transform (DCT): The DCT is used to decorrelate the Mel-scaled spectrum, reducing redundancy.

$$c_i = \sqrt{\frac{2}{N}}\sum_{j=1}^{M} m_j \cos\left(\frac{\pi i}{N}(j - 0{,}5)\right) \qquad (5)$$

MFCC Calculation: Finally, a subset of the DCT coefficients is selected as Mel-Frequency Cepstral Coefficients, which indicate the spectral properties of the audio signal.

B. BFCC

BFCC is similar to MFCC, but it uses the Bark scale instead of the Mel scale. In Fig. 3, the various stages required to acquire the BFCC coefficients are illustrated.

Pre-emphasis, Framing, Windowing, FFT: These initial steps are identical to those in MFCC.

Bark Scale: Instead of the Mel scale, the FFT results are transformed onto the Bark scale, which is another representation of auditory frequency perception.

$$\text{Bark}(f) = \frac{26{,}81f}{1960+f} + 0{,}53 \qquad (6)$$

DCT: The DCT is applied to the Bark-scaled spectrum to reduce redundancy and extract cepstral coefficients.

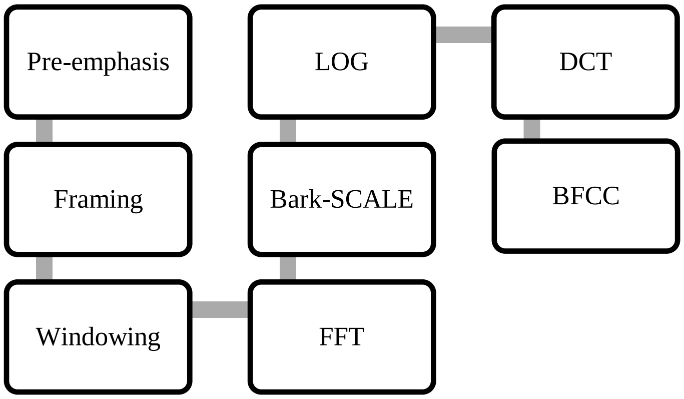

Fig. 3. The steps for calculating BFCC coefficients.

C. MSCC

MSCC is a variant of MFCC that directly uses the STFT instead of the FFT. The different procedures for obtaining the MSCC coefficients are presented in Fig. 4.

Pre-emphasis, Framing, Windowing: These steps remain the same as in MFCC.

STFT: Instead of the FFT, the STFT is used to attain a time-varying spectral representation for each frame.

Mel Scale and DCT: The Mel scale is implemented to the STFT results, followed by DCT, to calculate Mel Spectral Cepstral Coefficients.

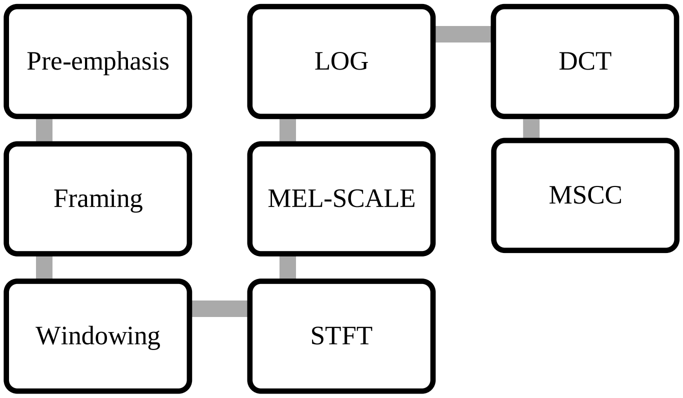

Fig. 4. The steps for calculating MSCC coefficients.

D. BSCC

BSCC is similar to MSCC, but it uses the Bark scale instead of the Mel scale in the final step. Fig. 5 outlines the sequential steps for deriving the BSCC coefficients.

Pre-emphasis, Framing, Windowing and STFT: These initial steps are identical to those in MSCC.

Bark Scale: Instead of the Mel scale, the STFT results are transformed onto the Bark scale, and then DCT is applied to extract Bark Spectral Cepstral Coefficients.

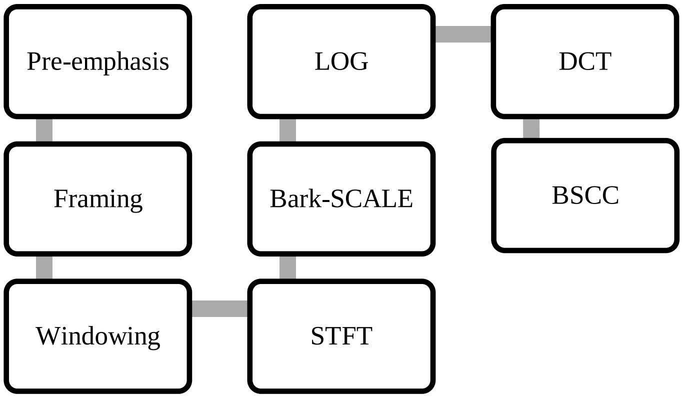

Fig. 5. The steps for calculating BSCC coefficients.

E. ANN

An Artificial Neural Network (ANN), modeled on the structure of biological neural networks, is a computational model composed of interconnected processing units, or neurons, organized into layers. These neurons process and transmit information through weighted connections. ANNs are designed for supervised learning and have the capacity to memorize complicated patterns and relationships within data. They include an input layer, one or more hidden layers, and an output layer. ANNs are widely employed for diversity of applications, including classification, regression, and function approximation.

F. *LSTM*

An LSTM is a form of RNN specifically created to tackle the challenge of the vanishing gradient issue encountered in conventional RNNs. LSTMs are notably effective for tasks that encompass sequential data. Time series data, or natural language processing. They incorporate specialized memory cells that can capture long-range dependencies in data, making them capable of retaining information over extended time intervals. LSTMs are crucial in applications such as speech recognition, and sentiment analysis, where understanding and modeling sequential patterns are essential.

G. *CNN*

A CNN is a deep learning structure mainly utilized for the analysis of images and spatial data. CNNs excel at automatically extracting hierarchical and spatial features from input data using convolutional layers, pooling layers, and fully connected layers. Convolutional layers apply convolutional operations to scan and detect local patterns within the input, making CNNs highly effective in image classification, object detection, and image generation tasks. They have also found applications beyond image processing, including in natural language processing and reinforcement learning.

V. Result

In this section, the experimental outcomes are presented and the performance of the new approaches is assessed, MSCC and BSCC, alongside the BFCC and MFCC, in the context of PD detection through speech analysis. We also discuss the outcomes obtained using ANN, LSTM, and CNN for classification. Fig. 6 to Fig. 9 sequentially display the MFCC, MSCC, BFCC, and BSCC coefficients obtained for an individual diagnosed with Parkinson's disease.

The Fig. 6, 7, 8, and 9 displays the initial twelve coefficient values of MFCC, MSCC, BFCC, and BSCC, respectively. These coefficients encompass numerous frames that demand significant processing time for classification, hindering the accurate diagnostic decision-making process. To address this issue, the average value of these frames is computed to obtain the voiceprint and mitigate the processing burden.

The results of our experiments reveal varying levels of accuracy across different feature extraction methods and classification algorithms. For Mel Spectrogram-based Cepstral Coefficients (MSCC), we observed high accuracy rates, with ANN achieving 90% accuracy and CNN also reaching 90%, underscoring their effectiveness. LSTM, while slightly lower at 81%, still performed well with MSCC. Similarly, Bark Spectrogram-based Cepstral Coefficients (BSCC) exhibited strong accuracy, with ANN achieving 81% accuracy and LSTM and CNN both reaching 90%. In contrast, conventional BFCC and MFCC yielded comparatively lower accuracy rates, with ANN achieving 54% and 64%, respectively, and LSTM and CNN hovering around 80%. These findings suggest that MSCC and BSCC may offer superior feature extraction capabilities in the field of diagnosing PD, potentially revolutionizing the field with their higher accuracy rates when coupled with advanced classification techniques like CNN and LSTM.

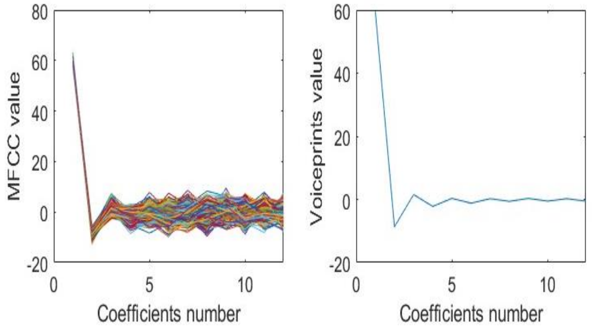

Fig. 6. The 12 MFCC coefficients for an individual with Parkinson's disease.

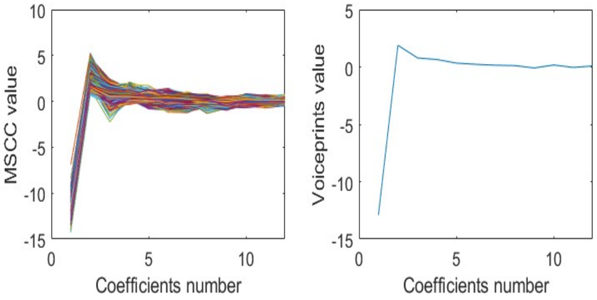

Fig. 7. The 12 MSCC coefficients for an individual with Parkinson's disease.

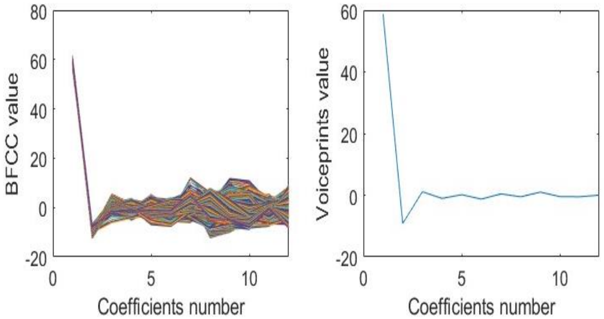

Fig. 8. The 12 BFCC coefficients for an individual with Parkinson's disease.

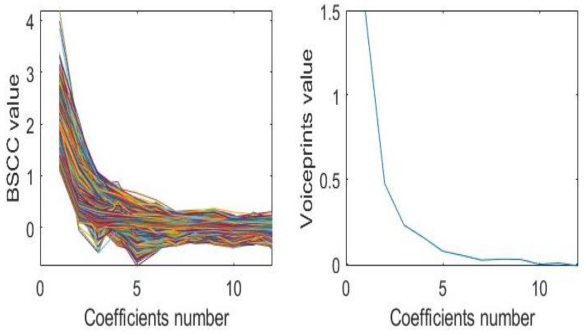

Fig. 9. The 12 BSCC coefficients for an individual with Parkinson's disease.

The achieved accuracy rates with MSCC and BSCC in combination with ANN, LSTM, and CNN are notable and indicate their promise as powerful features for PD detection. The consistent high accuracy rates of 90% with MSCC and BSCC when coupled with CNN highlight their efficacy in feature extraction. MSCC and BSCC capture spectral characteristics more effectively than traditional MFCC and BFCC, which may account for their superior performance. These findings suggest that MSCC and BSCC hold potential as valuable additions to the arsenal of voice-based PD detection methodologies.

In contrast, the results obtained using MFCC and BFCC, particularly with ANN, show comparatively lower accuracy rates of 54% and 64%, respectively. While these traditional coefficients have been widely used in voice analysis, our findings suggest that MSCC and BSCC surpass them in the context of PD detection. The improved accuracy achieved with MSCC and BSCC underscores their ability to capture nuanced vocal characteristics associated with PD more effectively.

TABLE I. RESULTS OBTAINED WITH THESE METHODS

	ANN			LSTM			CNN		
	Accuracy (%)	*Sensitivity (%)*	*Specificity (%)*	Accuracy (%)	Sensitivity (%)	Specificity (%)	Accuracy (%)	Sensitivity (%)	Specificity (%)
MSCC	90	60	87	81	50	50	90	50	100
BSCC	81	55	100	90	55	100	90	50	100
MFCC	54	100	100	81	66	100	81	71	100
BFCC	64	100	100	81	50	55	81	80	100

The accuracy rates obtained in this study are promising for the development of reliable voice-based PD detection systems. The utilization of MSCC and BSCC, combined with advanced deep learning techniques like CNN, offers a potential breakthrough in early PD diagnosis. These discoveries could hold noteworthy consequences for the development of non-invasive, cost-effective, and accessible PD screening tools, ultimately aiding in the timely intervention and management of this debilitating disease. Table I presents the results obtained for each of the MFCC, BFCC, MSCC, and BSCC coefficients using ANN, LSTM, and CNN.

In conclusion, our results suggest that MSCC and BSCC, in conjunction with CNN, represent a promising avenue for enhancing the accuracy of voice-based PD detection systems, potentially revolutionizing the way we diagnose and manage Parkinson's disease. Additional investigation and validation on larger datasets are warranted to confirm these findings and pave the way for practical clinical applications.

Three measures of performance were used in this study to evaluate the efficiency of classifiers on data sets: accuracy (see Eq. 7), sensitivity (see Eq. 8) and specificity (see Eq. 9). Accuracy is considered to be the percentage of precise results. Their definitions are as below:

$$\text{Accuracy} = \frac{\text{TN+TP}}{\text{TN+TP+FP+FN}} \quad (7)$$

$$\text{Sensitivity} = \frac{\text{TP}}{\text{TP+FN}} \quad (8)$$

$$\text{Specificity} = \frac{\text{TN}}{\text{TN+FP}} \quad (9)$$

With:

Subjects without Parkinson's disease correctly categorized are True Negatives (TP).

Subjects with Parkinson's disease correctly categorized are True Positives (TN).

Subjects with Parkinson's disease incorrectly categorized are False Positives (FP).

Subjects without Parkinson's disease incorrectly categorized are False Negatives (FN).

VI. DISCUSSION

In the domain of diagnosing PD through vocal analysis, several methods have been proposed in the literature. This paper stands out, utilizing a combination of BFCC, MFCC, MSCC, and BSCC, combined with LSTM, ANN and CNN classifiers. Notably, the CNN-based method with MSCC ET BSCC achieved the highest accuracy of 90%, suggesting promising results for PD detection. Table II provides a comparison of this study with recently published articles.

TABLE II. COMPARISON WITH RECENT RESEARCH

Study	Dataset	Method	Accuracy
El-Hasnony et al.[34]	Sakar dataset	ANFIS + PSOGWO	87,5 %
Vasquez-Correa et al. [35]	Spanish datasets	CNN	89 %
Gunduz [36]	Sakar dataset	CNN	86,9 %
Sakar et al. [37]	Sakar dataset	SVM	86 %
Belhoussine et al. [38]	Sakar dataset	DWT-MFCC	86,84 %
Zayrit et al. [39]	Sakar dataset	SVM rbf SVM lin	81 % 79 %

In the domain of diagnosing PD through vocal analysis, several methods have been proposed in the literature. This paper stands out, utilizing a combination of BFCC, MFCC, MSCC, and BSCC, combined with LSTM, ANN and CNN classifiers. Notably, the CNN-based method with MSCC et BSCC achieved the highest accuracy of 90%, suggesting promising results for PD detection. Table II provides a comparison of this study with recently published articles.

Comparatively, previous research has explored various techniques for PD diagnosis through vocal analysis. El-Hasnony et al. [34] introduced a fog-based ANFIS+PSOGWO model, achieving an accuracy of 87.5% and outperforming other optimization methods Vasquez-Correa et al. [35] employed a CNN approach using STFT and continuous wavelet transform, achieving an accuracy of up to 89% in distinguishing PD patients from healthy speakers. Gunduz [36] proposed two CNN frameworks with deep feature extraction and achieved an accuracy of up to 86.90%. Sakar et al. [37] utilized tunable Q-factor wavelet transform for feature extraction and obtained an accuracy of up to 86%. Belhoussine et al. [38] focused on optimized wavelet selection in combination with MFCC features and SVM classification, achieving an accuracy of 86.84%. Finally, Zayrit et al. [39] used SVM classification with RBF kernel with Daubechies wavelet transform and MFCC features, obtaining an accuracy of 81%, but an accuracy of 79% by using SVM with linear Kernel.

Comparing these methods to the novel approach, which leverages MSCC, and BSCC with CNN classification to reach a 90% accuracy rate, it is evident that these methods outperform most of the previously mentioned techniques. This suggests that the combination of these advanced cepstral coefficients and CNN classification represent a significant advancement in the field of PD diagnosis through vocal analysis, potentially offering more accurate and reliable results. Further research and validation are necessary to confirm these findings and assess the practicality of implementing the proposed method in clinical settings.

VII. Conclusion

In summary, this document has delved into the exploration of Parkinson's disease through the lens of voice analysis, employing various feature extraction methods MFCC, MSCC, BFCC, and BSCC, coupled with a classification approach employing ANN, CNN, and LSTM. Notably, our findings consistently demonstrate that MFCC and BFCC methods consistently outperform others, achieving an impressive accuracy rate of 90%. These results underscore the potential of voice-based diagnostic tools in advancing our understanding and early identification of PD, highlighting the promising avenues for future research and clinical applications in this critical domaine. Subsequent investigations into the diagnosis of PD ailment aim to employ diverse neural network architectures and algorithms for feature selection on an expanded dataset.

Artificial Intelligence for Confidential Information Sharing Based on Knowledge-Based System

Bouchra Boulahiat, Salima Trichni, Mohammed Bougrine, Fouzia Omary
Faculty of Sciences of Rabat-Computer Science Department, Mohammed V University in Rabat, Rabat – Morocco

***Abstract*—Ensuring the security of sensitive data and protecting user privacy remains one of the most significant challenges in our contemporary landscape. Organizations Companies cannot adopt a new technology without reassurance regarding data confidentiality. To address these challenges, we present an innovative system that draws upon extensive knowledge and expertise in the field of cryptography, especially in encryption methods. This system tailors its strategies to align with specific scenarios, prioritizing data confidentiality. Our solution is based on one of the Artificial Intelligence techniques, which is Knowledge-Based Systems (KBS) and extends the intelligent encryption methods from our previous research. However, this new system has taken a novel approach by reconfiguring this within KBS architecture. We have introduced additional technical components, including knowledge bases, an inference engine, and the Nearest Neighbor (NN) search algorithm. As a result, this revised architecture not only enhances security and system performance but also showcases improved maintainability and scalability.**

Keywords—IT security; cryptography; confidentiality; Knowledge-Based system; artificial intelligence

I. INTRODUCTION

IT security is an immensely influential domain that plays a pivotal role in shaping the trajectory of the broader IT landscape. The digital realm evolves exponentially, consistently introducing innovative concepts to simplify our lives and enhance our daily experiences. However, this technological evolution, when it intersects with fundamental human values and the need to uphold privacy, is stripped of its scientific significance and weight.

Security considerations have remained a persistent challenge from the inception of computer systems to the present day. The paramount question that incessantly prevails is that of data security. Initially, this question was primarily concerned with data confidentiality. Nevertheless, the emergence of the internet ushered in a multitude of additional requirements, including the assurance of data integrity, authenticity, availability, and non-repudiation. This evolution gave rise to various cryptographic primitives, encompassing both symmetric and asymmetric encryption algorithms, hash functions, digital signatures, and digital certificates.

However, the pace of creating new cryptographic tools tailored to evolving technological needs has significantly slowed down. Contemporary enterprises tend to gravitate towards well-established algorithms celebrated for their enduring performance and resilience over the years, as opposed to seeking novel cryptographic systems. Consequently, to adopt a new technology, these companies must establish a robust security policy to accommodate the requisites of the technology. This policy relies on a set of cryptographic primitives, along with additional methods for managing access and infrastructure.

Nonetheless, modern IT systems are increasingly characterized by their diversity, interactivity, and the need to interact with a continually expanding network of third parties. These third parties may not necessarily adhere to the same security standards as other established partners. This presents a dilemma of rigidity in security protocols: either rigidly enforces identical security policies across all interactions, a measure that may limit user participation, or continuously adapt the system to accommodate new customer requirements, an approach that can prove costly and impact existing customers. Existing methods might be too inflexible in their security protocols, making it challenging to adapt or align with varying security standards of third-party networks. This inflexibility could hinder effective collaboration with diverse partners.

To address this predicament, we propose a novel encryption model designed to flexibly align with the specific demands of each situation. By implementing this mediation, we can make informed decisions regarding the most suitable encryption algorithm.

The reasons that make the proposed encryption model suitable for addressing the challenges mentioned in the paragraph:

1) Flexibility and adaptability: The encryption model is designed to be flexible, allowing it to adapt to varying security standards and requirements specific to each situation.

2) Tailored security measures: It can accommodate diverse IT systems, interact with a broad network of third parties, and align security measures accordingly without compromising overall protection.

3) Customization for Different Situations: It enables customization based on individual demands, ensuring that security protocols can be adjusted as needed, even when dealing with partners who might not adhere to standard security practices.

4) Cost-effective solution: The model aims to balance the need for security enhancements with cost considerations, ensuring that implementing and adapting security measures remains economically viable.

5) Minimized Impact on Existing Customers: By offering flexibility, it minimizes the impact on existing customers while accommodating new requirements, avoiding disruptions in service or user experience.

Overall, the proposed encryption model aims to provide a versatile and adaptive solution that addresses security challenges in modern IT systems without excessively limiting user engagement or imposing exorbitant costs.

In the following sections, we will delve into the intricacies of this approach. We will commence by outlining our motivation and the prior research undertaken in this domain. Subsequently, we will expound upon the proposed solution, detailing its underlying principles and the various modules that constitute it, starting from data classification and extending to its inference engine. Lastly, we will elucidate the application and experimental aspects of this approach, which have been tested against a diverse array of the most renowned encryption algorithms.

A. Background

Reviewing the literature alongside various research endeavors concerning established encryption algorithms [1] [2] [3], and drawing from our own hands-on experience with these algorithms [4] [5] [6] [11], it becomes apparent that the level of security within each encryption system remains far from constant. This security profile tends to fluctuate from one study to another. What one might deem the ideal algorithm, such as AES, in one scenario, may not hold the same status in another [7]. In essence, the performance profile of each algorithm undergoes variations contingent upon the specific context and the environment in which it operates.

To illustrate this, let us consider a comparative study mentioned in [8]. This study assessed the performance of symmetrical encryption algorithms, namely DES, AES, and Blowfish, in the context of processing images. The study involved several images of varying sizes, each accompanied by their respective histograms. By comparing the encryption and decryption times of these algorithms, the research presented a comparative diagram in “Fig. 1”, as demonstrated below:

Examining “Fig. 1”, the following conclusions can be drawn:

- DES excels when dealing with small images.
- Blowfish stands out for its efficiency in processing large images in terms of cipher time.
- Blowfish and AES exhibit nearly identical performance levels during decryption.

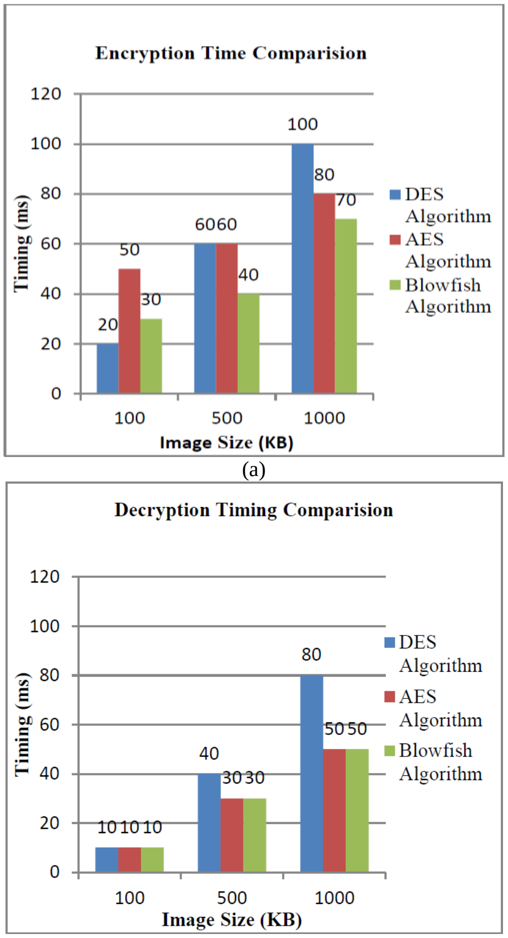
In a different study, which has also contributed to inspiring our approach and addresses various constraints, data types were considered [9]. This research explored the performance of encryption algorithms on mobile platforms, focusing on Triple DES, AES, and other methods based on elliptic curve arithmetic (ECC). The study sought to evaluate their performance across different Android platforms, including:

- Acer Iconia Tab A511
- Samsung Galaxy S4 i9505
- LG P500 Optimus One

Within each environment, numerous tests were conducted to assess algorithm performance based on the storage type, whether on an SD card or internal storage. The results from this study diverge from the previous one, highlighting the following insights:

- On the Samsung Galaxy S4 i9505, AES and DESede performed similarly, while ECC is not recommended.
- On the LG P500, AES remained the superior choice.
- On the Acer Iconia Tab A511, ECC and AES demonstrated comparable performance for smaller input file sizes, although ECC is not recommended for handling larger text files.

Hence, relying solely on a single encryption system for all communications could potentially undermine both security and system performance.



(a)

(b)

Fig. 1. Comparison between the timing of image encryption algorithms (a) and image decryption algorithms (b) using different image sizes.

In our prior works [5] [10], we devised a system that enables the categorization of various encryption scenarios within a decision-making database structured using a star modeling, comprising a central fact table and multiple dimensions. This system involves extracting the characteristics of each communication and employs data warehousing techniques to determine the most secure encryption algorithm for a case similar to or closely aligned with our own.

Building upon this foundational principle, this work introduces a substantial overhaul of the system, adopting a novel architecture based on a Knowledge-Based System (KBS). This innovative design offers distinct advantages over the basic idea, making the system more intelligent and autonomous, thus simplifying maintenance and enhancing result quality.

B. Related Works

To adapt the use of encryption systems to various environmental contexts and types of data exchanged, several research efforts have been undertaken to determine the most suitable encryption approaches. For instance, in [3], the authors directed their investigation toward the Smart Grid (SG), recognizing that devices within this network generate substantial data flows daily. To enhance security in this specific network, [3] proposed an approach grounded in multi-criteria analysis, designed to select the most appropriate encryption algorithm for optimizing energy production, consumption, and distribution. The PROMETHEE method was employed in this work, affirming the effectiveness of the AES-128 algorithm in alignment with decision-makers' preferences. Factors such as memory usage, encryption and decryption times, battery power consumption, and simulation time were taken into account.

Furthermore, the study in [10] represents another notable study that leverages a decision-making approach to determine the lightest and most secure encryption and authentication methods for Internet of Things (IoT) devices, particularly within the realm of IoHT (Internet of Healthcare Things). This research centered on data exchanges among IoHT devices operating within a healthcare environment. These devices generate sensitive data, possess limited processing capabilities, constrained bandwidth, and finite storage memory. The evaluation and decision-making approach introduced in [10] hybridized the CRITIC and TOPSIS methods, considering a diverse array of security criteria in line with the standards set by the International Organization for Standardization (ISO) and the National Institute of Standards and Technology (NIST). The experimentation from this study yielded insightful results, indicating KLEIN cipher as the most lightweight and secure choice among lightweight ciphers, including PRESENT-80, SEA, HIGH, LEA, AES Block Cipher, mCrypton, NOEKEON, Camellia, and the TEA numbers.

The uniqueness of our work lies in the fact that our proposal bases its decision-making on an extensive knowledge base, encompassing a wide array of encryption scenarios and cryptographic algorithms. Thus, our solution transcends the limitations of focusing on a specific domain or a well-defined environment. Instead, it strives to consolidate the wealth of expertise within the encryption field, with the aim of harnessing this knowledge for tailored decision-making in specific cases. Whether it's an ordinary network, an IoT network, or a P2P network, and whether the data is in the form of images, text, videos, or any other format, all these criteria serve as the parameters for our application in selecting the most appropriate encryption algorithm.

II. The Proposed Method

The proposed solution draws from one of the pioneering methods within the realm of artificial intelligence, known for its successful application in various fields. We've harnessed a Knowledge-Based System to address the domain of data encryption.

Our Knowledge-Based System comprises four fundamental modules [12], each encompassing a set of operations for knowledge processing and utilization:

- Module 1: Acquisition of Knowledge
- Module 2: Knowledge Representation
- Module 3: Knowledge Processing
- Module 4: Knowledge Utilization

In general, when crafting a Knowledge-Based System, three vital technical components are essential for system modeling and design [13]:

- The Knowledge Base
- The Fact Base
- The Inference Engine

Incorporating these technical components into a Knowledge-Based System, we adhere to the aforementioned modules, ensuring the system is enriched and leveraged effectively. In this work, we propose to adopt the architectural framework illustrated in the following diagram “Fig. 2” as the foundation for designing our decision-making Knowledge-Based System.

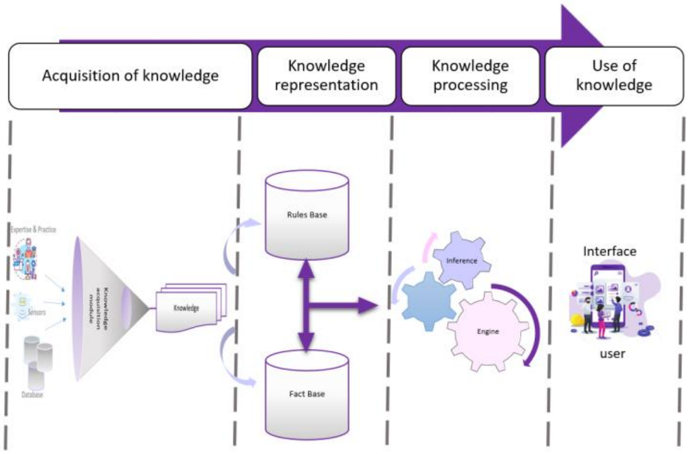


Fig. 2. The KBS Architecture for data ciphering.

This architecture offers precise control of the system, making maintenance more straightforward by segregating data analysis and classification from the decision-making component, which determines the most suitable rule.

To elaborate on the Ciphering Knowledge-Based System, the next section (see Section III) will begin by explaining the underlying principle of our proposed model within the context of data encryption. Subsequently, starting from Section III and continuing through to the end of this section, we will delve into the intricate steps carried out by Modules 1, 2, and 3 within this architectural framework. Notably, Module 4, which represents the graphical user interface (GUI) component of the application, is not covered in the forthcoming sections as it pertains to the user interaction and interface design.

III. Research Method

To construct a system of this nature, it's imperative to first establish a clear definition of knowledge and how it relates to our specific field of application. As articulated in [14], “Knowledge is the mobilization of one or more information in a well-defined context in order to trigger an action or produce knowledge” [14].

In the context of data exchange security, particularly in the pursuit of confidentiality, we will create a knowledge framework that encompasses various criteria influencing this confidentiality. As previously mentioned, these criteria span the source and destination environments, the network, data types, as well as the memory and energy capabilities of the devices involved in the process. Additionally, the encryption system itself must be highly reliable when employed under such conditions. Thus, our system must possess the capability to predict the most appropriate encryption algorithm to ensure that the ciphertext does not reveal any information about the plaintext. This can be quantified through metrics such as entropy or by considering factors like avalanche rate and other critical security criteria.

In the upcoming sections, we will provide a detailed explanation of the parameters that are taken into consideration within this solution.

A. Acquisition of Knowledge

The initial module crucial to the construction of this system is the acquisition of knowledge. Within this module, we must delineate the various potential sources for gathering knowledge pertinent to our issue. This acquisition can be realized through collaboration with experts in the field and/or by interfacing with databases from existing systems, which have been informed by established practices and historical data.

This module unfolds in three pivotal steps:

1) Data classification: As our approach involves data from diverse sources, our initial step is to classify this data based on the environment, structure, and nature of the information [15]. This classification allows us to extract the most critical insights. The outcomes of this classification process are subsequently consolidated in a temporary database.

2) Extraction of information: Next, we move on to extract the most relevant information that directly influences the effectiveness of the encryption system. This includes:

- Message type
- The percentage of images compared to all the data to be encrypted
- The percentage of the video to be encrypted compared to all the data to be encrypted
- The percentage of the Literal text compared to the set of data to be encrypted
- The size of the message
- Device type
- Device capacity
- Network type
- Network size
- Etc.

3) Building knowledge: The objective of this analysis is to enrich the knowledge base with the actual results of the encryption performed.

The goal of this analysis is to enrich the knowledge base with the real-world outcomes of the encryption procedures. During this phase of populating the knowledge base, we lay the foundation for utilizing it in the decision-making process. Here, we execute the integrated encryption algorithms within the system and subsequently compute indicators pertaining to their performance and security levels.

The knowledge we aim to capture during this phase includes:

Encryption execution time

Memory used for encryption

Decryption execution time

Memory used for decryption

Entropy of the encrypted message [16]

This stage is invoked at two distinct points in the life cycle of this approach:

In the Run-in phase: This phase is corresponds to the training phase of the system. It facilitates the generation of new experiences and the enrichment of the decision-making knowledge base.

In the Enrichment phase: This is the final step, occurring after each execution of this method, wherein the selected encryption algorithm is applied.

B. Knowledge Representation

Knowledge can take on various forms, including declarative knowledge, procedural knowledge, and a structured category that combines both, often referred to as meta-knowledge.

Declarative knowledge involves specifying how an action is performed using conditional statements (If... Then...). It's essentially the "facts" within a Knowledge-Based System (KBS). This type of knowledge encapsulates the logic of an operation, defining the objects and concepts that lead to a specific "fact." Declarative knowledge allows for the inclusion of diverse facts from different domains, making it versatile. However, this architecture tends to be slower because it relies on interpreting procedures during each execution.

On the other hand, procedural knowledge already provides instructions, as it outlines the logic of actions in the form of "rules, procedures, strategies, and agendas." The advantage of this architecture is speed, as knowledge is codified in compiled procedures, ready for execution. However, accessing data can be more complex, as it's embedded within the compiled code.

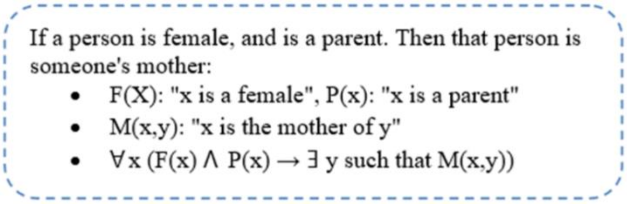
In the realm of AI, knowledge representation in each category is formalized differently and can take on various forms :

In “Fig. 3” we represent an example of the Triplet Knowledge such as: Triplet <object, attribute, value>:

In this context, the "object" refers to the subject that needs to undergo processing, the "attribute" represents the specific property or characteristic of interest, and the "value" corresponds to the specific value associated with this property.. Example:

Fig. 3. Example of triplet knowledge representation.

And “Fig. 4” represent Logical formula: Indeed, by employing predicates and propositions in logical formulas, we can effectively depict a particular situation. Example:



If a person is female, and is a parent. Then that person is someone's mother:

- F(X): "x is a female", P(x): "x is a parent"
- M(x,y): "x is the mother of y"
- $\forall x\ (F(x) \land P(x) \rightarrow \exists\ y$ such that $M(x,y))$

Fig. 4. Example of Logical formula of Knowledge representation.

Semantic network: Exactly, in a semantic network, concepts are represented as nodes, and the relationships between these concepts are depicted as arcs or edges. This visual structure “Fig. 5” helps convey how different concepts are interconnected. Example:

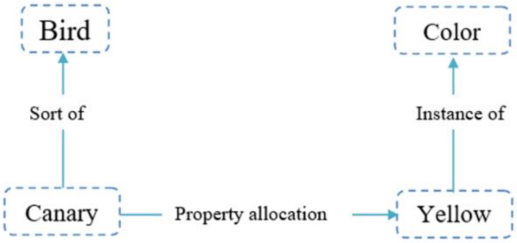


Fig. 5. Example of Semantic network of Knowledge representation

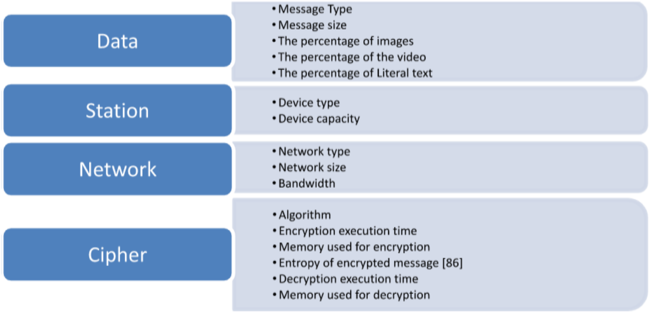
Rule: Establishing connections between pieces of information, thereby extracting additional insights, is pivotal for drawing conclusions regarding relationships, strategies, directives, heuristics, and more. Example:

If <Flower, Color, Rose> Then “I like the Flower”

If “I like the Flower” then “I buy the Flower”

If “I like the Flower” and <Packaging, Price, Free> Then “I buy a bouquet of Flowers”.

The embodiment of knowledge within our Knowledge-Based System (KBS) can be described as a fusion of the Triplet and Rules concepts. Consequently,, to present an encryption experiment applied to certain values of the previously defined criteria, we consider tables for each object. Each table serves as a dimension within our decision analysis framework, with each criterion serving as an attribute within that dimension, encompassing multiple potential values. If we consider the criteria discussed earlier, we will find ourselves working with, at the very least, the following sheme; “Fig. 6”:



Data
• Message Type
• Message size
• The percentage of images
• The percentage of the video
• The percentage of Literal text
Station
• Device type
• Device capacity
Network
• Network type
• Network size
• Bandwidth
Cipher
• Algorithm
• Encryption execution time
• Memory used for encryption
• Entropy of encrypted message [86]
• Decryption execution time
• Memory used for decryption

Fig. 6. Decision analysis of knowledge-based encryption.

For example, an experience in this knowledge base can be translated as following:

- If (Triplet <Data, type, 'image'> and Triplet <Data, size, '10587'> and Triplet <Station, type, IoT> and Triplet <Cipher, Time, 20ms>) Then Triplet “Cipher, Algo, AES”.

In a general context, each unit of knowledge can be subdivided into two distinct components. The first part embodies the conditions necessary to trigger an action, referred to as "Premises." The second part encompasses the consequences that result from the activation of this action, denoted as "Conclusions." These Conclusions, in turn, correspond to outcomes that may either initiate subsequent actions or determine the ultimate state of affairs, often characterized as "Facts."

To maximize the efficient utilization of the acquired knowledge, we opt for a knowledge base structured around a decision-making architecture in “Fig. 7”. This framework allows for the organization of these various elements into separate, independent structures. Specifically, we establish:

- A database of dimensions: This database consolidates the distinct characteristics pertaining to each object of analysis.

- A database of Facts: Within this repository, we house all the factual information that delineates diverse potential scenarios, along with their corresponding encryption outcomes.

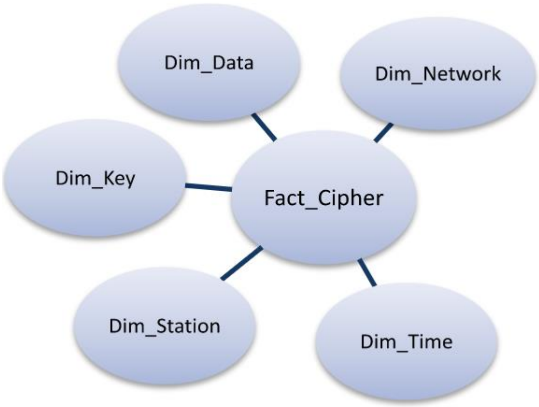


Fig. 7. Decision-making architecture of the knowledge-based encryption.

Going back to the example given above, we have:

- [Triple <Data, type, 'image'> and Triplet <Data, size, '10587'>]: represents a row of the Data dimension with a unique identifier: id_data.
- Triplet <Station, type, IoT>: represents a line of the Station dimension with a unique identifier: id_stat.
- Triplet <Cipher, Time, 20ms>: represents a line of the Cipher dimension with a unique identifier: id_cipher.

The rule is stored in the fact table as follows:

- If (id_data and id_stat and id_cipher) Then id_cipher.

C. *Knowledge Processing*

1) Inference engine: The inference engine, comprising a series of computer instructions, facilitates the process of logical reasoning in alignment with the knowledge and expertise encapsulated within the knowledge base. It harnesses the rule base, executing a sequence of logical inferences and ultimately deducing fresh insights to achieve predefined objectives [17]. To perform its task effectively, the inference engine must be able to detect and handle the following cases:

- Designate the set of rules of the BR to be compared with the facts of the BF.
- Specify the scheduling of these rules in line with the requested need.
- Trigger the execution of the chosen rules according to the sequence strategy previously specified.
- Detect and apply factbase updates.
- Manage duplicate rules and eliminate rules that are already in use.
- Detect rules that can cause confusion and eliminate contradictions.

a) Designate the set of rules: In this phase, we recommend employing the Nearest Neighbor search (NN) algorithm to identify the rules that closely align with our specific real-world case. This algorithm actively queries the knowledge base, taking into account the pre-established criteria, and retrieves all the rows that exhibit dominance concerning these criteria.

b) Nearest Neighbor Search Algorithm (NN)

i) Dominance concept: In a dataset comprising multidimensional objects, a relationship is deemed one of dominance if the dominant object excels in at least one dimension while maintaining a high level of performance across all other dimensions [17]. To identify all such dominant objects within a database of multidimensional entities, we leverage the Skyline operator. This operator empowers our query to retrieve a collection of points that remain unchallenged by any other object, aptly referred to as Skyline points [18].

Illustrating the concept of the Skyline operator, consider the common scenario of seeking a hotel near the beach at a significantly reduced cost. The criteria for this search may often entail trade-offs and appear somewhat contradictory, potentially yielding no results with a conventional selection query. However, it becomes crucial to assist the user in finding a combination that aligns more closely with their preferences. The Skyline operator fulfills this need by presenting the user with a set of the most appealing hotels in accordance with their specified requirements. As depicted in the example below, the curve highlights the Skyline hotels, each of which stands unchallenged by any other hotel in terms of the defined criteria specified in “Fig. 8”.

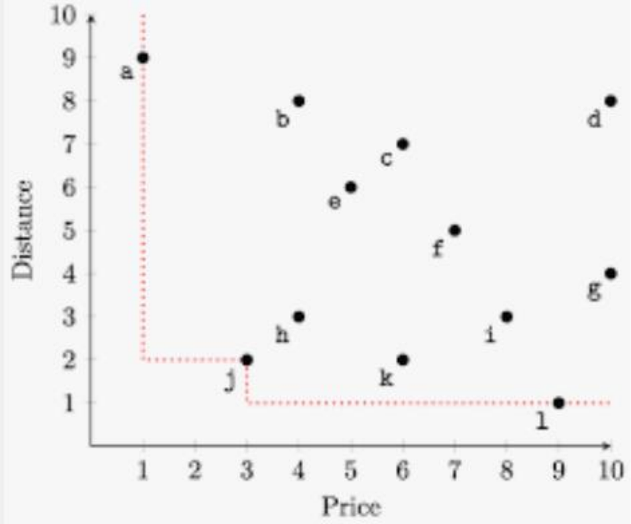

Fig. 8. Curve of elected skyline hotels.

Nonetheless, processing Skyline requests presents a substantial challenge due to the requirement of handling vast amounts of data in memory, a factor that considerably amplifies the algorithmic complexity of this operator [19]. To address this issue, multiple solutions have been developed, focusing on leveraging secondary memory in the Skyline point search process. These solutions fall into two distinct categories: non-index-based algorithms and index-based algorithms.

In our research, we opt for the latter category, specifically embracing index-based algorithms. One such algorithm is the Nearest Neighbor (NN) algorithm, which employs a nearest neighbor search method based on an appropriate distance function suited to various values within the targeted search set. The algorithm effectively partitions the space into regions and systematically identifies points closest to the origin of each region based on a monotonically decreasing distance function, often exemplified by the Euclidean distance. Furthermore, the algorithm continuously evaluates the dominance of candidate objects within each region. Regions dominated by a candidate are progressively eliminated from consideration, and this process continues until the list is ultimately empty [20].

c) Specifying rule ordering: After obtaining all the Skyline points using the Nearest Neighbor (NN) method, the next step involves arranging these points in a user-preferred order and categorizing them based on the name of the encryption algorithm. The chosen encryption algorithm is then identified as the first entry in the sorted list.

d) Detect database updates: The selected encryption algorithm is subsequently applied to the data source to secure its exchange. Simultaneously, the pertinent values associated with the execution of this specific experiment are recorded within our knowledge base.

At this juncture, the application process reaches its conclusion. It's worth noting that the system does not incorporate steps related to managing duplicate rules or addressing potential confusions, as each encryption operation carried out within the system is treated as an independent case.

IV. Results and Discussion

A. Experiment

The tests carried out in this work are based on a technical environment of 16GB of RAM and an Intel(R) Core(TM) i7-6700HQ, 2.60GHz, 64bit OS processor.

The data stored in the knowledge base was generated via an application combining the following five encryption algorithms: AES, Blowfish, DES, TripleDES and ASEC.

The application takes different types of input; it performs an analysis to be able to identify their fixed characteristics (type, size, and environment). Then, it applies the encryption algorithms mentioned above, and as an output, it sends the performance study of each algorithm (execution time, memory capacity used, entropy). Initially, we focused on a sample of 200 different entries, including 100 with the same fixed characteristics.This makes a total of more than a thousand lines of tests.

1) Test scenarios: The experiments conducted within the scope of this contribution were structured around a defined set of test scenarios. Each test case was meticulously designed in accordance with the number of dimensions and their specific types. An effort was made to encompass as many diverse choices as possible, tailored to our specific context. The application, as part of its execution, queries the previously configured knowledge base and deploys the Skyline Nearest Neighbor (NN) algorithm [20], using the input criteria. Subsequently, it returns the Skyline points that correspond to the chosen encryption algorithm.

The primary objective of these experiments is to showcase the efficacy of Skyline algorithms across various specified cases, ranging from scenarios with as few as two dimensions to more complex scenarios with up to ten dimensions. Additionally, some test scenarios incorporate additional dimensions featuring fictitious values, enabling us to consider a broader spectrum of dimensions that are typically associated with network, platform, or transport channel criteria. Unfortunately, not all of these dimensions could be simulated and integrated into the system.

The details of the different test scenarios are outlined in Table I.

TABLE I. Test Scenarios to Experiment the Knowledge-Based Encryption

N°	No. Dimension	Dimensions	Dominance criterion
Scenario 1	2	CipheringRuntime	Min
		Entropy	Max
Scenario 2	2	DecipheringRuntime	Min
		DecipheringMemory	Min
Scenario 3	3	CipheringRuntime	Min
		CipheringMemory	Min
		Entropy	Max
Scenario 4	4	CipheringRuntime	Min
		DecipheringRuntime	Min
		CipheringMemory	Min
		Entropy	Max
Scenario 5	6	CipheringRuntime	Min
		DecipheringRuntime	Min
		CipheringMemory	Min
		DecipheringMemory	Min
		Entropy	Max
		Dim_fictive_1* (limited No. values)	Min
Scenario 6	6	CipheringRuntime	Min
		DecipheringRuntime	Min
		CipheringMemory	Min
		DecipheringMemory	Min
		Dim_fictive_1* (limited No. values)	Max
		Dim_fictive_2* (limited No. values)	Min
Scenario 7	10	CipheringRuntime	Min
		DecipheringRuntime	Min
		CipheringMemory	Min
		DecipheringMemory	Min
		Entropy	Max
		Dim_fictive_1 (limited No. values)	Min
		Dim_fictive_2 (limited No. values)	Min

		Dim_fictive_3* (limited No. values)	Min
		Dim_fictive_4* (limited No. values)	Min
		Dim_fictive_5* (limited No. values	Min
Scenario 8	10	CipheringRuntime	Min
		DecipheringRuntime	Min
		CipheringMemory	Min
		DecipheringMemory	Min
		Dim_fictive_1 (limited No. values)	Max
		Dim_fictive_2 (limited No. values)	Min
		Dim_fictive_3 (limited No. values)	Min
		Dim_fictive_4 (limited No. values)	Min
		Dim_fictive_5 (limited No. values)	Min
		Dim_fictive_6* (limited No. values)	Min

[* : The Dim_fictive_i represent fictitious dimensions whose values have been generated with an approximate rule to designate other constraints. These dimensions have been added as an indication in order to test the impact of the number of dimensions on the performance of the system.]

B. Results

1) Test of Solution quality: To test the quality of the elected solution, we will focus more on the scenarios with 2, 3 and 4 dimensions containing the entropy and in which we have the real values of their executions. Indeed, focusing on the entropy dimension will allow us to decide whether the chosen cipher is well secured or not since this dimension reflects the amount of information on the source and contained in the cipher.

a) Result of scenario 1: The first scenario goes up 16 Skyline lines, the first four of which all designate the Blowfish algorithm, followed by the AES, ASEC and then 3DES algorithms. The following Table II shows the results of this run:

TABLE II. ELECTED SKYLINE ENCRYPTION OF SCENARIO 1

Algorithm	Runtime	Entropy
BLOWFISH	25	3.8870066417181426
BLOWFISH	49	3.8777830337525954
BLOWFISH	55	3.857533855872884
BLOWFISH	65	3.852401615754532
AES	67	3.821903635277186
AES	73	3.808205259874092
AES	77	3.769139091307226
AES	78	3.7276250338839367
ASEC	107	3.1246923931800934
ASEC	110	2.992846680894221
3DES	123	2.8588450604683873
3DES	229	2.8533695224817235
3DES	334	2.8444354220858403
3DES	353	2.837662090839393
3DES	500	2.830898867431037
3DES	721	2.8282605678748394

b) Result of scenario 2: Scenario 2 pulls up 5 Skyline lines, all of which point to the Blowfish algorithm. The following Table III shows the results of this execution:

TABLE III. ELECTED SKYLINE ENCRYPTION OF SCENARIO 2

Algorithm	Ciphering Time	Memory Used	Entropy
BLOWFISH	25	8.492485106920858	3.8870066417181426
BLOWFISH	29	7.911124302269485	3.9116333559383376
BLOWFISH	37	7.264124532937471	3.903903802424076
BLOWFISH	135	7.234850719105421	3.8894956802766205
BLOWFISH	169	7.231180846946539	3.856438845863682

c) Result of scenario 3: Scenario 3 pulls up 6 Skyline lines, all of which point to the Blowfish algorithm. The following Table IV shows the results of this run:

TABLE IV. ELECTED SKYLINE ENCRYPTION OF SCENARIO 3

Algorithm	Ciph-ering Time	Mem-ory Used	Entropy	Decip-hering Time
BLOWFISH	24	9.09971086299	3.922074380780725	36

BLOWFISH	188	7.2223061583614765	3.8935354899007044	282

C. Discussion

1) Solution quality: Based on all the executed experiments, it is evident that the data intended for encryption in this study can be effectively secured using the BLOWFISH algorithm. The system's predictions consistently favored the selection of the BLOWFISH algorithm in all scenarios, particularly those emphasizing the "entropy" dimension, as well as dimensions related to encryption time and memory usage. These dimensions collectively provide a robust basis for evaluating the chosen solution.

Entropy, as a metric, serves as a reliable indicator of the security level and the solution's resistance to various forms of attacks [16], while the dimensions of encryption time and memory usage offer valuable insights into the solution's performance and associated costs.

Furthermore, it's noteworthy that the Skyline points returned by the system exhibit a growing level of agreement, consistently converging on the same solution [18]. This marks a notable departure from the previous encryption method [11], where multiple solutions were viable. Such convergence obviates the need for managing preferences and priorities among the criteria used.

To validate the predictive results and ensure their accuracy, the chosen solution is executed, and pertinent measurements are calculated. The ensuing graph visually depicts the outcome of this comparative analysis.

The following graph shows in “Fig. 9” the result of this comparison:

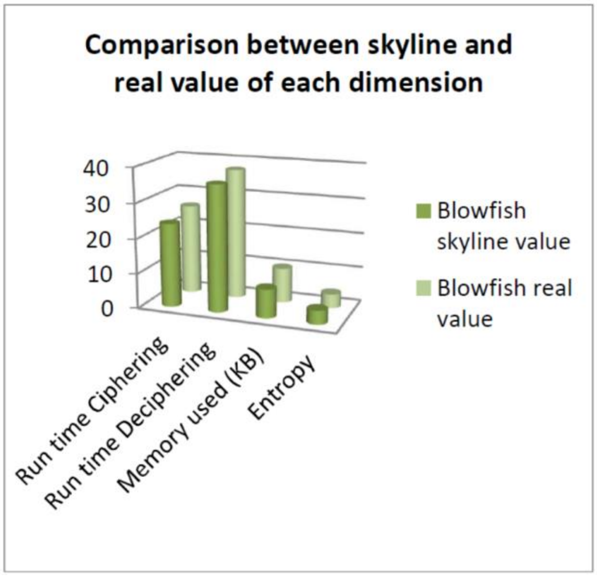

Fig. 9. Comparison between skyline solution value and real value of each dimension.

From this comparison, we can conclude that the difference between the values that were reported by the predictions of the system and the concrete values given by the application of the chosen solution is really negligible. The new values are very close to those predicted by the system.

2) System performance: Now, to see the performance of this system, we ran the set of predefined scenarios and we calculated the time that the system takes to return its results. The graph below “Fig. 10” shows the evolution of the execution time of the system according to the number of dimensions while comparing with the evolution of the old method:

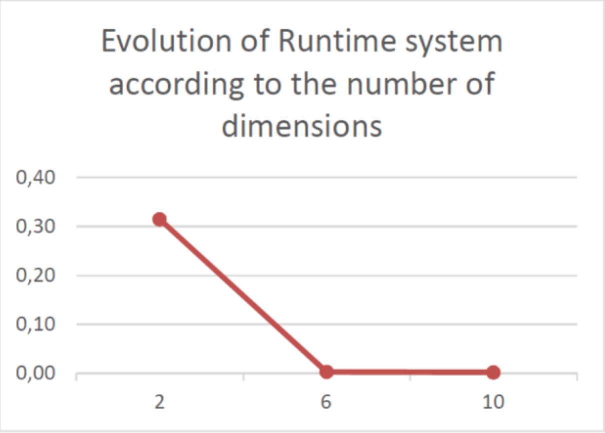

Fig. 10. Evolution of runtime system according to the number of dimensions.

As per the data illustrated in the graph, it becomes evident that the system's performance consistently improves as the number of dimensions increases. This observation suggests that the Nearest Neighbor (NN) algorithm is highly suitable for our configuration, offering enhanced scalability for accommodating various settings. In contrast, the previous intelligent encryption method [11], reliant on the BNL algorithm, experiences a decline in performance as the number of dimensions increases.

The accompanying graph in “Fig. 11” further elucidates this comparative analysis, emphasizing the advantages of the NN algorithm in handling increased complexity and dimensionality, making it a preferred choice for our system.

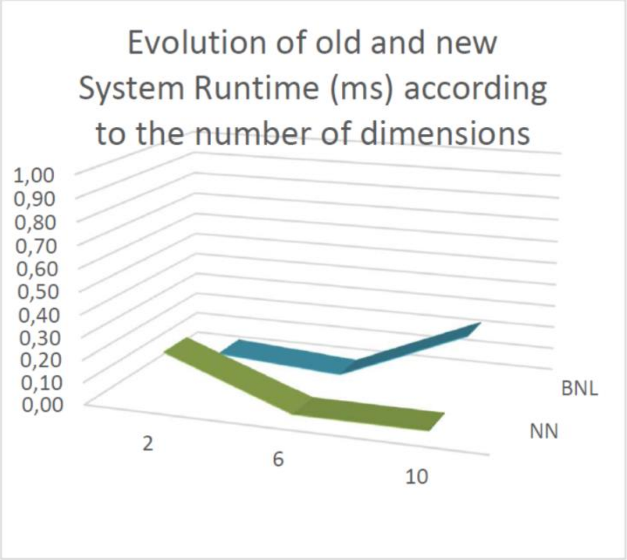

Fig. 11. Evolution of old and new System Runtime (ms) according to the number of dimensions.

3) System maintainability: As previously discussed, the new Knowledge-Based System (KBS) encryption system is constructed upon a modular architecture, where it comprises distinct modules, each responsible for specific functions. This modular design enhances code organization and simplifies system maintenance [22] [23]. Furthermore, the system incorporates a collection of well-established, standardized encryption algorithms, each with a proven track record of robustness and security.

These two key attributes, modularity and standardization, play a pivotal role in the quality of computer system development [21]. They promote system evolution and facilitate maintenance in a flexible and straightforward manner, ultimately contributing to the overall efficiency and effectiveness of the system.

V. Conclusion

Throughout this work, our focus has been on the novel approach to intelligent encryption, one grounded in decisional concepts to enhance the security of data exchanges. To boost its performance, this new approach harnesses the framework of a knowledge-based system. This architectural choice allows us to effectively segregate the processes of data analysis and classification from the construction of knowledge to decision-making. This separation significantly bolsters the system's performance in terms of both the quality of the selected solution and the execution cost.

Our Knowledge-Based System (KBS) for Ciphering incorporates well-defined technical components. The knowledge base, for instance, has been meticulously modeled in a multidimensional fashion, and the inference engine is enriched with the Nearest Neighbor (NN) algorithm within its inference engine to formulate the encryption policy to be adhered to. We have subjected the system to various test cases, each of which explores a different combination by altering the number and type of dimensions (criteria). This approach has allowed us to quantitatively assess the quality and performance of this innovative solution.

Consequently, we've conducted a comprehensive comparative study, juxtaposing the primitives used in this work with the old method. This examination serves to highlight the advantages and advancements brought about by our new architecture, which is built upon separate modules and established security standards. Ultimately, this design choice renders the system more flexible and easier to maintain.

In summary, our system has demonstrated the potential to offer an excellent quality-to-cost ratio for the encryption processes it facilitates, underscoring its efficiency and effectiveness in securing data exchanges.

Enhancing Software User Interface Testing Through Few Shot Deep Learning: A Novel Approach for Automated Accuracy and Usability Evaluation

Aris Puji Widodo[1*], Adi Wibowo[2], Kabul Kurniawan[3]
Dept. of Computer Science, Universitas Diponegoro, Semarang, Indonesia[1, 2]
Dept. Information Systems and Operations Management, Vienna University of Economics and Business (WU), Vienna, Austria[3]

Abstract—**Traditional user interface (UI) testing methods in software development are time-consuming and prone to human error, requiring more efficient and accurate approaches. Moreover, deep learning requires extensive data training to develop accurate automated UI software testing. This paper proposes an efficient and accurate method for automating UI software testing using Deep learning with training data limitations. We propose a novel deep learning-based framework suitable for UI element analysis in data-scarce situations, focusing on Few-shot learning. Our framework initiates with several robust feature extraction modules that employ and compare sophisticated encoder models to be adept at capturing complex patterns from a sparse dataset. The methodology employs the Enrico and UI screen mistake datasets, overcoming training data limitations. Utilizing encoder models, including CNN, VGG-16, ResNet-50, MobileNet-V3, and EfficientNet-B1, the EfficientNet-B1 model excelled in the setting of Few-Shot learning with five-shot with an average accuracy of 76.05%. Our proposed model's accuracy was improved and compared to the state-of-the-art method. Our findings demonstrate the effectiveness of few-shot learning in UI screen classification, setting new benchmarks in software testing and usability evaluation, particularly in limited data scenarios.**

Keywords—Deep learning; efficientnet; few-shot; software testing; UI screen classification

I. Introduction

Evaluating a User Interface (UI) in computer science requires expertise and partnership to assess its practical benefits for the intended users [1]. Improved UI design enhances user satisfaction and contributes to increased retention and revenue [2]. Fundamental principles in UI design involve exploring solutions, identifying specific attributes, and actively engaging users in the design process [3]. Despite these principles, the manual testing of UIs remains cumbersome due to the hands-on verification of requirements [4]. Nowadays, computer vision based on neural networks is used to advance UI understanding and address this challenge [5].

This study's main contribution is applying the few-shot learning approach, a notable advancement in computer vision based on neural networks, to effectively classify UI screens. This approach becomes particularly relevant when dealing with limited dataset availability and a diverse range of classes. Our implementation involves applying the few-shot learning technique to the Enrico dataset, a dataset of UI screens, and curating a novel dataset encompassing ten classes that represent common UI mistakes. This strategic combination of few-shot learning and creating a dedicated dataset allows us to explore and enhance UI screen classification in a data-driven manner, especially in scenarios with limited data.

A key advantage of few-shot learning is its ability to handle the constraints of limited sample sizes. This is crucial in fields like UI testing, where obtaining large, diverse datasets can be challenging. Few-shot learning techniques are designed to learn effectively from a few examples, making them ideal for situations where data scarcity is a critical issue. By leveraging this approach, our study aims to demonstrate how advanced computer vision based on neural network (see Fig. 1) techniques can overcome traditional data limitations, opening new avenues for efficient and accurate UI testing.

II. Related Work

Deep learning models have brought numerous benefits to the software development industry, significantly enhancing various tasks, including UI testing [6]. Deep Residual Networks (ResNet) have improved considerably image classification, surpassing previous methods on ImageNet. The successful implementation of ResNet signifies a crucial advancement in utilizing deep learning for image classification tasks [7]. The success of deep learning frameworks extends to automating test case generation and repairing unstable tests in functional UI testing [8].

The application of deep learning in UI understanding, particularly addressing Graphical User Interface (GUI) complexity, has been demonstrated in studies such as OwlEye, which achieved an 85% precision and 84% recall. It uncovers previously-undetected UI display issues in popular Android apps [9]. The use of an enhanced dataset from Rico further illustrates the effectiveness of deep learning in UI topic modeling, achieving notable accuracy in screenshot representation [10]. Challenges in machine learning datasets for UI modeling, mainly due to manual collection limitations, have led to the introduction of large datasets like WebUI, emphasizing the need for enhanced visual UI understanding in domains with limited labeled data [11].

Furthermore, researchers thoroughly analyzed current few-shot image classification techniques, categorizing algorithms into transfer learning, meta-learning, data augmentation, and multimodal approaches to address challenges posed by limited sample data [12]. For example, the study introduced GenericConv, a new few-shot learning model for scene classification. Evaluation of benchmark datasets showed that GenericConv successfully addressed imperfections in previous attempts, outperforming benchmark models on three datasets [13]. Another study focused on Few-shot Class Incremental Learning (FSCIL) in real-world applications, introducing the Efficient Prototype Replay and Calibration (EPRC) method. EPRC significantly improved classification performance on CIFAR-100 and miniImageNet compared to mainstream FSCIL methods [14]. In medical imaging, a groundbreaking study proposed a novel few-shot learning method for classifying heart diseases, achieving high segmentation performance and a remarkable 92% accuracy in classifying cardiomyopathy patient groups, even without additional clinical features [15].

III. Proposed Method

A. Neural Network Architecture

Our method utilizes a neural network architecture comprising an encoder and an adaptive classifier for few-shot learning. We compare commonly used encoders, including basic CNN, VGG-16, ResNet-50, MobileNet-V3, and EfficientNet-B1, as illustrated in Fig. 3. This experiment marks a novel chapter by leveraging these robust architectures to train the Few-Shot Classification model. The output of these encoders is fed into an adaptive classifier model configured for a few-shot setting.

1) Basic CNN consists of alternating layers of convolution and pooling. Convolutional layers detect local features in the image, while pooling layers reduce the spatial size of the representation, decreasing the number of parameters and computation in the network, which helps prevent overfitting.

2) VGG-16 [16], developed by the Visual Geometry Group at the University of Oxford, is a widely used convolutional neural network (CNN) architecture for image classification. With 16 layers, including 13 convolutional layers and three fully connected layers, VGG-16 excels in feature extraction. The convolutional layers employ small, local filters, capturing hierarchical features as input progresses. The subsequent pooling layers enhance computational efficiency and translation invariance. The final fully connected layers process high-level features, mapping them to specific classes for classification. While VGG-16's deep and intuitive design proves effective in various computer vision tasks, its computational cost limits real-time applications despite being a foundational model for advanced CNN architectures.

3) ResNet-50 [17], developed by Microsoft Research, is a deep convolutional neural network (CNN) renowned for overcoming challenges in training intense networks. Utilizing the concept of residual learning, it introduces skip connections to mitigate the vanishing gradient problem, facilitating the training of deeper networks. Its architecture, featuring residual blocks with skip connections, allows the extraction of intricate features. The initial convolutional layers detect low-level features, while residual blocks, incorporating multiple convolutional layers, use skip connections to learn residual functions. Maximum-pooling layers aid computational efficiency, and fully connected layers map the known features for classification. ResNet-50's innovative architecture enables the training of intense networks, proving highly effective in various computer vision tasks, notably image classification and object recognition.

4) MobileNet-V3 [18], developed by Google, is a lightweight convolutional neural network (CNN) tailored for efficient and accurate computer vision tasks on mobile and edge devices. The model prioritizes high performance while minimizing computational resources, introducing innovative features like inverted residuals and linear bottlenecks to optimize efficiency. Inverted residuals utilize lightweight depthwise separable convolutions, reducing parameters and computational load, while linear bottlenecks balance representational capacity and computational cost. Integration of Squeeze and Excitation (SE) blocks enhances feature recalibration, focusing on crucial channels. MobileNetV3's multiple building blocks collectively form a streamlined and efficient architecture suitable for resource-constrained environments. This design makes it ideal for applications on devices with limited computational resources, offering a commendable trade-off between accuracy and model size in various computer vision tasks, particularly on mobile and edge platforms.

5) EfficientNet-B1 [19], a member of the EfficientNet family developed by Google, is a convolutional neural network (CNN) designed to attain high accuracy with minimal computational complexity. Characterized by balanced scaling of depth, width, and resolution, it optimizes performance across these dimensions. Employing a compound scaling method, EfficientNet-B1 ensures efficient feature extraction at various abstraction levels. Increasing depth, width, and resolution enhances the model's capacity to capture complex and diverse features. Compounding scaling achieves a harmonious balance, maximizing computational resources and performance. This enables EfficientNet-B1 to achieve state-of-the-art accuracy on various computer vision tasks while maintaining a low computational cost. Its adaptability in handling different scaling factors makes it particularly advantageous for resource-constrained environments, striking an optimal balance between accuracy and model size.

B. Few Short Classification

The classification model was built using the few-shot learning approach to deal with restricted data. In itself the meta-learning mode, few-shot terminology is used to train many samples during the training phase; an episode of $\mathcal{T}_i$ was made up of two types of sets: support set $S = \{(x_{1,1}, c_{1,1}), \dots, (x_{N,K}, c_{N,K})\}$ and query set $Q = \{q_1, \dots, q_{N\times M}\}$. The number of S and Q was restricted for each iteration based on N-way, which specifies the number of classes, and K-short or M-query, which denotes the number of samples in each class. The few-shot model is divided into two parts: encoder and classifier.

In this work, a dynamic classifier based on an adaptive subspace [20] was applied. The subspace was used for classification, as well as the shortest distance between the data points and their projection into the subspace. A collection of samples encoded by may be stated as $\tilde{X}_c = [f_\theta(x_{c,1}) - \mu_c, \dots, f_\theta(x_{c,k}) - \mu_c]$, where $\mu_c = \frac{1}{K}\sum_{x_i \in X_c} f_\theta(x_i)$. For instance, q is the query set, and the subspace classifier computation is as follows:

$$d_c = -||(I - M_c)(f_\theta(q) - \mu_c)||^2 \tag{1}$$

where, $M_C = P_C P_C^T$ and μ_c signify the offset between the data point and the subspace, P_C is the truncated matrix of matrix C_C with an orthogonal basis for linear subspace spanning $\mathbb{x}_C = \{f_\theta(x_i); y_i = c\}$ $(hence, B_C^T B_C = I)$.

The chance of a query falling into class c may be calculated using the SoftMax function, which is written as follows:

$$p_{c,q} = p(c|\boldsymbol{q}) = \frac{\exp(d_c(\boldsymbol{q}))}{\sum_{c'} \exp(d_c(\boldsymbol{q}))} \tag{2}$$

Backpropagation through singular value decomposition can be used to minimize the negative log from $p_{c,q}$.

During training, the projection metric on Grassmannian geometry was utilized as a discriminative approach to maximize the margin between two subspaces P_i and P_j, and it is defined as follows:

$$\delta_p^2(P_i, P_j) = \left|\left|P_i P_i^T - P_i P_j^T\right|\right|_F^2 = 2n - 2\left|\left|P_i^T P_j\right|\right|_F^2 \tag{3}$$

the projection metric was maximized by reducing $||P_i^T P_j||_F^2$ and then developing a loss function as stated in Eq. (4); $\mathcal{L}_t$ may then be used to update θ.

$$\mathcal{L}_t = -\frac{1}{NM}\sum_c \log(p_{c,q}) + \lambda \sum_{i\neq j} ||P_i^T P_j||_F^2 \tag{4}$$

IV. Empirical Research Methodology

A. Dataset

1) Enrico dataset [10], is a carefully selected subset originating from Rico, an extensive mobile app dataset. Enrico, a short form for Enhanced Rico, comprises 1,460 UIs categorized into 20 specific design topics. Each category delineates particular UI features, contributing to a detailed comprehension of mobile app design. These topics encompass diverse aspects such as Bare (largely unused area), Dialer (number entry), Camera (camera functionality), Chat (chat functionality), Editor (text/image editing), Form (form-filling functionality), Gallery (grid-like layout with images), List (elements organized in a column), Login (input fields for logging), Maps (geographic display), MediaPlayer (music or video player), Menu (items listed in an overlay or aside), Modal (popup-like window), News (snippets list: image, title, text), Other (everything else, considered as a rejection class), Profile (information on a user profile or product), Search (search engine functionality), Settings (controls to change app settings), Terms (terms and conditions of service), and Tutorial (onboarding screen).

2) The Mistake Dataset is a dataset proposed by this paper as shown in Fig. 2. This dataset consists of 200 user interfaces (UI) categorized into 10 specific design topics. Each category describes specific UI features that contribute to a detailed understanding of mobile device UI design. These topics encompass various aspects such as pointless inconsistency design, inapproriate use of shadows, lack of text hierarchy, bad iconnography, unaligned elements, low contrast, poor typography choices, tiny touch targets, text overlap, and error message clarity. For detailed explanations regarding the 10 design topics, (see Table I).

TABLE I. DESCRIPTION MISTAKE DATASET

No	UI Component	Description
1	Pointless inconsistency design	Identifying inconsistencies in layout across different screens or resolutions
2	Inapproriate use of shadows	Pay attention to the depth of the shadow, they should create a sense of realism and hierarchy
3	Lack of text hierarchy	The text format must have a contract between each text style and the title style
4	Bad iconnography	Ensuring icons are correctly displayed and recognizable
5	Unaligned elements	Detecting misaligned text, buttons, image or other
6	Low contrast	Identifying poor contrast between text and background, affecting readability
7	Poor typography choices	Font selection, font size, spacing and alignment must be taken into account to facilitate readability
8	Tiny touch targets	The size of the touch target must be taken into account with the size of the screen
9	Text overlap	Spotting instances where text overlaps with UI elements
10	Error message clarity	Ensuring that error message are clear, concise, and appropriately placed

B. UI Understanding and Methodology

The initial technologies developed for understanding app user interfaces operate at either the application or screen level, aiming to inspire new designs by exploring existing relevant ones. For instance, [21] creates a searchable gallery of UI element ideas based on app pictures. Enrico [10] draws inspiration from extensive datasets that are too vast to browse effectively, showcasing the evolving landscape of UI exploration.

To enhance design analysis and automation, screen type or functionality classification from a screenshot proves beneficial. Enrico [10], a dataset with 1460 samples (a subset of Rico [22]), categorizes each screenshot into one of 20 design categories. However, the limited dataset size poses challenges for training deep learning classification models. Despite having a vast online dataset, it lacks screen type annotations, preventing the utilization of the pre-training method employed for element recognition.

In the methods section of our research, we present a strategic solution to overcome the limitations of small datasets in training deep learning models for UI screen classification. By integrating a Few-Shot Learning Approach for UI Screen Classification, we enable our models to perform effectively with the Enrico [10] dataset, which comprises a modest collection of 1460 samples. This approach is tailored to efficiently learn from a constrained number of data points, thus allowing accurate classification of each screenshot into one of the proposed 20 design categories. The few-shot learning technique is pivotal in our methodology, as it addresses the challenge of dataset scarcity, a common obstacle in the realm of UI design analysis.

Further augmenting our methodological framework, we have developed a dataset named “Mistake of UI Screen”, encompassing 10 classes of prevalent UI design errors, alongside the use of the Enrico dataset. This dataset is crafted to refine our models' ability to not only discern various UI elements but also to detect and classify typical design flaws systematically. The development of this dataset, alongside the application of few-shot learning, constitutes a robust approach to enhancing the precision of screen classification, thereby contributing significantly to the field of UI design and evaluation.

V. EXPERIMENTAL RESULT

In this study, a few-shot learning approach was applied using Enrico dataset with 20 class and Mistake dataset with 10 class. Randomly selects 40 data per class and splits them to 50% training and 50% validation phase with balanced class distribution. During testing phase, we randomly sampled query images along with the support set from the validation phase, repeating this process twenty-five times and ultimately applying majority voting in a few-shot setting. Settings used were five-way for all phases, five-shot on support and query sets, and 200 episodes for each epoch. Training iteration using 10 epochs for Enrico dataset referring to original paper and 25 epochs for Mistake dataset with learning rate of 1 x 10^{-3} optimized by Adam and lambda of 0.03. Few-shot model ran on an i7 processor with RTX 2060 SUPER.

A. Model Implementation

1) Model and shot setting in enrico dataset: Our assessment of model performance involved a sequence of experiments using the validation subset of the Enrico dataset. Table II compiles the accuracy figures for five models: CNN, VGG-16, ResNet-50, MobileNet-V3, and EfficientNet-B1, across five separate experiments. The table outlines each model's individual experiment results, along with their respective average accuracies and standard deviations. EfficientNet-B1 emerged as the top performer, boasting an average accuracy of 76.05% with a standard deviation of 1.1618%. The findings suggest that models, particularly those with depth and designed for efficiency that leverage pre-trained networks, have the potential to enhance generalizability.

The comparison across models were proposed to further investigated the influence of training variation on the performance of EfficientNet-B1. Table III shows the accuracy results for EfficientNet-B1 when trained with varying shots numbers on validation subset of the Enrico dataset. These conditions ranged from 1 to 5-shot training, with each tested over five experimental runs. The data indicates that increasing the number of shots enhances both the accuracy and stability of the model's performance. Definitely, the five-shot trained EfficientNet-B1 achieved a highest average accuracy, prominence that a greater number of shots correlate with improved model performance.

TABLE II. ACCURACY RESULT FOR DIFFERENT MODELS APPLIED TO THE ENRICO DATASET ON THE VALIDATION SUBSET

Model	Experiment 1	Experiment 2	Experiment 3	Experiment 4	Experiment 5	Average	Standard Deviation

Experiment 1	0.3737
Experiment 2	0.4800
Experiment 3	0.3820
Experiment 4	0.4670
Experiment 5	0.4302
Average	0.4266
Standard Deviation	0.0431

2) *Model and shot setting in mistake dataset:* The assessment of the performance EfficientNet-B1 model with five-shot by testing were applied on the validation subset of the Mistake Dataset. The results of this investigation are shows in Table IV about details the model's accuracy across five experiments. These experiments were designed to evaluate the model's ability to predict accurately under different conditions. The overall performance is summarized by the mean accuracy, calculated to be 42.66%. Additionally, the standard deviation of the accuracy, at 0.0431, indicates a relatively small variability in the model's performance throughout the trials, suggesting a stable accuracy profile for the EfficientNet-B1 on this dataset.

B. Comparison with other Method

Table V shows a brief accuracy comparison of various models on Enrico dataset. It contrasts the performance of a model trained on the Screenshot data from the Enrico dataset, achieving 75.8% accuracy, with that of the VGG-16 and Noisy ResNet-50 models trained on the Enrico dataset, which have accuracies of 47.4% and 46.5% respectively. Our adaptation of the EfficientNet-B1 model also performed notably well, with an accuracy close to the top-performing Screenshot model at 76.1%. These outcomes demonstrate the strong performance of our EfficientNet-B1 model, which nearly matches the leading model and substantially exceeds the performance of established architectures like VGG-16 and Noisy ResNet-50. EfficientNet-B1 achieves higher accuracy than CNN, VGG-16, ResNet-50, and MobileNet-V3 due to its optimized balance of depth, width, and resolution in the network architecture. It is designed using a compound scaling method to scale these three dimensions efficiently and in harmony. This results in more effective and efficient use of computational resources and better performance on limited data, as in Few Shot learning scenarios, making it particularly suitable for the complex task of UI screen classification.

TABLE V. ACCURACY COMPARISON ON OTHER METHOD

Model Configuration	Accuracy
Screenshot [10]	75.8%
VGG-16 [23]	47.4%
Noisy ResNet-50 [23]	46.5%
EfficientNet-B1 (our)	**76.1%**

VI. DISCUSSION

In the discussion section of our analysis, we delve into the substances and insights derived from our research findings. We initiate by examining our model's impact on the Enrico and Mistake datasets, scrutinizing how the few-shot learning approach adapts to each dataset's unique characteristics. The transition was used to discuss the broader implications of our model on UI screen classification, highlighting the advancements and the potential it unlocks for future applications. Finally, we address the limitations encountered during our research and offer suggestions for future studies to build upon our work.

A. Model Impact on each Dataset

The application of our neural network model to the Enrico dataset demonstrated remarkable adaptability, as evidenced by the high accuracy rates achieved across diverse UI screen types. This success is attributed to the model's ability to learn from limited examples, a testament to the efficacy of few-shot learning. Conversely, when applied to the Mistake dataset, which contained a different array of UI screen errors, the model faced distinct challenges, reflecting the nuances and complexity of classifying a wider variety of mistakes. These observations underscore the need for tailored approaches when dealing with datasets of varying natures.

B. Improved UI Screen Classification

Our model represents a significant step forward in the realm of UI screen classification. By leveraging few-shot learning, we have shown that it is possible to achieve high levels of precision with limited training data, a scenario common in real-world settings. This advancement is particularly promising for the development sector, where rapid and accurate UI assessment can streamline the design process, reduce costs, and enhance the end-user experience.

C. Limitation and Suggestion

Our primary constraint was the size and diversity of the datasets, which may affect the model's ability to generalize across a broader range of UI designs. For future work, we suggest expanding the datasets to include a more varied set of UI screens and errors. Further, investigating other few-shot learning configurations and incorporating user feedback in the training loop could refine the model's performance and applicability.

VII. Conclusion

In this paper, we propose an efficient and accurate method for automating user interface (UI) testing using Deep learning with training data limitations. This research proposes a novel deep learning-based framework that marks a pivotal advancement in user interface (UI) testing, demonstrating the powerful capabilities of few-shot learning in UI screen classification. The framework initiates with several robust feature extraction modules that employ and compare sophisticated encoder models (CNN, VGG-16, ResNet-50, MobileNet-V3, and EfficientNet-B1) to be adept at capturing complex patterns from a sparse dataset. EfficientNet-B1 achieves higher accuracy than CNN, VGG-16, ResNet-50, and MobileNet-V3 due to its optimized balance of depth, width, and resolution in the network architecture. It is designed using a compound scaling method to scale these three dimensions efficiently and in harmony. This results in more effective and efficient use of computational resources and better performance on limited data, as in Few Shots learning scenarios, making it particularly suitable for the complex task of UI screen classification. Moreover, our proposed model's accuracy was improved and compared to the state-of-the-art method using the Enrico dataset. Our utilization of the Enrico and Mistake datasets confirmed the model's ability to accurately classify a broad spectrum of UI screens with limited training data, illuminating its proficiency in detecting and categorizing intricate UI errors. For the rapidly evolving domain of software development, our model offers a scalable and efficient solution to the perennial challenge of UI testing. This is crucial for the development sector, where quick, reliable UI assessments can significantly expedite the design process, cut costs, and elevate the end-user experience. Moreover, this study paves the way for future research endeavors. The challenges we encountered due to our datasets limited size and diversity underline the need for more expansive and varied data in further investigations. Such efforts could refine the model's applicability and accuracy, integrating user feedback and diverse learning configurations into the development process.

***Abstract*—The optimization of crop yield projections has arisen as a major problem in modern agriculture, due to the increasing demand for food supply and the necessity for effective resource management. Precision and scalability are hampered by the limits associated with conventional agricultural production prediction techniques, which mostly rely on observations and simple data sources. While methods like random forest (RF) and K-nearest neighbors (KNN) are widely used, their reliance on personal assessments and insufficient knowledge of crop attributes typically results in less accurate forecasts and makes them unsuitable for agricultural precision. The suggested method combines deep learning, spectral unmixing, and hyperspectral imaging methods to overcome these obstacles. With the use of hyperspectral imaging, which records a vast array of data that is not visible to the human eye, crop attributes may be thoroughly examined and can identify the unique spectral fingerprints of different agricultural constituents by using spectral unmixing approaches, which makes it easier to evaluate the health and growth phases of the crop. Then, using this augmented spectral data, deep learning algorithms create a solid, data-driven basis for precise crop production prediction. MATLAB has been used in the suggested workflow. The combination of deep learning, spectrum unmixing, and hyperspectral imaging provides a comprehensive, cutting-edge approach that goes beyond the constraints of conventional techniques were implemented in python. Some of the algorithms that were examined, this one with integration has the lowest Root Mean Square Error (RMSE) of 0.15 and Mean Absolute Error (MAE) of 0.14, demonstrating higher prediction accuracy above other current models. This novel method represents a substantial breakthrough in precision agriculture while also improving crop production prediction.**

Keywords—Crop yield prediction; hyper spectral image; spectral unmixing; resource management; precision agriculture

I. Introduction

Demand for premium agricultural products will increase exponentially as people's standard of living rise. The amount of farmland has, regrettably, decreased due to environmental harm. Therefore, to meet increasing need for food, livestock and agricultural producing operations have become more importance. With the goal of reducing the financial and environmental costs associated with food production, precision agriculture is a technique for boosting productivity [1]. Crop conditions are measured using remote sensing, which is subject to large variation. In order to manage resources and make judgments on crop development, agriculturalists need to have equipment that is technologically advanced. By giving information on crop health and development phases, hyperspectral photography facilitates targeted farming by allowing for effective insect and herbicide treatments. Globally, there is a growing need for modern technology, namely multispectral and hyperspectral pictures, to increase farming precision and control [2]. The hyperspectral images are able to distinguish between artefacts and physicals in a wide range of application fields, including precise agriculture, minerals recognition, analysis of the environment, and urban development [3].

Agriculture and forestry are anticipated to hold the biggest market share among other end-user sectors in the hyperspectral imagery industries. Hyperspectral imaging is utilized in farming and forestry for a number of tasks, including weed mapping, plant recognition, seed yield analysis, and forest management [4]. In addition, over the past ten years, sensors have collected an increasing amount of data on farms. Therefore, offers for data optimization as well as apps for farmers have been coordinated by hyperspectral service providers [5]. Key elements of successful agriculture include the monitoring of nutrient crops, water stress, disease, pest infarction, and general plant health. By using conventional optical detection methods like imaging or spectroscopy, it is difficult to guarantee adequate spatial and spectrum data for the analysis of food and agriculture harvests [6]. The limitations of conventional imaging approaches for sorting vegetables and fruit include their inability to separate internal from exterior product structures and to collect spectral information. The commonly used systems imitate human vision using colour video cameras; nevertheless, these approaches are costly, time-consuming, and frequently result in sample obliteration. Furthermore time-consuming, costly, and sometimes obliterative, current procedures make it challenging to find product flaw [7].

Due to the rapid development of information science, image analysis, and precision agriculture over the past few years, optical detectors have developed into scientific tools. Particularly, the incorporation of a strategy to produce a spectral variation spatial map has led to substantial study and development in imaging and spectroscopic techniques, which has contributed to several well-liked applications in agriculture [8]. Precision agricultural methods have expanded and been more widely used as a result of the development of airborne and ground-based hyperspectral and multispectral imagery equipment. Along with its predictive skills, this technology has made it possible to characterize soils and vegetative cover, evaluate crop pressures, identify bruises in fruits and vegetables and estimate yield [9]. Hyperspectral and multispectral images provide a number of benefits, including inexpensive prices (in comparison to traditional scouting), reliable, simple use, rapid, non-destructive, extremely precise assessments, and a wide range of usages. Typical spectral images are made up of a number of monochromatic images that represent various wavelengths [10]. In comparison to traditional computer vision as well as human perception, hyperspectral imaging systems offer a natural advantage. Using hyperspectral imaging systems, any appearance features that are challenging or difficult to extract with systems may be retrieved [11]. A significant use for hyperspectral imaging is the assessment of the overall quality of agricultural and food items.

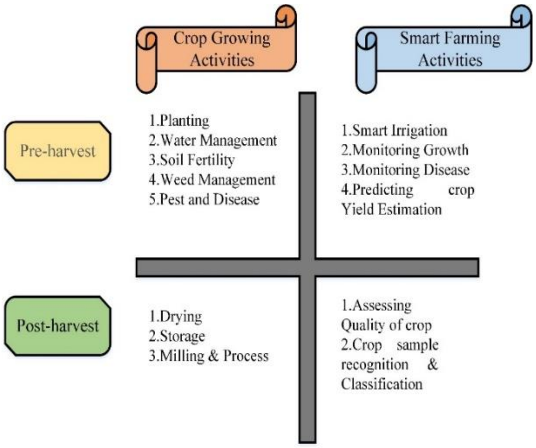

Fig. 1. Process in agriculture.

Fig. 1 shows pre-harvest and post-harvest stages of crop-growing and smart farming practices. The first step is planting, which is followed by direct sowing or transplanting. Water levels are maintained via smart irrigation according to development stages. To guarantee a sufficient supply of water and lessen the load of field weeds, weed control is essential. This strategy lowers the cost of agriculture [12]. The monitoring of soil fertility is a crucial for maximizing plant development. In order to minimize losses, prompt and accurate identification of crop diseases and pest management are crucial. For example, categorizing, identifying, and forecasting infestation patterns in fields are examples of operations included in the agricultural disease monitoring.

Analyzing crop growth utilizing vegetation, remotely sensed data, and climate variables is known as crop growth monitoring. There is also mapping of crop-growing zones at the field level. Vegetation indices, remotely sensed data, and hyper spectral data are used to estimate agricultural production. Harvesting, managing, organizing, cleaning, and transporting are examples of post-production jobs. The quality of crops may be assessed using machine learning techniques [13]. Activities like evaluating the crop's quality or looking into how climate change may affect crop production are frequently included in determining the crop's quality. The crop will next be dried using conventional or mechanical methods in the following stage of the process. The milling procedure, which eliminates the husk, is the final step in the post-production stage. Using image processing and machine learning methods, classification is to distinguish and categorize crop sample objects based on color and texture properties. Key contributions of this research are,

- Advanced Sensing Technology Integration: The research introduces a pioneering approach by utilizing Unmanned Aerial Vehicles (UAVs) equipped with hyper spectral sensors, showcasing the integration of cutting-edge sensing technologies for detailed spectral data collection in agricultural landscapes.

- Precise Hyper spectral Data Processing: The study emphasizes meticulous data pre-processing techniques, including radiometric calibration and geometric corrections using the Hyperspace program. This ensures the accurate conversion of digital data into radiance data, enabling the separation of mixed spectral signals associated with crops, soil types, and other agricultural variables.

- Innovative CNN Framework for Feature Extraction: The research employs a Convolutional Neural Network (CNN) framework to extract key features from hyper spectral data, such as NDVI, CCCI, CVI, contrast, and entropy indices. This innovative approach enhances insights into crop health and landscape dynamics, contributing to the field of precision agriculture.

- Optimized CNN-LSTM Model for Crop Yield Prediction: The study introduces a novel Optimized CNN-LSTM model for accurate crop yield prediction. By integrating deep learning with Firefly Algorithm optimization, the model leverages hyper spectral feature extraction through multiple hidden layers, showcasing a sophisticated and effective methodology for yield estimation.

- Robust Evaluation Metrics and Validation: Rigorous evaluation using metrics like R2, RMSE, MAE, and cosine similarity underscores the robustness and accuracy of the proposed Optimized CNN-LSTM model. The validation of the methodology's dependability provides confidence in the reliability of the findings, contributing to the advancement of agricultural remote sensing and predictive modelling.

Dataset In summary, the methodology combines advanced techniques from remote sensing, deep learning, and optimization to provide a comprehensive and effective approach for crop yield prediction and agricultural assessment. The contributions of this study have the potential to significantly impact precision agriculture by enabling farmers to make data-driven decisions for resource management and crop production. The remainder of this work is structured as follows: Section II offers a full analysis of these as well as related previous work. Details of the problem statement are included in Section III. In Section IV, the suggested Optimized CNN-LSTM architectures are covered in more depth. The results of the trials are discussed in Section V, and the proposed technique is thoroughly compared with existing best practices. Section VI concludes the paper.

II. Related Works

A predicted scientific approach is the integration of self-governing computing and artificial intelligence technology for agricultural ideas. With its extensive coverage, great spectral resolution, and wide range of narrow-band selection, the aerial hyperspectral system is a fantastic instrument for predicting crop physiological parameters and yield. It has been difficult to spread awareness of this technology due to the substantial and redundant three-dimensional analysis and computing. Based on three crop classifications with multi-functional cultivation, this research included two significant publicly available systems (R and Python), automatic hyperspectral narrow-band vegetation index estimation, and the most advanced machine learning (ML) modern equipment to calculate yield. Li et al.[14] demonstrated that AutoML regression model's predicted capacity was considerable. For single variety planting wheat, the best determination coefficient and normalized root mean square error (NRMSE) were 0.96 and 0.12, correspondingly; The restriction of the Auto-Sklearn approach, which prevents the investigation of the relevance ranking of individual feature, limits the capacity to retrace all regressors in this study, which may have an influence on the choice of appropriate vegetation indices.

Alfalfa is an important farmed feed crop. Due to effectiveness in data collecting, unmanned aerial vehicles (UAVs) are attracting in precision agriculture. hyperspectral data can provide a better level of spectral fidelity compared to other imaging techniques. Feng et al. [15] used UAV-based hyperspectral images, a feature selection is conducted to diminish the size of the data and retrieved a significant number of hyperspectral indices of the original image. Then, by merging three frequently used base learners, namely, support vector regression (SVR), K-nearest neighbors (KNN) and random forest (RF), an ensemble machine learning model was created. It demonstrated that ensemble model outperforms all base learners, and when employing the chosen features, an R_2 of 0.874 was obtained. The outcomes further support the effectiveness of the suggested ensemble model. The performance of the model might be affected by variables that were not taken into account for this research, such shifting field conditions, climatic variations, or insect infestations.

Artificial intelligence has easily migrated into a number of economic sectors, particularly for surveillance and control in agriculture. One of the main factors reducing crop output is biotic stress. Albanese, Nardello, and Brunelli [16] proposed Automatic recognition of hassle using images has emerged as a key study area for timely crop disease diagnosis by the advent of deep learning technologies. In order to continuously identify infestations of pests inside fruit orchards. The embedded approach is built on sensor device. The platform's capabilities have been shown through the training and deployment of three distinct ML algorithms. Furthermore, the incorporation of energy-harvesting functions into the suggested system guarantees extended battery lifetime. One drawback of this research is that the energy harvesting system's effectiveness heavily relies on the availability of sufficient sunlight, making it less practical in regions with limited sunlight or during extended periods of overcast weather.

Weed growth out of control has a negative impact on crop quality and productivity. Herbicide usage to eradicate weeds changes biodiversity and pollutes the environment. Instead, pinpointing weed-infested areas can help with targeted chemical remediation of these areas. There are now ways to detect weed plants due to improvements in agricultural image analysis. Supervised learning techniques needs a massive volume of human annotated images. Because there are so many different plant species being grown, these supervised systems are therefore economically unviable for the small-scale farmer. In this research, Shore Wala et al. [17] present a semi-supervised deep learning method. This weed quantity and distribution may be helpful in autonomous robot-assisted targeted treatment of diseased regions. Convolutional Neural Network (CNN) is used to identify the foreground vegetation indices including crops and weeds. The requirement for manually developing features is therefore removed by utilising a fine-tuned CNN to identify the weed-infected areas. The method is tested on two datasets (1) images of carrot plants, and (2) the Sugar Beets dataset. The suggested approach has an optimal recall of 0.99 and an average accuracy of 82.13% for estimating weed density in weed-infested areas. The limitation of this work is time consuming.

Techniques for proximal sensing may be used to examine soil and crop factors that affect agricultural output. By combining this precision agricultural technology with cutting-edge data processing techniques like machine learning (ML) algorithms, it is possible to fully realize their promise for managing crop productivity. In order to forecast potato tuber yield, four machine learning (ML) algorithms, namely elastic net (EN), linear regression (LR), and support vector regression (SVR), k-nearest neighbor (k-NN) were employed by Abbas et al. [18]. Data of soil were sampled for soil chemistry, moisture content of the soil and normalized-difference vegetative index (NDVI). At the conclusion of the growing season, manual data collection and yield sample collection took place. The data from three fields were then combined to create four datasets, PE-2017, NB-2018, NB-2017 and PE-2018which reflect the provincial data for the corresponding years. To develop yield projections evaluated using various statistical factors, modelling approaches were used. SVR models excelled all other models. The performance can be improved by using deep learning methods.

Crop supervision is changing as a result of neural networks and self-driving computers being integrated into agriculture. Crop production predictions are more accurately made thanks to overhead hyperspectral sensors and sophisticated predictive methods like combined models and AutoML regression. The accuracy of farming is improved by drones that operate using hyperspectral data; lucerne cultivation is one example of this. Using picture recognition and sensor devices, deep learning technologies facilitate the prompt identification of agricultural diseases. Promising results have been obtained using a semi-supervised deep learning approach to detect weeds, and machine learning methods are used to predict the yield of potato tubers depending on crop and soil characteristics. Even though these developments solve important issues, issues like consuming time and dependent on the climate energy collecting systems are still recognized.

III. Problem Statement

The existing methods may face limitations in feature ranking, energy availability for sensor devices [16], economic viability for small-scale farmers, time-consuming processes [17] and inefficient. To address these challenges, the proposed approach combines self-governing computing, hyperspectral feature extraction via Convolutional Neural Networks (CNN), and machine learning optimization techniques. Optimized CNN-LSTM model is introduced, integrating hyperspectral data analysis and yield prediction through multiple hidden layers. The model enhances performance through Firefly Algorithm optimization. This comprehensive approach contributes to accurate crop yield prediction, thereby improving precision agriculture practices.

IV. Methodology

This research capitalizes on Unmanned Aerial Vehicles (UAVs) equipped with hyperspectral sensors to meticulously capture intricate spectral data across agricultural terrains. The reliability and usability of the created models in actual agricultural contexts are ensured by modifying testing techniques to account for temperature, humidity, precipitation, and other meteorological parameters. Data preprocessing encompasses radiometric calibration and geometric corrections via the HyperSpec program, ensuring the precise conversion of original digital data into radiance data. Using NFINDR algorithm, mixed spectral signals in hyperspectral images are separated, revealing distinct fingerprints associated with crops, soil types, and agricultural variables. Integral to precision agriculture, a Convolutional Neural Network (CNN) framework extracts key features from hyperspectral data, including NDVI, CCCI, CVI, contrast, and entropy indices, heightening insights into crop health and landscape. A pioneering Optimized CNN-LSTM model is introduced for accurate crop yield prediction. Fusing deep learning employed with Firefly Algorithm optimization, the model integrates hyperspectral feature extraction, enabling precise yield estimation through multiple hidden layers. Rigorous evaluation, incorporating metrics like R^2, RMSE, MAE, and cosine similarity, underscores the Optimized CNN-LSTM model's robustness and accuracy, thus validating the proposed methodology's dependability. It is illustrated in Fig. 2.

A. Data Collection and Preprocessing

Sensors attached on UAV flying over the countryside take hyperspectral images. Each pixel in the images has specific spectral characteristics [19]. The maker of the sensor used the HyperSpec program to perform radiometric calibrating and geometrical corrections on the UAV hyperspectral imagery. The sensor's laboratories evaluation factors, which may be represented as in Eq. (1), were used to convert the original digital number data into radiance data for the radiometric evaluation.

$$D_N = (R_1G_1 + R_2G_2) \times T_E + F_D \tag{1}$$

where, R_1 is the anticipated radiometric standard radiance for the first-order reflected image, R_2 is the radiometric standard radiance for the second-order reflected image, R_1 and R_2's system gains are G_1 and G_2, while the sensor's exposure time T_E is and the darkness of field measurement is F_D. Since the R2 strength is so poor, a spectral filter may be used to filter it. In most cases, the calibration variables are determined by the producer using an integrated sphere in the lab, and they are then stored in the calibration program. According to a correlated equation, GPS (Global Positioning System) and also inertia measuring units (IMU) modules' location and orientation data, and other data, the geometric correction can be carried out. The input parameters for the HyperSpec program include the original hyperspectral information, its frame indices, timestamps, digital surface model (DSM) information, and the GNSS/IMU files containing yaw, pitch, roll, latitude, and longitude [20]. Further enhancing the precision of the geometric correction may be done by using ground control points (GCPs).

B. Spectral Unmixing using NFINDR Algorithm

The process of "spectral unmixing" is employed to separate the mixed spectrum signals generated by hyperspectral images to its constituent parts. This entails recognizing and isolating the spectral fingerprints of numerous factors in relation to farming, such as distinct crops, different kinds of soil, and sometimes even pests or illnesses that may be detected in the fields. The landscape's structure will benefit from knowing that data. Five distinct groups, containing soil, shadows, spikes, crop leaves and gray panels, were present in hyperspectral imagine data. Thus, each of these five groups can all contribute to the spectral sensitivity of a pixel to varying degrees and with somewhat different spectral signatures. Five endmembers, every indicating one group, were found from the images taken at five-meter height to show the large number of these categories of each pixel found in the images obtained at 20-meter height. When these images are made, the ensuing dataset mimics one that can be logically collected anyway. The NFINDR technique is used to execute spectral unmixing at the subsequent step. The NFINDR approach is essentially an automated method for locating the cleanest pixels in a picture. The primary goal of this approach is to precisely replicate the effective (non-automated) method of locating the highest and lowest points of scatter chart. The convex structure of the available hyperspectral data makes it possible to use the NFINDR methodology in a reasonably simple and rapid manner. Endmembers = nfindr (inputData, numEndmembers, Name, Value) is a built-in MATLAB code that has been used in the suggested workflow. This function uses the NFINDR technique to obtain endmember signals out of hyperspectral data. The amount of endmember signatures to be retrieved with the NFINDR technique is denoted by numEndmembers. This form is employed when both reduction of dimensionality and parameters for the number of cycles are necessary. The extracted endmembers relate to certain soil constituents at specified wavelengths. For a variety of uses, such as crop detection and tracking in agriculture utilizing UAV-based hyperspectral imaging, the NFINDR technique has shown to be excellent for unmixing hyperspectral data efficiently on the computer [21].

C. NFINDR Algorithm

1) Minimize the incoming data's spectral dimensionality and estimate the primary component bands. Decide the quantity of PC wavelengths and endmembers will be extracted, and then extract that amount.

2) As a first group of endmembers, randomly select n pixel spectrum out of the minimized data.

3) Initialize iteration 1 and first collection of endmembers to determine the volume using $V\left(M^{(1)}\right) = |\det(M^{(1)})|$

where, $M^{(1)} = \begin{bmatrix} 1 & 1 & \ldots & 1 \\ m_1^{(1)} & m_2^{(1)} & \ldots & m_p^{(1)} \end{bmatrix}$

4) Choose a new pixel spectrum s, for this second cycle., such that: $s \notin \left\{m_1^{(1)}, m_2^{(1)}, \cdots m_p^{(1)}\right\}$.

5) Calculate the area of the resultant simplex $V(M^{(2)})$ after replacing all endmember of the collection with r.

6) If the calculated volume $V(M^{(2)})$ is higher than $V(M^{(1)})$, update the ith endmember of the collection with r. A revised list of endmembers generated.

7) Choose a different pixel spectrum for each subsequent iteration, then repeat steps 5 and 6 with that new spectrum. Once the overall level of iterations reaches the desired number, the iterations come to an end.

D. Accuracy Prediction using Cosine Similarity

The accuracy for the spectral unmixing is assessed using cosine similarity as in Eq. (2), as well as it is also determined if the endmember frequencies acquired can be coincided with to the wavelengths originally utilized to create the hyperspectral images.

$$\text{Similarity=} \cos(\theta) = ((\mathrm{E} * \mathrm{P}) / (\|\mathrm{E}\| * \|\mathrm{P}\|)) \tag{2}$$

where, || || stands for the vector's magnitude (Euclidean norm), P is the vector representing each pixel's spectrum signature, and E is the chosen endmember option vector.

E. Extracted Features of Hyper Spectral Images using Convolutional Neural Network (CNN)

Precision agriculture, which applies resources like water, fertilizer, and pesticides especially when and where they are required, depends on the ability to extract features of hyperspectral crop images. Farmers may use resources more efficiently, cut down on waste, and boost crop output by having a better grasp of the variation in crop nutritional demands throughout a field. The features were extracted using CNN.

1) Normalized Difference Vegetation Index (NDVI): NDVI represents the health and vigor of plants in an area. It is estimated as of the reflectance of two bands, typically the near-infrared (IR_N) and the red (R) bands, using the following Eq. (3).

$$NDVI = \frac{IR_N - R}{IR_N + R} \tag{3}$$

NDVI values range from -1 to +1, where positive values point to healthy vegetation, zero represents non-vegetated areas (e.g., water bodies), and negative values (closer to -1) typically represent cloud cover or man-made surfaces.

2) Canopy Chlorophyll Content Index (CCCI): CCCI is another vegetation index used to estimate the chlorophyll content in vegetation canopies. It is particularly useful for monitoring the greenness and health of vegetation. The CCCI involves the red-edge band (R_E) is given in Eq. (4).

$$CCCI = \frac{\frac{IR_N - R_E}{IR_N + R_E}}{NDVI} \tag{4}$$

Higher CCCI values indicate higher chlorophyll content and healthier vegetation.

a) Chlorophyll VI (CVI): Chlorophyll VI is an index designed to provide a more accurate estimation of chlorophyll content in vegetation as in Eq. (5). It utilizes the red band (R), and the green band (G).

$$CVI = IR_N \times \frac{R}{G^2} \tag{5}$$

CVI values are positively correlated with higher chlorophyll content.

b) Contrast: Contrast is a statistical measure used to describe the difference in pixel intensities within an image or a specific region. In hyperspectral imagery, contrast refers to the variation in spectral values across different bands. Higher contrast indicates more pronounced differences between spectral signatures, which can be useful for discriminating between different materials or classes as shown in Eq. (6).

$$contrast = \sum_{k,l=1}^{N} P_{k,l}(k-l)^2 \tag{6}$$

c) Entropy: Entropy is another statistical measure that quantifies the amount of uncertainty or disorder in an image or a specific region as in Eq. (7). In hyperspectral images, entropy can be used to assess the complexity and variability of spectral signatures. High entropy values indicate greater spectral diversity and complexity, which can be helpful for identifying diverse land cover types.

$$Entropy = \sum_{k,l=1}^{N} P_{k,l} (\ln P_{k,l})^2 \tag{7}$$

NDVI, CCCI, and CVI are all vegetation indices that provide information about the health and vigor of crops. By calculating these indices from hyperspectral data, it becomes possible to monitor the growth status, stress levels, and overall health of crops [22].

F. Yield Estimation using LSTM

LSTM [23] By including a gradient superhighway in the structure of a state of a cell c as well to the hidden state h, a unique type of RNN was developed to address this problem. The LSTM architecture features gates that allow both the addition and removal of data from the cell state. The forget gate determines whether data should be eliminated from the current state of the cell and is described as follows:

$$f'_{t=\sigma\left(W'^{T}_{f'}\left[h'_{t-1,x'_t}\right]+b'_f\right)} \tag{8}$$

The definition of the input gate that chooses the data to be fed to the state of the cell is in Eq. (9).

$$i'_{t=\sigma(W'^{T}_{i^{i'}}\left[h'_{t-1,x'_t}\right]+b'_{i'})} \tag{9}$$

Utilizing both and it, the cell state c'_t is derived in the way shown in Eq. (10).

$$\dot{c}'_{t=tanh\left(W'^{T}_{c'}\left[h'_{t-1,x'_t}\right]+b'_c\right)} \tag{10}$$

$$c'_{t=\tanh(}f'^{T}_{t}\,c'_{t-1+}i'^{T}_{t}\,\dot{c}_t \tag{11}$$

The concealed and outgoing state o'_t of the LSTM, respectively, are specified as.

$$o'_{t=\sigma(W'^{T}_{0}\left[h'_{t-1,x'_t}\right]+b'_0)} \tag{12}$$

$$h_t = o'^{T'}_{t}\tanh(c_t) \tag{13}$$

Fig. 3 depicts the architecture of proposed CNN-LSTM model. Due to a more efficient gradient flow during back propagation, LSTM is more successful at simulating lengthy sequences than a straightforward RNN.

G. Optimization using Firefly Algorithm

An optimization approach was utilized to determine the parameters for which the cost function was minimized throughout the training procedure. The variation in light intensity and the evolution of attraction serves as the two pillars of the firefly optimization approach. A measure of attraction is the intensity, which is connected to the objective function. The relative attractiveness (α) as judged by other fireflies fluctuates when the distance d_{ij} between fireflies i and j shifts. Light loses intensity as it moves farther away from its source due to air absorption. Additionally, as shown in Eq. (14), the attractiveness varies according to the degree of absorption and the brightness I(d) varies in accordance with the inverse square law.

$$I(d) = \frac{I_s}{d^2} \tag{14}$$

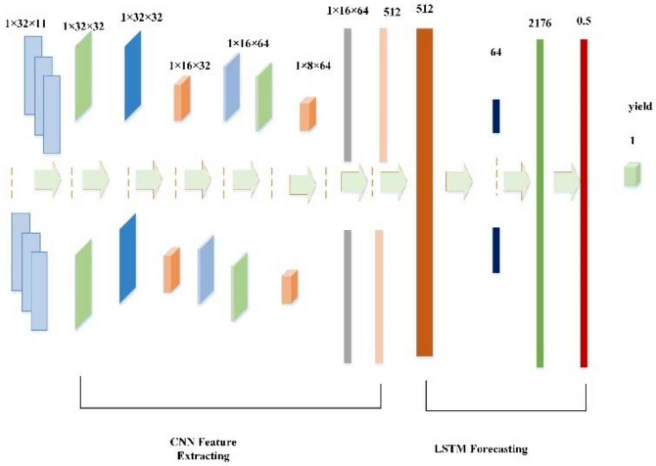

Fig. 3. The architecture of proposed CNN-LSTM model.

where, d is the distance between the source and the light, δ is the absorption coefficient of light, and I_s is the source intensity. Eq. (15) states that the light's intensity (I), which is dependent on its coefficient of absorption, varies with distance d.

$$I = I_0 e^{-\delta d^2} \tag{15}$$

where,,I_0 is the initial brightness of the light, and $e^{-\delta d^2}$ is the sum of the intensities at the source and at a distance. The chosen attributes that each firefly location represents are used to assess the effectiveness of the crop Yield detecting model. Each firefly's attractiveness (α) in comparison to others is determined based on the fitness values received during the evaluation, as stated in Eq. (16).

$$\alpha = \alpha_0 e^{-\delta d^2} \tag{16}$$

Higher fitness values make fireflies attractive. After that, transport the firefly in that direction so they can explore the search area. To strike a balance between exploration and exploitation, adjust the Firefly Optimization algorithm's control parameters, such as the attraction coefficient, absorption coefficient, and iterations. Decide on the termination criteria, which govern when the optimization process should be stopped. Reaching a predetermined number of iterations or obtaining a good fitness value are frequent reasons for termination [24].

Algorithm 1: Firefly Algorithm

```
Initialize fireflies randomly
Set control parameters (alpha, delta, iterations)
Repeat for a predefined number of iterations:
 Calculate fitness values for each firefly
 Update the attractiveness (alpha) based on fitness and distance
 Move fireflies towards more attractive ones
 Explore the search space
Until termination criteria met
```

V. Result and Discussion

Following is an explanation of how to test the accuracy of the CNN-LSTM model using the coefficient of determination (R2), mean absolute deviation (MAE), and root mean square error (RMSE):

A. *Model Accuracy Assessment Parameters*

To assess the accuracy of the yield prediction approach, the coefficient of determination (R^2), mean absolute deviation (MAE), and root mean square error (RMSE) were utilized. R^2, MAE, and RMSE are calculated as in Eq. (17), Eq. (18) and Eq. (19).

$$R^2 = 1 - \frac{\sum_{k=1}^{N}(\hat{y}_k - y_k)^2}{\sum_{k=1}^{N}(y_k - \bar{y})^2} \tag{17}$$

$$RMSE = \sqrt{\frac{\sum_{k=1}^{N}(\hat{y}_k - y_k)^2}{N}} \tag{18}$$

$$MAE = \frac{1}{k}\sum_{k=1}^{N}|y_k - \widehat{y_k}| \tag{19}$$

where, $\bar{y}$ is the mean for the detected crop yield, y_k and $\hat{y}_k$ are the observed and estimated crop yields, respectively; N represents the number of evaluation samples. A greater prediction performance of the model is shown by an increased R^2 and a decreased RMSE [25].

The assessment parameters for the Optimized CNN-LSTM model in Table I demonstrate its exceptional performance. The hyperspectral image dataset's underlying patterns are very well captured and understood by the model, as seen by the Coefficient of Determination (R2) value of 0.893, demonstrating the model's capacity to explain variations in observed data. Furthermore, the model's accuracy and dependability in predicting crop yields are shown by the low Root Mean Square Error (RMSE) of 0.13 and Mean Absolute Error (MAE) of 0.14. These findings demonstrate Optimized CNN-LSTM potential as a formidable tool for hyperspectral image-based yield forecasting, providing insightful information for remote sensing and precision agricultural applications. Fig. 4 depicts the Assessment parameter of Optimized CNN-LSTM.

B. *Statistical Analysis*

To investigate the impact of variation in breeds, irrigation methods, and their relations on the observed and anticipated crop yield, a mixture of linear model was used. The model's equation is given in Eq. (16).

$$Y = \alpha X + \gamma Z + e \tag{16}$$

where, X and Z stand for static effects and random effects accordingly, Y is the response shown by fixed effect (α) as well as random effect (γ) by a random error (e). With an interval from zero to one, broad-sense heritability measures the proportion of genetic variance to all phenotypic variation. The variance in phenotype is totally influenced by genetic and environmental variables, respectively, as indicated by the heritability of 0 and 1. The following Eq. (17) was used to compute the heritability.

$$h^2 = {v_g}\Big/{\left(v_g + {v_e}/{r}\right)} \tag{17}$$

where, v_g and v_e stand for the genetic and erroneous variances, correspondingly, and r stands for the number of reproductions per treatment.

Table II presents the Coefficient of determination (R^2) performance metrics for different predictive models. Random Forest (RF) achieved an R^2 value of 0.882, indicating a strong ability to explain the variance in the data. Support Vector Regression (SVR) performed well with an R^2 of 0.824, capturing a substantial portion of the data's variability. Optimized CNN-LSTM model exhibited the highest performance, attaining an R^2 of 0.893, signifying its superior capability in predicting and understanding the underlying patterns within the dataset. Fig. 5 shows comparison of various models with R^2.

TABLE I. Assessment Parameter of Optimized CNN-LSTM

Assessment Parameters	Values
R2	0.893
RMSE	0.15
MAE	0.14

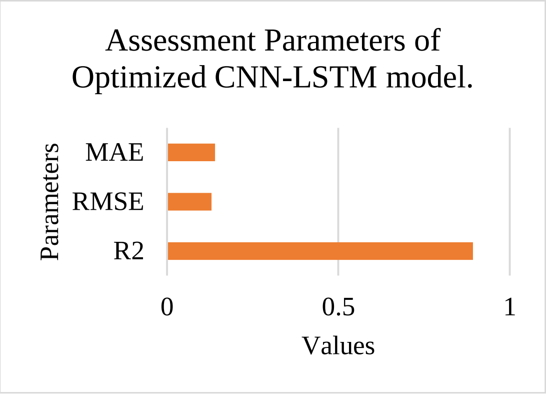

Fig. 4. Assessment parameter of optimized CNN-LSTM.

TABLE II. Accuracy Assessment Parameter

Model	R^2
RF	0.882
SVR	0.824
Optimized CNN-LSTM	**0.893**

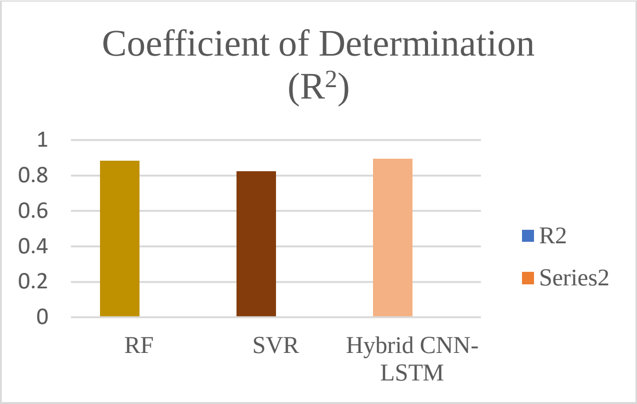

Fig. 5. Comparison of R^2 for various models.

Fig. 6 which depicts the training accuracy of proposed Optimized CNN-LSTM model. The accuracy model is plotted based on the value of R^2. It clearly shows that the proposed method outperforms other algorithms.

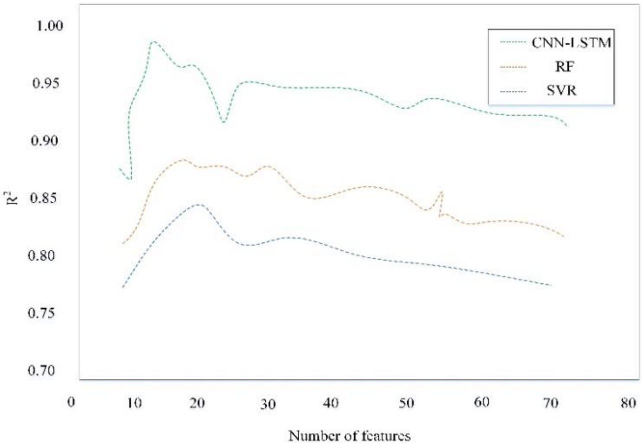

Fig. 6. Training accuracy with existing model.

This research used a dataset obtained from Unmanned Aerial Vehicles (UAVs) to analyze hyper spectral images in agricultural areas. The dataset was divided into two subsets for model development and evaluation. 80% of the dataset was allocated for the training phase, where the model learns patterns and relationships from the hyper spectral data. The remaining 20% was used for the testing phase, where the model encounters new data and evaluates its performance. This division is a standard practice in machine learning to gauge performance, prevent over fitting, and ensure reliability in real-world applications. The careful consideration of dataset partitioning is crucial for establishing the effectiveness and generalization of the developed models in agricultural hyper spectral image analysis. The training and test dataset were illustrated in Fig. 7.

The NFINDR algorithm is utilized to perform spectral unmixing on hyperspectral images. This technique separates mixed spectral signals into their constituent parts, identifying and isolating spectral fingerprints associated with different crops, soil types, and other factors relevant to agriculture. End members were selected as shown in Fig. 8.

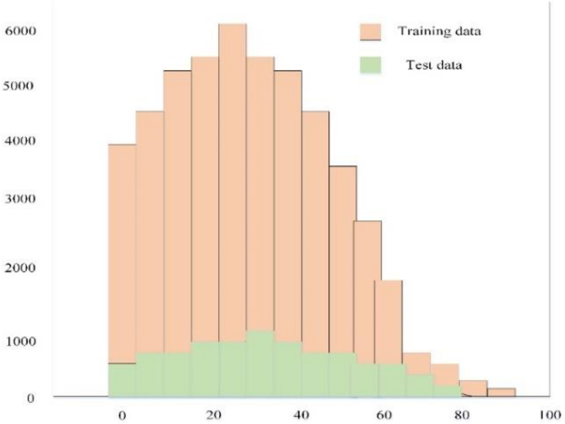

Fig. 7. Training and test dataset.

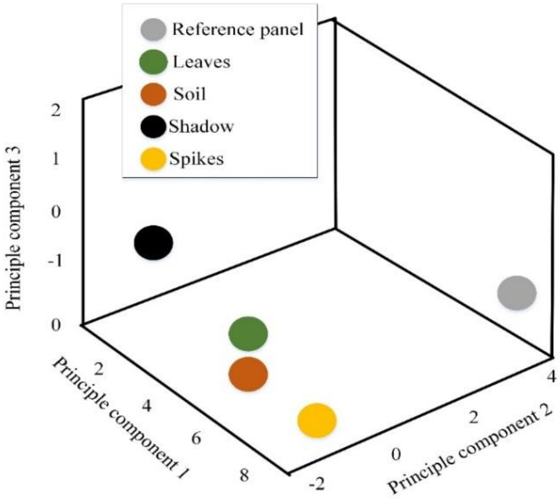

Fig. 8. Spectral unmixing using end members selection in NFINDR.

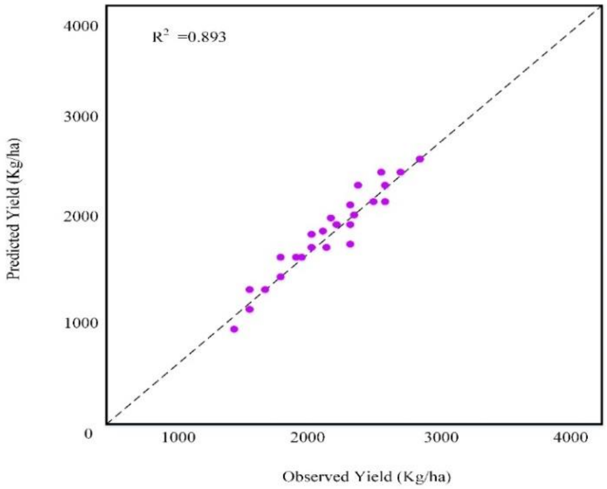

Fig. 9. The relation between observed and predicted yield with R^2.

Fig. 9 depicts the relationship between observed and predicted yields with a coefficient of determination (R^2) value of 0.89. The data points closely follow a linear trend, indicating a link between the predicted and actual yields. The high R^2 value suggests that approximately 89% of the variability in the observed yield can be explained by the predictive model, affirming its accuracy and reliability in forecasting agricultural yields. This alignment between predicted and observed values underscores the model's effectiveness in capturing the underlying patterns and factors influencing crop production.

Table III presents Root Mean Square Error (RMSE) values for different predictive models. The Random Forest (RF) model yielded an RMSE of 0.22, reflecting the average magnitude of prediction errors in relation to the observed values. The Support Vector Regression (SVR) model produced a slightly higher RMSE of 0.23, indicating a slightly greater overall error compared to RF. In contrast, the Optimized CNN-LSTM model demonstrated the lowest RMSE at 0.13, signifying its superior accuracy in predicting outcomes and minimizing prediction errors. These RMSE values provide insights into the precision and effectiveness of each model, with Optimized CNN-LSTM model. model emerging as the most precise in this analysis. The Training and testing loss is plotted based on RMSE value.

One of the most important aspects of this study's model evaluation is the training and validation loss analysis. The model's learning process and its capacity to generalize to new data are revealed by the plot of training and validation loss based on the Root Mean Square Error (RMSE) value. The model is effectively learning from the training data, indicating a successful training procedure, as seen by the decreasing trend in both training and validation loss. Given that there is little substantial divergence between the training and validation loss curves, it is possible that the model is not over fitting. This alignment shows that the model may generalize effectively to new, unexplored data points, increasing its dependability in real-world situations.

The model's accuracy and precision in forecasting crop yields are further supported by the low RMSE values linked to the training and validation loss, securing its application in remote sensing and precision agriculture settings. The training and testing loss expressed as RMSE is shown in Fig. 10.

Table IV showcases Mean Absolute Error (MAE) values for different predictive models. The Random Forest (RF) model achieved an MAE of 0.17. The Support Vector Regression (SVR) model exhibited a slightly lower MAE of 0.16, indicating a marginally improved accuracy in prediction compared to RF. Remarkably, Optimized CNN-LSTM model. Model outperformed the others with the lowest MAE of 0.14, underscoring its exceptional precision in forecasting and its ability to minimize absolute prediction errors. These MAE values provide valuable insights into the predictive capabilities of each model, with the Optimized CNN-LSTM model. It demonstrates the highest level of accuracy in this context.

The crop yield prediction models' accuracy was assessed using the accuracy assessment metrics coefficient of determination (R2), mean absolute deviation (MAE), and root mean square error (RMSE). The effectiveness of several prediction models, such as Random Forest (RF), Support Vector Regression (SVR), and Optimized CNN-LSTM model. It was evaluated using these measures. The outcomes showed that the Optimized CNN-LSTM model. It performed better than the competing models, earning the greatest R2 value of 0.893, demonstrating its improved capacity to account for the variance in the crop production data. Optimized CNN-LSTM model further demonstrated the lowest RMSE and MAE values at 0.13 and 0.14, respectively, emphasizing its outstanding accuracy in predicting crop yields. These findings highlight the value of combining deep learning, spectrum unmixing, and hyperspectral imaging in precision agriculture, with Optimized CNN-LSTM model demonstrating the most promising outcomes. The observed and projected yield connection, which has an R2 value of 0.89 and indicates that almost 89% of the variability in observed yield can be explained by the predictive model, provided more evidence of the model's accuracy. With useful insights for large-scale farming operations, this research shows the potential of cutting-edge technology and machine learning approaches to improve crop output estimates.

TABLE III. ROOT MEAN SQUARE ERROR (RMSE)

Model	RMSE
RF	0.22
SVR	0.23
Optimized CNN-LSTM	**0.15**

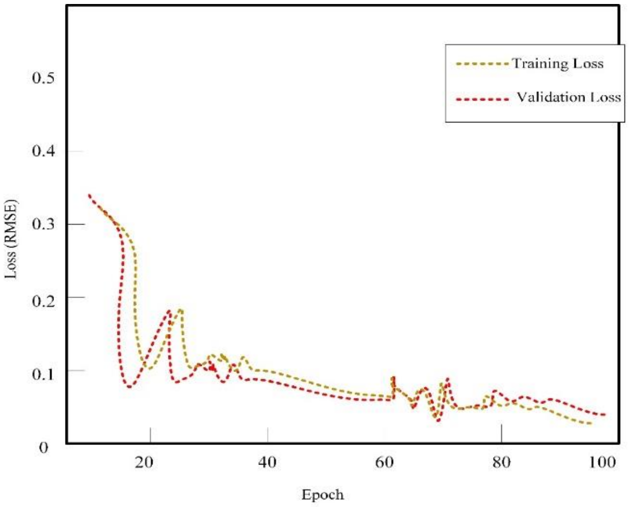

Fig. 10. Training and validation loss.

TABLE IV. MAE VALUES COMPARISON

Model	MAE
RF	0.17
SVR	0.16
Optimized CNN-LSTM	**0.14**

C. Discussion

The integration of self-governing computing and artificial intelligence in agriculture, particularly in crop monitoring and yield prediction, shows promise. Utilizing aerial hyper spectral systems and UAVs, combined with advanced machine learning techniques, improves crop yield predictions. Examples include AutoML regression models for wheat and an ensemble model for alfalfa. Deep learning technologies are used for disease identification and semi-supervised weed detection. Despite challenges like time-consuming processes and climate-dependent energy-harvesting systems, the adoption of neural networks and precision agriculture technologies is transforming crop management.

VI. Conclusion and Future Work

The suggested model combines deep learning, spectral unmixing, and hyper spectral imaging in a way that improves upon earlier methods for projecting crop production. As opposed to traditional methods that depend on subjective evaluations, this new approach makes use of hyper spectral photography to gather copious amounts of non-visible data, which enables a thorough analysis of crop characteristics. Spectral unmixing methods allow for the accurate assessment of crop health and growth stages by identifying distinct spectral signatures. This improved spectral data is then used by deep learning algorithms to create a solid, data-driven basis for precise crop production forecasts. A model with the lowest Root Mean Square Error (RMSE) of 0.15 and Mean Absolute Error (MAE) of 0.14 is produced by integrating these cutting-edge approaches with MATLAB, demonstrating improved prediction accuracy over existing models. This novel strategy overcomes the drawbacks of traditional approaches and greatly improves crop output forecast capabilities, marking a significant advance in precision agriculture. Future research in precision agriculture ought to concentrate on improving data integration by investigating the fusion of various sensors, IoT devices, and remote sensing technologies to capture a thorough dataset for crop monitoring. In order to provide openness and confidence in yield projections, explainable AI models also need to be developed.

Abstract—**By offering flexible and adaptable infrastructures Software-Defined Networking (SDN) has emerged as a disruptive technology that has completely changed network provisioning and administration. By seamlessly integrating Hybrid Generative Adversarial Network-Recurrent Neural Network (GAN-RNN) modeling into the foundation of SDN-based traffic engineering and accessibility control methods, this work presents a novel and comprehensive method to improve network efficiency and security. The proposed Hybrid GAN-RNN models address two important aspects of network management: traffic optimization and access control. They combine the benefits of Generative Adversarial Networks (GANs) and Recurrent Neural Networks (RNNs). Traditional traffic engineering techniques frequently find it difficult to quickly adjust to situations that are changing quickly within today's dynamic networking environments. The models' capacity to generate synthetic traffic patterns that nearly perfectly replicate the complexity of real network traffic demonstrates the power of GANs. Network administrators can now allocate resources and routing methods more dynamically, as well as in responding to real-time network inconsistencies, due to this state-of-the-art technology. The technique known as Hybrid GAN-RNN addresses the enduring problem of network security. With their reputation for continuous learning and by utilizing Python software, recurrent neural networks (RNNs) are at the forefront of developing flexible management of access rules. With an incredible 99.4% accuracy rate, the "Proposed GAN-RNN" approach outperforms the other approaches. A comprehensive evaluation of network traffic and new safety risks allow for the immediate modification of these policies. This work is interesting because it combines hybrid GAN-RNN algorithms to strengthen security protocols with adaptive access control while also optimizing network efficiency through realistic traffic modeling.**

Keywords—Software-defined networking; generative adversarial networks; recurrent neural networks; traffic engineering

I. Introduction

Network performance directly impacts the efficiency of operations within an organization. Faster data transfer and lower latency lead to increased productivity, reduced downtime, and better user experiences, all of which are critical in today's fast-paced digital world [1]. Slow or unreliable networks result in poor user experiences. This can frustrate customers, employees, and partners, leading to dissatisfaction and potentially driving them away. Ensuring a high-performing network enhances user satisfaction and loyalty. In an era where data is a valuable asset, efficient network performance is crucial for transferring large volumes of data quickly and securely [2]. This is especially important for industries like healthcare, finance, and media, where sensitive information needs to be transmitted reliably. Cyber security threats are on the rise, and networks are prime targets for attacks. A secure network helps protect sensitive data, prevents unauthorized access, and mitigates risks associated with data breaches, which can have severe legal, financial, and reputational consequences. Many industries and organizations must adhere to strict regulatory compliance standards regarding data security and privacy. Maintaining a secure network is essential to meeting these requirements and avoiding legal penalties. A well-optimized network ensures that network resources, such as bandwidth and hardware, are used efficiently. This reduces costs associated with network maintenance and upgrades while maximizing resource availability [3]. Network failures or security breaches can disrupt business operations, leading to downtime and financial losses. Ensuring network resilience and security is crucial for business continuity and disaster recovery planning. As businesses grow, their network needs often grow too. A well-optimized network can scale to accommodate increased traffic, new devices, and expanding operations without sacrificing performance or security. Organizations with high-performing, secure networks can gain a competitive advantage [4]. They can offer faster services, better customer experiences, and innovative solutions that competitors with subpar networks may struggle to match. Improved network performance and security enable the adoption of advanced technologies like IoT (Internet of Things), cloud computing, and AI, which can drive innovation and digital transformation within an organization. Innovative solutions are required due to the constantly changing network infrastructure landscape in order to improve security and performance. SDN, or software-defined networking, has become a game-changing network management technology that gives network administrators the freedom to customize access control and traffic engineering [5]. In order to enhance network performance and security in SDN settings, this study investigates a unique method that combines hybrid generative adversarial networks (GANs) with recurrent neural networks (RNNs). The project intends to address important issues in traffic engineering and access control by smoothly integrating these cutting-edge machine learning approaches, leading to ultimately more effective and secure network operations [6]. The article digs into the principles of Software-Defined Networking (SDN) and discusses how it applies to contemporary network architecture. It gives an overview of how SDN can provide centralized network administration and dynamic traffic engineering by separating the control and data planes. As a prelude to the suggested remedy, the section also illustrates the difficulties in optimizing traffic flows in SDN settings [7].

The use of techniques based on machine learning has a lot of potential to enhance network performance in several ways. ML algorithms have the capacity to analyses network data, adjust to changing circumstances, and make choices in real time, which can improve network operations' efficiency, dependability, and security. ML models can spot unusual network activity that may indicate security risks or performance problems. Network assaults may be swiftly detected and responded to by intrusion detection systems (IDS) and intrusion prevention systems (IPS) driven by ML, improving security while minimizing service interruption [8]. Applications will perform better and use resources more effectively as a result of getting the resources they require when they need them. To maintain equitable server utilization, ML models may track server load and distribute requests that arrive around servers. Based on past data and user behavior, ML may help forecast future network requirements [9]. This can assist network administrators in making plans for infrastructure or capacity modifications so that the network is ready to meet growing demand. For instance, during periods of high demand, they might give priority to particular sorts of traffic. GANs use a loss function that guides the training process. The generator's loss depends on how well the discriminator is fooled, while the discriminator's loss is based on its ability to distinguish real from fake data. The training aim to find a balance where the generator generates highly convincing data and the discriminator becomes uncertain about its classifications. Access control in the context of SDN is covered in the second part. It explains the idea of dynamic access control lists and discusses the significance of access control for network security [10]. It examines the difficulties with access control in SDN, highlighting the requirement for more sophisticated and flexible security mechanisms.

The merging of Hybrid GANs and RNNs, the research's main novelty, is presented in the publication. It describes how RNNs may examine this data to find patterns and abnormalities using synthetic network traffic data produced by GANs. This hybrid strategy tries to simultaneously improve network security and performance. The practical use of the hybrid GAN-RNN models for traffic engineering is covered in this section. It offers information on how dynamic network traffic flow optimization may be accomplished using synthetic traffic data produced by GANs. The advantages of this strategy are explored in terms of decreased congestion, enhanced Quality of Service (QoS), and effective resource utilization. The research examines the use of hybrid GAN-RNN models in SDN access control. It explains how RNNs may inspect network traffic data for irregularities and security risks. The flexibility of this strategy to changing security threats is discussed, as is how it enhances access control by dynamically updating access lists in response to threat detection in real time. The article covers the overall effects of incorporating Hybrid GAN-RNN models into SDN settings, highlighting the enhancements to network security and performance. It also describes possible future avenues for study and application in the area of SDN-based traffic engineering and access management. The current limitation of these investigations is the lack of focus on scalability and real-world implementation, which makes it difficult to actually apply suggested security solutions in intricate network systems. Furthermore, there isn't much talk about possible interoperability issues, resource limitations, and how well these solutions may change to meet new threats in the cyberspace. A more thorough examination of these factors might improve the research findings' relevance and efficacy in real-world contexts.

Key contributions of the research include:

- Using traffic trends produced by GANs, SDN controllers can optimize the allocation of network resources, reducing latency and enhancing QoS.RNN-based authorization rules continuously identify trends in network activity, minimising potential vulnerabilities and adapting to new threats.
- By automating both access control and traffic design, the method lessens the operational load on the network's management and promotes more effective resource utilization.
- Assessing the efficacy of the hybrid GAN-RNN models in SDN scenarios through multiple simulations and real-world experiments. The results show notable gains in network security and effectiveness, highlighting the approach's potential for contemporary network management.
- This study offers a ground-breaking framework for utilizing the powers of hybrid GAN-RNN models to optimize software-defined networking. The next phase of network administration is anticipated with the

integration of flexible access controls and realistic traffic generation.

The Section I provides an overview of the paper. The Section II reviews existing literature and emphasizes the gap in addressing techniques for network security enhancement. Section III defines the central research problem concerning driver drowsiness detection complexities. Section IV outlines data collection, preprocessing, feature extraction, and the integration of Hybrid GAN-RNN. Section V presents empirical findings, compares classifier performance, and explores implications and future research directions is in Section VI, which is solidifying the research's significance in Network security.

II. Related Works

Ramprasath and Seethalakshmi [11] examines a crucial element of SDN, focusing on the requirement for improved security controls in SDN systems. By separating the information plane from the control plane, SDN enables on-demand services and the ability to configure networks dynamically. The study correctly highlights the fact that, despite the fact that SDN controls traffic flows and flow labels based on Open Flow virtual switches successfully, it lacks built-in security safeguards to combat malicious traffic, such as Denial-of-Service (DoS) assaults, which can significantly lower service availability. It is laudable that the paper's main emphasis is on identifying and reducing DoS threats by dynamically setting firewalls within SDN setups. The study makes an effort to close this security gap by using dynamic access control lists. This study's noteworthy feature is the use of Mininet to simulate SDN with dynamic access control list attributes. This enables real-world testing and experimentation. The practical relevance of the findings is given more weight by this empirical confirmation. The work would benefit from a more thorough examination of the exact methods and tools employed for DoS attack detection and mitigation inside the SDN environment to further strengthen its contribution. Readers would have a better grasp of the suggested strategy if more information was provided about the dynamic access control list implementation and the standards for differentiating malicious from normal traffic. In order to reduce DoS attacks, the article tackles a critical security issue in SDN systems and offers a potential solution using dynamic access control lists. The research offers important insights towards strengthening the security of SDN systems by fusing theoretical understanding with real-world testing. The study would be even more helpful and effective if it elaborated on the technical specifics of the suggested strategy.

Vimal et al. [12] provides a fascinating and current investigation into how integrating Internet of Things (IoT) devices might improve the security of Software-Defined Networks (SDN), with an emphasis on boosting information access control using encryption. The research's emphasis on creating a strong infrastructure for IoT devices is well-placed given the quick spread of IoT devices. The notion of a stability routing protocol, which evaluates the reliability of devices and packet flows, is introduced in this work. To create dependable SDN routes, this method makes use of the mutual trust between network components, Quality of Service (QoS), and energy circumstances. An important advancement is the incorporation of SDN architecture into the Cognitive Protocol Network (CPN) technology platform to improve energy efficiency. A novel strategy for tackling security issues is the use of stochastic neural networks (SNNs) for decentralized decision-making based on data gleaned from perceptual packets. It is a praiseworthy effort to include these components into SerIoT approaches to provide IoT encryption for information access control. The implementation of various techniques and technologies, particularly the precise approaches utilized for IoT encryption and access control, might need more explicit explanations in the study. The complexity of the study would also be increased by providing more detail on how the suggested network infrastructure solves issues like erratic connectivity, constrained cryptographic capacity, and energy restrictions. The study emphasizes the significance of tackling cluster instability for platform efficiency as well as the necessity of collaboration. A deeper grasp of the research's practical relevance might be provided by providing additional information on the difficulties and potential solutions linked to these issues.

Shin et al. [13] addresses the potential of Software-Defined Networking to improve network security as it goes into a crucial and modern junction of technology. Because it can separate control logic from conventional network hardware, SDN has attracted a lot of interest as a transformational technology that can improve network administration and innovation. The authors note that despite its capabilities, SDN is still largely disregarded by the security community, highlighting the underutilized potential of SDN in the area of network security. The article presents a thorough overview of the prospects offered by this technology by meticulously evaluating how the distinctive features and capabilities of SDN may strengthen network security and the larger information security process. This in-depth analysis of SDN's potential to advance network security research creates fresh directions for future study in this crucial area. The article does a good job of outlining the main ideas and goals, but it might make a bigger impact if it went into more detail with examples or case studies of how SDN has been used to successfully handle security issues. Giving readers specific examples of how SDN is used to enhance network security can help readers understand the real-world applications of the technology and may encourage more research projects. The report effectively discusses the important role that SDN may play in strengthening network security and sheds light on an exciting yet underappreciated field of study. It is a useful tool for academics and professionals who want to strengthen network security in the context of a changing technological environment by utilizing SDN's capabilities. Extending on actual use cases and useful implementations might increase the paper's impact and usefulness.

Ahmad et al. [14] focuses on the use of machine learning (ML) approaches to thwart Denial of Service (DoS) and Distributed DoS (DDoS) attacks inside the SDN framework. It provides a timely analysis of the essential confluence between Software Defined Networking (SDN) and security. With its logically centralized control plane, SDN offers enhanced network administration as a viable response to a number of issues in conventional networks. But because of the security flaws introduced by this centralization, SDN control systems are becoming tempting targets for malicious attacks. Given ML's shown efficacy in finding security vulnerabilities, the paper made a sound decision to use ML approaches for recognizing and mitigating DoS and DDoS attacks. It is a useful addition to test these ML approaches in practice in an SDN system, especially by subjecting the SDN controller to DDoS attacks. It offers useful perceptions on the applicability and constraints of ML-based security methods for upcoming communication networks. The work may benefit from a more in-depth examination of the various ML approaches used and the standards for judging their efficacy. Readers would comprehend the use of ML models or algorithms to SDN security more clearly if examples or case studies of these applications were given. This article discusses security flaws resulting from centralized control, a serious issue in the SDN space. The work offers a significant addition to the area by outlining and assessing ML strategies to defend against DoS and DDoS assaults within SDN. It highlights the value of ML-based solutions in securing upcoming communication networks and provides a viable path for boosting network security. The paper's usefulness and effect would be increased with additional clarification of the ML approaches employed.

Pérez-Díaz et al. [15] provides a significant and pertinent addition to the continuing problem of LR-DDoS attack mitigation in the context of Software-Defined Networks (SDN). Due to the notoriously difficult-to-detect nature of LR-DDoS assaults and the potential harm they pose in SDN environments, a flexible modular architecture for their detection and mitigation has been developed. The study utilizes Machine Learning models such as J48, Random Tree, REP Tree, Random Forest, Multi-Layer Perceptron and Support Vector Machines to train an Intrusion Detection System (IDS). Despite the inherent difficulties presented by LR-DDoS assaults, the assessment of these ML models using the Canadian Institute of Cyber security (CIC) DoS dataset showed a remarkable detection rate of 95%. One of the key advantages of this study is the practical implementation of the open network operating system (ONOS) controller within a Mini-net virtual machine, which tries to faithfully imitate real production network circumstances. This strategy strengthens the paper's credibility and explains how it may be used in real-world network security settings. The article also emphasizes that the intrusion prevention detection system successfully mitigates all assaults identified by the IDS, highlighting the usefulness of the suggested architecture in LR-DDoS attack detection and mitigation. This study presents a novel approach that combines ML approaches with a flexible modular architecture to solve the ongoing problem of LR-DDoS assaults in SDN systems. Its potential as a formidable tool for network security is highlighted by its easy deployment and remarkable detection results. The impact of the work would be increased and new insights would be provided for security practitioners and academics with a more thorough investigation of the difficulties and model choices.

Latif et al. [16] discusses security, a key concern in the context of the Industrial Internet of Things environment. Smart cities, agriculture, and healthcare are just a few areas where IIoT is crucial due to its integration of sensors, devices, and databases. This study acknowledges the distinct security risks that the IIoT presents as a result of its integration into more complex operational systems. In this research, a unique method for anticipating and detecting several cybersecurity attacks—including denial of service, malicious operation, malicious control, data type probing, espionage, scan, and incorrect setup—that are frequently seen in IIoT contexts is presented. It undertakes a comparison analysis with conventional machine learning methods including artificial neural networks, support vector machines, and decision trees, and proposes a lightweight random neural network (RaNN) as the foundation for its prediction model. The study's main conclusions show that the suggested RaNN-based model performs admirably, with accuracy rates of 99.20%, precision, recall, and the F1 score all above 99%. The model also has short prediction duration of 34.51 milliseconds. These findings show how well the RaNN model predicts and recognises IIoT cybersecurity threats. The work makes an important addition to the area since it tackles the urgent demand for reliable security solutions in IIoT. It is an intriguing option for boosting IIoT security since it uses a lightweight RaNN model and performs better than conventional approaches.

The claimed accuracy gains of 5.65% for IoT security over cutting-edge machine learning algorithms is notable and demonstrates the practical applicability of this study. Nevertheless, when using this approach in complex IIoT contexts, it's critical to take into account potential limits, such as the range and variety of attack scenarios, and scalability, including real-world deployment issues. Despite this, the article offers a useful framework for more study and advancement in the field of IIoT security, including the potential for real-world use in securing vital industrial systems. While the previously discussed works provide important insights into various aspects of protecting SDN and addressing cybersecurity concerns within the IIoT framework, a common shortcoming of these studies is the lack of comprehensive real-world implementation and evaluation. Although some studies employ simulation techniques, little is known regarding whether the proposed solutions can be scaled and applied in complex, real-world large-scale network environments. A more thorough analysis of the potential challenges and setbacks that came across throughout the development of their safety processes, such as issues with interoperability, resource constraints, and adaptability to evolving attack strategies, would also greatly increase the study's practical significance and utility.

III. Problem Statement

Although SDN presents the possibility of dynamic and adaptable network management, efficiency optimization and security remain major obstacles. Lack of integrated security measures to thwart malicious traffic, particularly Denial-of-Service (DoS) attacks, is one of the major problems that can seriously impair service availability. Many times, existing SDN solutions are unable to adequately handle these security issues. As such, the development of a comprehensive strategy that enhances security protocols while simultaneously optimizing network performance is imperative. The purpose of this research is to determine how well a hybrid GAN-RNN approach, which sets firewalls dynamically using dynamic access control lists, can handle this dual challenge. Furthermore, it aims to provide a new solution that improves network safety and efficiency in SDN environments.

The ability of the proposed Hybrid GAN-RNN method to focus on both security concerns and network efficiency optimizing in SDN systems is what makes it effective. By using Generative Adversarial Networks (GANs) to simulate feasible traffic patterns and Recurrent Neural Networks (RNNs) for adaptable controls on access, this method offers a multidimensional solution. GANs can be used to model various traffic scenarios, and RNNs can be used to flexibly set access control rules based on real-time threat detection to achieve optimal network designs. This hybrid paradigm effectively adapts to changing network conditions and security threats, significantly enhancing the overall resilience of SDN systems. Moreover, employing the Mini net for real-world assessment boosts the practical value of the results and increases the possibility of their successful implementation in operational networks. More information about the specific methods and tools employed for DoS attack detection and avoidance in an SDN environment is required in order to improve the strategy's effectiveness.

IV. Proposed Hybrid GAN-RNN for Network Security

The proposed methodology represented in Fig. 1 starts with the collection of network traffic data, which is then meticulously pre-processed to cleanse, format, and extract relevant features. A tailored Generative Adversarial Network (GAN) architecture is crafted to generate synthetic traffic patterns that closely resemble real network data. These synthetic patterns are crucial for enhancing security analysis. Simultaneously, a Recurrent Neural Network (RNN) is employed to predict network attacks based on the generated traffic patterns. The RNN learns to recognize temporal patterns and anomalies in the data, aiding in the proactive identification of potential security threats. Following the hybrid GAN-RNN approach, the system's performance is thoroughly analyzed, assessing its ability to generate realistic traffic and predict attacks accurately. Additionally, a comparative evaluation is conducted to benchmark the proposed methodology against existing approaches, providing insights into its effectiveness in bolstering network security.

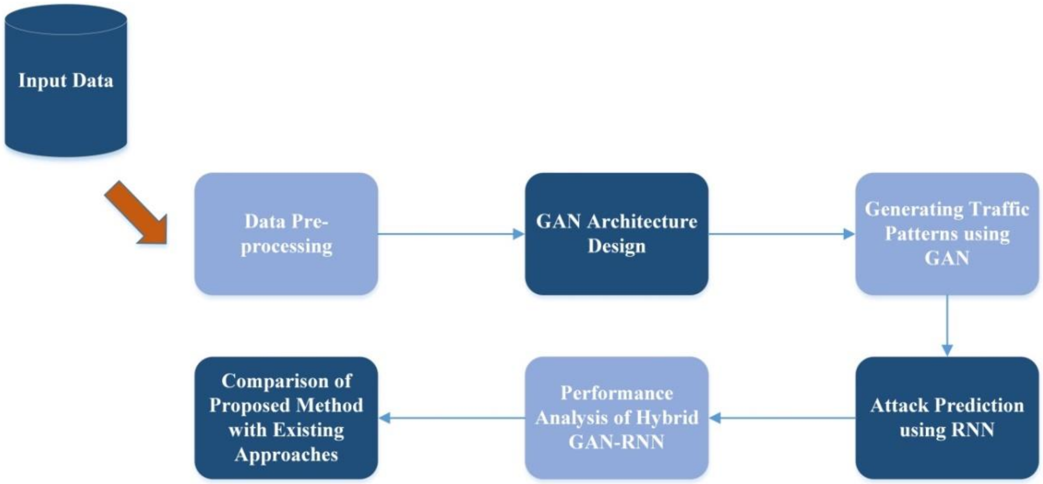
A. Data Collection

The CICIDS2017 dataset provides a valuable resource for improving network performance and security through the utilization of Hybrid GAN-RNN models within Software-Defined Networking (SDN) environments. This dataset incorporates both benign network traffic and a wide range of common attacks, making it a suitable foundation for our research and development in the field of networks security and optimization. The CICIDS2017 dataset offers a comprehensive view of network traffic, encompassing benign background traffic and real-world attack scenarios. The dataset is constructed with meticulous attention to realism, featuring the following key components: Generated using the B-Profile system, the dataset simulates the naturalistic behaviors of 25 users engaging in various protocols such as email, HTTP, FTP, HTTPS, and SSH. This component mimics real-world user interactions, contributing to the authenticity of the dataset. The dataset represents a complete network infrastructure, including components like Modem, Firewall, Switches, Routers, and a diverse array of operating systems (e.g., Ubuntu, Windows, and Mac OS X). This realistic topology ensures that the dataset mirrors complex network environments. The CICIDS2017 dataset incorporates real attacks from the Attack-Network, enabling researchers to analyze and develop security measures against a wide range of threats. This includes the most up-to-date common attacks, adding relevance to the research context [17].

B. Data Pre-processing using Handling Missing Values

The time series dataset representing network-wide traffic states, which is denoted as$X$. This dataset encompasses observations collected over time, each of which corresponds to a specific time step. The dimensionality of the dataset is determined by the amount of sensor stations in the network, denoted as$D$. Mathematical representation of this time series dataset X as follows in Eq. (1):

$$X = \{x_1, x_2, \dots, x^{\mathrm{T}}\}^T \in \mathbb{R}^{T \times D} \quad (1)$$



Input Data
Data Pre-processing
GAN Architecture Design
Generating Traffic Patterns using GAN
Attack Prediction using RNN
Performance Analysis of Hybrid GAN-RNN
Comparison of Proposed Method with Existing Approaches

Fig. 1. Proposed workflow.

T Signifies the total number of time steps in our dataset. D signifies the number of sensor stations distributed across the network. Each vectorx^t, associated with time step$t$, belongs to the real numbers$\mathbb{R}^D$. This vector encapsulates the traffic state information of the D sensor stations at that specific time [18].

Within this vector, each element x_t^d corresponds to the traffic speed observed at the d-th sensor station. This research discusses "traffic state," It specifically focuses on traffic speed. This definition aligns with the characteristics of the datasets we employ, particularly those used in our experimental section. Traffic sensors, such as inductive looping detector, may encounter failures due to various reasons, including wire insulations breakdown, damage from building activities, or electronic unit failures. These sensors failures result in missing values within our collected data. To address the issue of missing values, Research employs a masking vectormt, which is binary and takes values from the set {0, 1}, to indicate whether traffic states are missing at a specific time step t. The masking vectors for xt is defined as follows in Eq. (2):

$$m_t^d = \begin{cases} 1, if\ x_t^d\ \ is\ observed \\ \quad 0, otherwise \end{cases} \qquad (2)$$

Consequently, for a given traffic state data sample X in$\mathbb{R}^{T\times D}$, derivation of a corresponding masking data sample M, is represented in Eq. (3):

$$M = \{m_1, m_2, \dots, m^T\} \in \mathbb{R}^T \times D \qquad (3)$$

The traffic state prediction problem revolves around the objective of learning a function$F$ $(\cdot)$. This function is designed to map T historical traffic state datas observations to the subsequent traffic state data at the next time step. This problem can be formally described as in Eq. (4):

$$F([x_1, x_2, \dots, x^T];\ [m_1, m_2, \dots, m^T]) = [x_{T+1}] \qquad (4)$$

where, F aims to predict the traffic state at time step $T + 1$ depend on the historical traffic state data up to time step$T$, taking into account the masking information to handle missing values.

C. Hybrid GAN-RNN Architecture for Generating Traffic Patterns and Access Control

The Hybrid GAN-RNN architecture is designed to enhance network security by generating realistic network traffic patterns and making access control decisions based on those patterns. This architecture comprises two main components: a Generative Adversarial Network (GAN) for traffic pattern generation and a Recurrent Neural Network (RNN) for access control. The hybrid GAN-RNN architecture is shown in Fig. 2. In the GAN component, the generator (G) takes random noise (z) as input and generates synthetic traffic patterns (X_synthetic). The discriminator (D) then evaluates these synthetic patterns and real traffic patterns (X_real), aiming to distinguish between them. The objective is to train the generator to produce traffic patterns that are indistinguishable from real ones, while the discriminator becomes more adept at differentiating real from synthetic patterns. This adversarial training process is guided by a GAN loss function that encourages the generator to improve its pattern generation capabilities. The discriminator's formal objective is to acquire characteristics θd that maximize the likelihood of properly categorizing both training and produced data; the generator's objective is to discover settings θg that minimize $log\ 1 - D(G(z))$. the following two-player minimax game with value functions $V(G, D)$is therefore played by the two neural networks.

$$V(G, D) = max\ D\ min\ G\ \{Ex\ [log\ D(x)] + Ez[log(1 - D(G(z)))]\} \qquad (5)$$

where, G(z) is the created false data provided by the noise vector z, D(G(z)) is the estimated chance of a fake instance being honest, and D(x) is the estimated likelihood of an actual model being real generated by the discriminating neural networks. The generator theoretically learns to produce genuine samples when it reaches equilibrium.

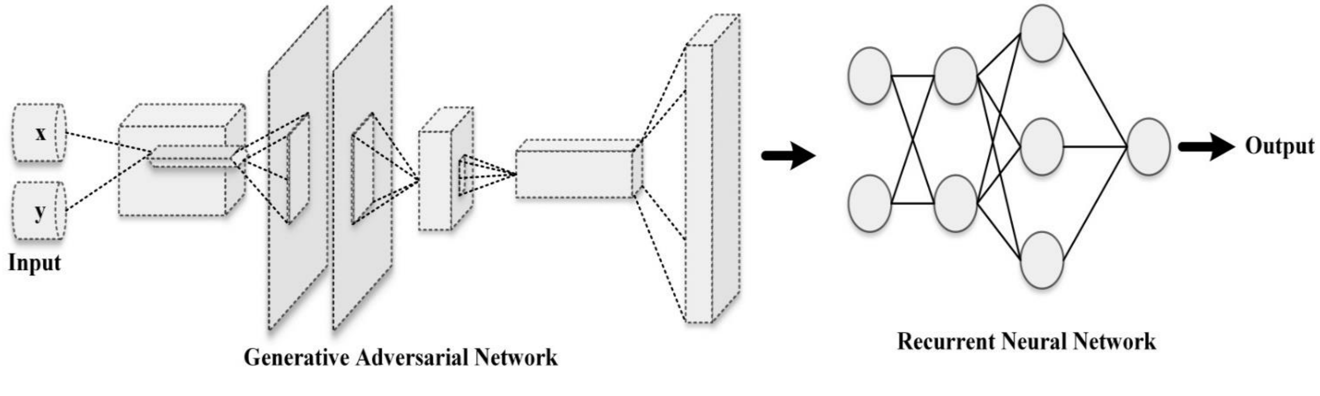


Fig. 2. Hybrid GAN-RNN architecture.

```
Algorithm 1: Hybrid GAN-RNN Algorithm for Network Security Enhancement
Input:  Network Traffic data
Output: Predicting the attack in Network traffic data
Load input data
                    $X = \{x_1, x_2, \ldots, x^{\mathrm{T}}\}^T \in \mathbb{R}^{T\times D}$          // data acquisition
Preprocess network traffic data
    Cleanse and Handling missing traffic data's, and normalize.                          //handling missing values
Split the data into training and testing sets.
Generation of Traffic Patterns                                                           // GAN Training
    Initialize the GAN model with a generator (G) and discriminator (D).
    Train the GAN by iteratively optimizing G and D
    Generate synthetic traffic patterns using G
    Calculate the GAN loss based on D's ability to distinguish real from synthetic patterns.
    Back propagate the loss and update the G and D weights.
    Repeat until convergence or a predefined number of epochs
Attack Prediction                                                                        //RNN Training
    Initialize the RNN model for attack prediction.
    Define the RNN architecture, loss function, and optimizer.
    Train the RNN using the generated synthetic traffic patterns
    Input the synthetic traffic data sequence to the RNN
    Calculate the loss based on the predicted attacks and actual labels (ground truth).
    Back propagate the loss and update the RNN weights
    Repeat until convergence or a predefined number of epochs
 Prediction of Attack in Network                                                         //RNN
Evaluate the hybrid GAN-RNN system's performance using testing data                      //Performance Evaluation
    Measure the accuracy of attack predictions
    Calculate other relevant metrics such as precision, recall, and F1-score
    Assess the quality of generated traffic patterns
```

The RNN component processes the generated traffic patterns (X_synthetic) and performs access control. For this purpose, the RNN can employ a LSTM architecture, which allows it to consider temporal dependencies in the traffic data. The RNN's internal state (ht) evolves as it processes the traffic patterns, and at each time step, it produces access control decisions (yt) through a Softmax layer. These decisions can take various forms, such as binary access control (allows or deny) or multiclass access policies based on the traffic content and context.

The key innovation of this architecture lies in its combination of GAN and RNN components. The GAN generates synthetic traffic patterns that are realistic and diverse, reflecting various network activities. The RNN, in turn, leverages these patterns to make access control decisions in real-time. This approach enables a more dynamic and adaptable access control system that can respond effectively to evolving network conditions and potential security threats. During training, the entire hybrid architecture is optimized through a joint loss function that balances the GAN loss and the access control loss. This ensures that the generated traffic patterns are not only realistic but also suitable for access control decision making. The RNN's parameters are fine-tuned to make accurate access control decisions based on the generated patterns, thereby enhancing network security.

V. Results and Discussion

The result section provides a comprehensive evaluation of the proposed network security enhancement method, employing various evaluation metrics such as accuracy, precision, recall, and F1-score. The analysis begins with a comparison of the method's accuracy on different datasets, highlighting the notably high accuracy of the "Proposed GAN-RNN" approach on the CICIDS2017 dataset. A comparative assessment with existing methods further underscores the method's superiority, showcasing exceptional precision, recall, and F1-score. Graphs depict the performance trends, demonstrating the model's convergence and its ability to generalize to unseen information. The training and testing graphs illustrate the model's progression, while the loss graph reveals its capacity to avoid overfitting. The results validate the effectiveness of the proposed methods in network intrusion detection, emphasizing its potential to enhance network security with impressive accuracy and robustness. The practical usefulness of the Hybrid GAN-RNN technique extends to dynamic business networks, allowing for adaptive routing and resource allocation. Its 99.4% accuracy in cybersecurity guarantees quick access policy changes, which are essential for sectors like banking and healthcare and improve overall network security and efficiency.

A. Evaluation Metrics

Four assessment measures were used in the study to evaluate the designs: F1-score, accuracy, precision, and recall. Such specific variables are described as in Eq. (6), (7), (8) and (9):

$$Accuracy = \frac{TP+TN}{TP+TN+FP+FN} \tag{6}$$

$$Recall = \frac{TP}{TP+FN} \tag{7}$$

$$Precision = \frac{TP}{TP+FP} \tag{8}$$

$$F1score = \frac{2*Recall*Precision}{Recall+precision} \tag{9}$$

TP is the number of information that, irrespective of every one of the types of information which was genuinely positive, was precisely identified as positive. TN is the number of information that, irrespective of all the results which was truly negative, were properly identified as negatives. The number of variables that the equation incorrectly categorized as negative despite the fact they had been positive in the input data is represented by the letter FN. The number of values that the algorithm incorrectly categorized as positive when they had been negative in the source data is known as false positives, or

FP. The percentage of the number of information that the algorithm identified as being positive to the number of positive results that were really present in the collection of data is known as recall. Precision can be defined as the proportion of the entire amount of information that the model properly identified as positive to the number of data which the algorithm categorized as positive. Lastly, as mentioned in, the F1-score represents the harmonious average of recall and precision Top of Form [19].

This Table I present the performance results of different intrusion detection methods on these datasets, with the "Proposed GAN-RNN" method achieving notably high accuracy on the CICIDS2017 dataset at 99.4%. It's important to note that the choice of dataset and the specific evaluation metrics used can significantly impact the reported accuracy, and the effectiveness of a method may vary depending on the dataset's characteristics and the complexity of the network security task.

The graph in Fig. 3 depicts, the methods consistently outperform others across multiple datasets and which ones may excel in specific contexts. This comparison aids in the selection of the most robust intrusion detection method for diverse network security environments, contributing to informed decision-making in network security strategy.

Table II presents a comparative overview of different methods applied to network intrusion detection, showcasing their performance across multiple evaluation metrics. It includes the methods GRU, CNN, B-GRU, and the "Proposed GAN-RNN." the "Proposed GAN-RNN" method exhibits exceptional accuracy, achieving an impressive 99.4%, surpassing the other methods in the accuracy metric.

Furthermore, it excels in precision with a score of 99.25%, ensuring a high proportion of correctly classified positive predictions. It demonstrates remarkable recall at 99.6%, effectively capturing a significant portion of actual positive instances. The F1-score, a balanced measure of precision and recall, remains strong at 99.4%, further affirming the method's robustness in network intrusion detection, making it a highly promising approach for bolstering network security.

The Graph represents in Fig. 4 shows the performance comparison of different intrusion detection methods on various metrics, including accuracy, precision, recall, and F1-score.

Fig. 5 represents the training and testing graph for the proposed network security enhancement method illustrates the model's performance throughout the training process. During the training phase, the metrics are plotted as they evolve with each epoch, showing how the model learns and improves its performance over time. The testing phase is also depicted on the same graph, showcasing how the model generalizes to unseen data. This graph provides a clear visualization of the model's convergence and its ability to avoid overfitting or underfitting, thus assisting in the evaluation and refinement of our network security enhancement approach. The testing accuracy attained is 99.4%.

Fig. 6 represents the training and testing loss graph is a graphical representation that illustrates the changes in the loss function values of a machine learning or deep learning model during both the training and testing phases. The testing loss curve reveals the model generalizes to unseen data, and ideally, it should exhibit a similar decreasing trend, indicating that the model is not overfitting.

TABLE I. ACCURACY COMPARISON OF DATASET

Dataset	Methods	Accuracy
KDD99 [20]	DT	92.3
UNSW-NB15 [20]	LR	85.56
CICIDS2017	Proposed GAN-RNN	99.4

TABLE II. PERFORMANCE COMPARISON WITH EXISTING METHODS

Methods	Accuracy	Precision	Recall	F1-score
GRU [21]	99	99	99	99
CNN [21]	97.7	97.4	98.2	99
B-GRU [21]	98.74	98.9	99	99
Proposed GAN-RNN	99.4	99.25	99.6	99.4

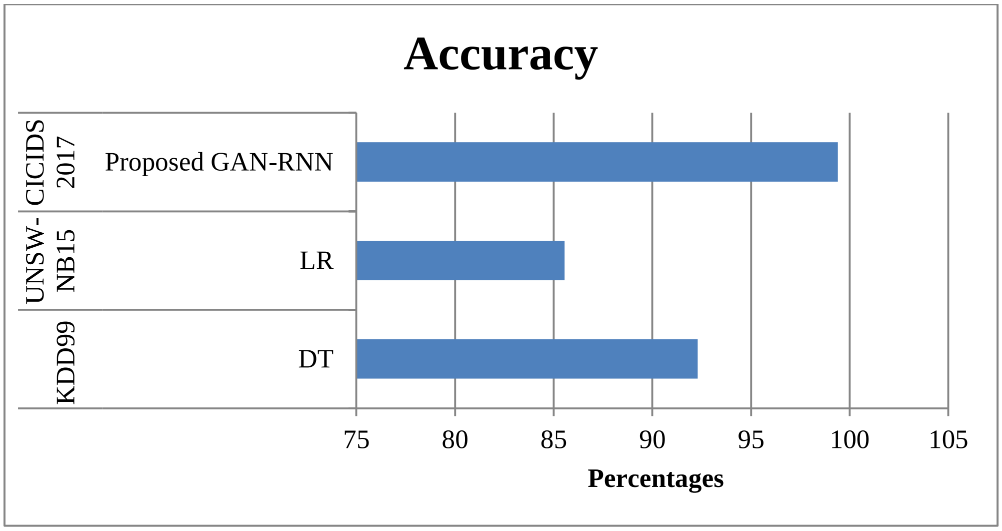

Fig. 3. Dataset comparison.

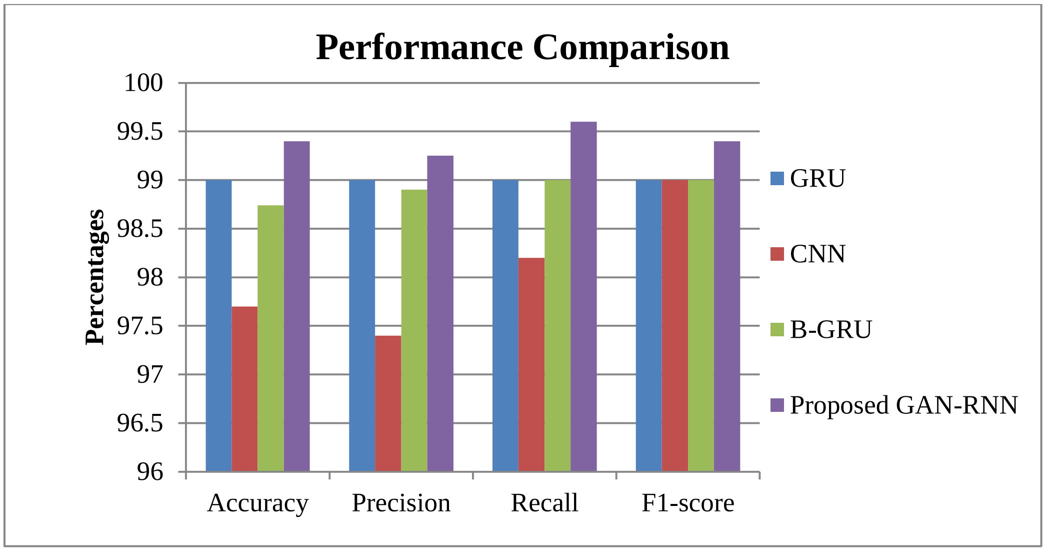

Fig. 4. Evaluation of performance with existing approaches.

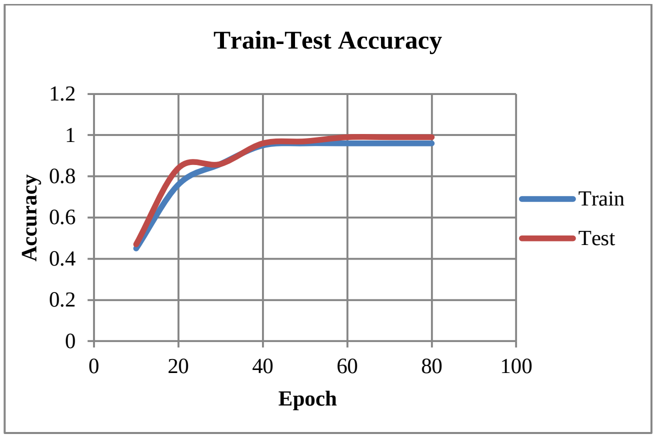

Fig. 5. Training and testing accuracy.

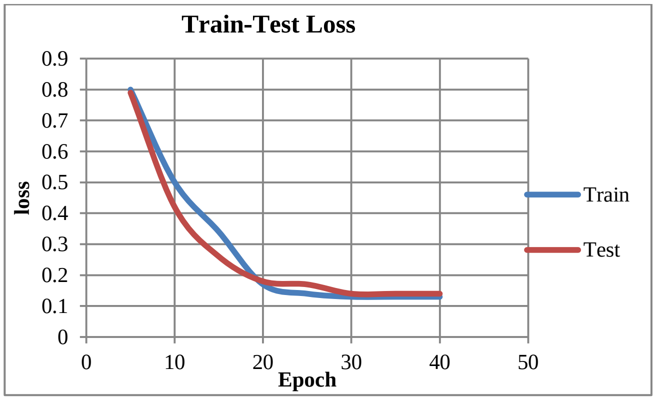

Fig. 6. Training and testing loss.

The Fig. 7 displays a Generative Adversarial Network with Recurrent Neural Network (GAN-RNN) model's Receiver Operating Characteristic (ROC) curve. The model's ability to distinguish between classes, especially in issues with binary classification, is represented graphically by the ROC curve. The true positive rate (sensitivity) during each threshold, which ranges from 0 to 0.7, is paired with a corresponding threshold value in the table. The true positive rate tends to rise in tandem with the threshold, suggesting that the model is becoming more accurate at identifying positive instances. The true positive rate increases gradually from 0.07 to 0.994 to be the threshold increases, indicating that the GAN-RNN model has high discriminatory power. This indicates that the model performs well in classifying positive instances, demonstrating its efficacy in achieving high sensitivity across a range of threshold values.

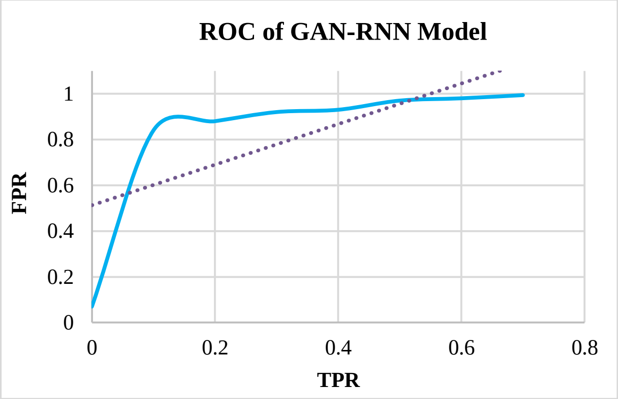

Fig. 7. ROC of GAN-RNN model.

B. Discussion

The accuracy of several methods for identifying intrusions on a range of datasets is assessed at the outset of the findings section. The efficiency results for the three different datasets—KDD99, UNSW-NB15, and CICIDS2017—are shown in Table I. On the CICIDS2017 dataset, the "Proposed GAN-RNN" approach notably obtains a very high accuracy value of 99.4%. This extraordinary accuracy demonstrates how well the approach works in a specific dataset to recognize network security problems. However, given that network data can differ greatly in complexity and feature sets, it is imperative to recognize that the selection of dataset is a critical factor in deciding accuracy. As a tool for comparing datasets, the chart in Fig. 3 shows how the techniques continually perform better than others on a variety of datasets. It makes it possible to pinpoint the approaches that work best in certain situations. The comparison is essential because it helps choose the most reliable intrusion detection technique for various network security scenarios. The graph presents the overall efficacy of the "Proposed GAN-RNN" approach, indicating a potential option for improving network security on a variety of datasets.

Table II provides an extensive comparative analysis of various intrusion detection techniques, such as GRU, CNN, B-GRU, and the "Proposed GAN-RNN." The "Proposed GAN-RNN" approach performs exceptionally well according to a number of evaluation parameters. It is noteworthy for achieving a 99.4% accuracy rate, which is higher than the other approaches. The technique also performs exceptionally well in terms of precision (99.25%), guaranteeing a large percentage of accurately identified positive predictions. Furthermore, it exhibits exceptional memory (99.6%), successfully catching a substantial proportion of true positive cases. At 99.4%, the F1-score—a measure that strikes a compromise between recall and precision—remains robust. All of these findings support the "Proposed GAN-RNN" approach's robustness and dependability in detecting network intrusions. Because of its exceptional performance, the approach offers both accuracy and precision in spotting security issues, making it a very viable alternative to strengthen network security. The suggested network security enhancement approach is thoroughly evaluated in the results section, which highlights its remarkable accuracy, precision, recall, and F1-score. It demonstrates how the approach can continuously beat other approaches on various datasets, which makes it a strong option for secure network application. These results provide insightful information that may be used to make well-informed decisions about network security planning and technological implementation. The access control as well as traffic engineering systems that are now dependent on network security may not be scalable, may have trouble adapting to changing threats in real-time, and may find it difficult to properly handle growing cyber threats [8].

VI. Conclusion and Future Work

In the framework of SDN-based traffic management and access control, hybrid GAN-RNN models were proposed and their efficacy was shown in the present investigation. The results obtained suggest that this novel technique holds significant potential for improving software-defined network security and performance. The Hybrid GAN-RNN design has demonstrated notable gains in network effectiveness and threat reduction through the creation of realistic patterns of traffic and accurate access control choices. In today's intricate and constantly evolving network systems, the capacity to detect abnormalities, adjust to changing conditions, and optimize traffic flows is an essential skill. The suggested technique's high recall, accuracy, and precision highlight its potential as a vital resource for network managers and security experts. This strategy has the ability to enable enterprises to strengthen their safety posture, maximize resource efficiency, and handle their networks more effectively as the network environment changes. Through the integration of Hybrid GAN-RNN models within SDN, this study considerably improves knowledge while improving the efficiency and security of networks. Results validate hypotheses and lay the groundwork for more investigation into adaptive access management and optimizing traffic in dynamic contexts in the future.

Provide means by which access control policies can be automatically modified in response to threat assessments and network conditions in real time, enabling more flexible and responsive security. Instead of depending only on historical data, investigate real-time analysis abilities that allow the system to identify and address security threats and operational issues as they arise. To convert created traffic trends into useful network configurations and rules, tighten the connection with SDN controllers. In multi-domain or mixed-cloud situations, when network intricacy and safety issues are heightened, expand the Hybrid GAN-RNN technique to optimize network security and performance. To ensure resilience in the midst of sophisticated dangers, assess the proposed method's resistance against adversarial assaults that attempt to interfere with traffic patterns or evade control of access. To handle increasing threats, future research might focus on improving the hybrid GAN-RNN method's scalability and flexibility. A more thorough and forward-thinking approach would involve looking into effective ways of managing larger networks and new security challenges.

The Contribution of Health Management Information Systems to Enhancing Healthcare Operations

Majzoob K.Omer
Department of Computer Science, Al-Baha University, Al-Baha, Saudi Arabia

***Abstract*—Various strategies for enhancing quality have been implemented by developed and developing countries in light of the worldwide emphasis on bolstering healthcare systems. Many nations are currently directing their attention towards bolstering their existing information systems or establishing new ones, recognizing the critical role of information in the functioning of healthcare systems. The study aimed to assess the impact of leadership style, organizational factors, technology, and healthcare provider behavior on the implementation of health management information systems in healthcare organizations. While the study was informed by the performance framework of routine information systems, it was primarily based on system theory. After conducting the analysis in Python and SPSS, the data was presented using descriptive statistics, such as means and standard deviations, and inferential statistics including regression analysis. The study observed that information timelines significantly moderated the connection between the technical factor and the integration of health management information systems.**

Keywords—Health management information system; cronbach alpha; moderator; information timelines

I. Introduction

Various forms of innovations have emerged due to the heightened international emphasis on reinforcing health systems to guarantee the delivery of higher-quality healthcare services. However, the objective has not been completely achieved. The [WHO], 2007 defines health system strengthening as a collection of programs and strategies that enhance one or more core elements of the health system, resulting in improved health. Each element within the World Health Organization framework holds significance. Conversely, rapid, precise, and relevant information is vital for effectively bolstering the health system to enhance its performance. It can also facilitate the sharing of common data and practices and enable the production and access of information in a real-time environment, as indicated by [1].

The objective is to furnish decision-makers with up-to-date information. Thus far, large-scale organizations, particularly in the manufacturing industry, have incorporated integrated ERP systems. These systems have been employed to streamline various business operations, encompassing sales, finance, production, and dispatching. It also facilitates the segmentation of healthcare functions in terms of information exchange and flow. A well-executed integrated information system offers numerous potential benefits and might even be indispensable for the survival and efficiency of an organization. The integration of IHMIS can assist healthcare organizations in managing their operations more efficiently, offering advantages such as inventory reduction, improved coordination in the supply chain, streamlined process flow, enhanced data analysis, decision-making using quality data, and improved patient care services [2]. Over the next decade, the ERP market is anticipated to be one of the application software industry's most rapidly expanding and crucial segments. Currently, it stands as one of the swiftest-growing software markets.

This remains true even though about sixty percent of information system implementation initiatives fail globally and across all organizations [3]. The author in [4] emphasizes that managers should take a proactive approach and actively encourage other users and staff members to adopt the system. Successful adoption would likely lead to improved patient care coordination and an elevated standard of care across all areas [5].

The health management information system (HMIS) initiative in India seeks to encourage healthcare professionals across various government levels about the potential of high-quality data to enhance patient care, representing an effort to leverage technology for public health improvement. Similarly, countries like Iran, Malawi, Kenya, and Uganda have adopted web-based systems to facilitate data access for decision-making. According to research, the management information provided by DHIS2, an open-source program that can be customized to include HIM functions, is found to be ineffective [6].

The methodology employed in this study is highly valuable. In this approach, the author utilized Independent Variables (IV), a Moderator, and a Dependent Variable (DV).

The structure of the remaining article is outlined as follows: Section II is Literature Review, Section III is Hypotheses, Section IV is Descriptive Statistics, Section V is Methodology, Section VI is Results and Discussion, and Section VII is Conclusion.

II. Literature Review

The idea of integrating information systems facilitates more efficient coordination and control of organizational activities and healthcare delivery was emphasized by Finnish researcher [7]. However, [7] does not delve into the facilitation of the integration process. A study conducted in African countries Ghana and Tanzania identified obstacles to HMIS integration, including limited capacity for data analysis and decision-making, redundant and parallel reporting, and communication channels. Establishing amicable connections and partnerships is crucial for the effective implementation of

IHMIS, as it necessitates the cooperation and commitment of numerous stakeholders. Previous studies have highlighted the benefits of information-sharing within healthcare partnerships [8].

A study conducted in China highlighted seven primary factors crucial to the success of the HMIS. These factors encompass strong motivation, a shared vision, a multidisciplinary implementation team, seamless integration with internal information systems, advanced legacy information systems and infrastructure, and adherence to industry standards [9]. To record and track population health data, most low-income nations still mostly rely on paper-based systems [10]. In regions with little infrastructure and resources, paper-based systems are frequently the most economical and useful modern option accessible. Coordinating data collection among government agencies can be challenging, especially when dealing with local healthcare service providers that perform similar tasks. However, donor policies typically encourage the implementation of vertical programs that support their own information systems and administrative structures [6].

Embracing modern technology represents just one of the various approaches healthcare organizations can utilize to enhance productivity and reduce costs. This investigation examines the technical aspect in line with the conceptual framework, considering:

1) IT infrastructure, comprises two distinct yet interrelated components: Technological infrastructure and human infrastructure. The technical infrastructure supports business applications (hardware, software, and data) with a collective set of tangible IT resources. b) Organizational and human skills, knowledge, expertise, commitments, values, and norms are all included in the human infrastructure. It is crucial to evaluate the sufficiency and accessibility of the human and technology infrastructure. It tackles the essential question of whether the information system would technically work, as mentioned by [11]. c) System interoperability. The primary emphasis of the laissez-faire approach is on organizational performance. Under laissez-faire leadership, employees are granted the autonomy to operate as they deem appropriate with minimal intervention. Leaders in this model assign responsibilities and make decisions, staying informed about corporate affairs and available for consultation as needed. However, they adopt a hands-off approach, enabling team members to work autonomously while meeting established organizational goals [12].

Data quality is delineated by four attributes: accuracy, timeliness, completeness, and consistency. Consistency refers to the level of correspondence between patient data recorded on patient cards and the registry. Meeting the reporting deadlines is the criteria used to gauge timeliness, as highlighted by [13]. The assessment of data quality is currently widely embraced in standard public health practices to ensure the reliability of data in Health Information Systems (HIS). To make evidence-based decisions, there is a need for both the demand and utilization of information. During their working hours, healthcare professionals collect a great deal of patient data; However, at the time of gathering, this data is hardly evaluated or utilized [14]. Therefore, an effective Health Management Information System (HMIS) should ensure that data collection is closely aligned with user requirements, encompassing only relevant data, and should possess processing capabilities that enable the easy retrieval of information, requiring only the essential data for expeditious analysis [13].

The results showed that Brazil does not use information effectively enough for planning or decision-making [13]. A prevalent deficiency in effectively using data to monitor service usage trends over time, thereby evaluating the impacts of policy and service delivery changes, is a significant vulnerability that impacts the entirety of the Sub-Saharan Africa [15].

An effective HMIS streamlines reporting by advocating for unified reporting to development partners and discouraging the implementation of parallel reporting systems whenever possible (WHO & ROWP, 2004). According to [16], work was classified into two main categories: (i) the type, capacity, specialization, and skills required for a specific task; and (ii) the diversity of knowledge and expertise from different individuals. This distribution of tasks highlights the potential to optimize the diverse talents and expertise of various healthcare workers, fostering the development of specialization. It also minimizes the time lost in duplicating tasks that could be efficiently handled by individuals based on their specific skill sets.

An organization's capacity to embrace technology was evaluated based on its utilization of Information and Communication Technology (ICT) and the promptness of information delivery, denoting the immediate and simultaneous exchange of information among all users. ICT facilitates electronic communication, information processing, and transmission, fostering the sharing of knowledge. This encompasses all forms of digital and analog information and communication technology, excluding non-electronic technologies. Examples of ICT in this context include computers, radios, televisions, phones, digital texts, and audio-video recording. The absorption and dissemination of innovation have served as the central analytical framework in investigating the adoption of information technology (IT) and information systems (IS). In their report, [17] underscores the significant role of an organization's technological proficiency and resources in its ability to adapt to new technologies.

According to study [18], healthcare professionals encounter challenges in implementing IT systems due to their complexity, resulting in a reliance on manual paper filing systems that compromise and mismanage information. According to study [19], information technology use and application are new ideas in modern developing-nation organizations. In situations involving emerging diseases and urgent health crises, where timely notification, investigation, and response can prevent widespread outbreaks and even global pandemics, as well as save lives, the need for precise information is particularly crucial [20]. The Government of [21], states that the main goals of the IHMIS are to improve clinical outcomes, decrease redundancy, boost efficiency, improve access and coordination, and strengthen connections between various care tiers and support services. Moreover, integrated healthcare harnesses the diverse skills and expertise of various healthcare professionals, along with crucial support services such as information management. Many people consider healthcare to be one of the foremost concerns for humanity, encompassing both societal and personal life objectives.

The correlation between information technology and healthcare is symbiotic. Accurate information is indispensable for the healthcare sector, and achieving precision in information is contingent on a person’s mental, physical, and psychological well-being [22]. The study in [23] objective is to aid both administrators and medical managers by elucidating the influence of the health information system on the decision-making process and highlighting the system's importance in facilitating these decisions.

III. Hypothesis

A hypothesis must be put to systematic testing or observation to see if it is true or not (Bradford, 2015). Only then can it be deemed scientific. The following hypotheses were examined in the study:

(H1): Behavioral factors play a substantial role in the integration of HMIS within the healthcare sector.

(H2): The leadership style of the health system is crucial to the successful integration of HMIS in healthcare facilities.

(H3): Healthcare organization’s HMIS integration is significantly impacted by technical aspects.

(H4): The timely delivery of information has a significant impact on the interaction between HMIS integration in healthcare organizations.

IV. Descriptive Statistics

An overview of the study's conclusions and descriptive statistics based on the data gathered are given in this section. There were 219 questionnaires distributed in total; 214 were collected, and five were discarded because the responses were not complete after the 214 surveys' data were processed, analyzed, and thoroughly examined for any missing values or anomalies.

According to the data presented in Table I, approximately 47% of the samples fell within the age range of 25 to 35, while 35% were aged between 35 and 45, with the remaining 18% being over the age of 45.

Table II indicates that 51% of the samples are male, while 49% are female.

Table III displays the sample's perspectives on the questionnaire statements regarding the data collection strategy. The average data collection strategy in the table is 3.38, indicating that the assessment of the data collection strategy was at a moderate level. The findings indicate that the statement means ranged from 3.28 to 3.49.

Table IV presents the sample's viewpoints on the questionnaire statements regarding the influence of the health system's leadership style on IHMIS. The average score for the impact of the health system's leadership style on IHMIS is 3.432, indicating a moderate level of influence. According to these findings, the statement means ranged from 3.15 to 3.74.

On the other hand, Table V displays the results of the Means & Sd. analysis for the statements concerning the Integrated HMIS Model.

Regarding the Integrated HMIS Model (Dependent variable), the statements were assessed using Means & Sd. The results are displayed in Table V.

The data in Table V reflects the sample's perspectives on the questionnaire statements related to the Integrated HMIS Model. The average for the Integrated HMIS Model was recorded as (3.635), indicating a moderate level of estimation. The results indicate that the statement means ranged from (3.37 to 3.95). Concerning the Information Timeliness (Moderating variable), Means & Sd. were used to evaluate the statements. Table VI presents the findings.

TABLE I. The Age Distribution of Participants' Frequency

Age	Frequency	Percent
25-35	100	46.7
35-45	75	35.0
45 & Above	39	18.2
Total	214	100.0

TABLE II. The Distribution of Participants' Gender Frequencies

Gender	Frequency	Percent
Male	109	50.9
Female	105	49.1
Total	214	100.0

TABLE III. Means and STD. Deviation of Data Collection Strategy

S#		Mean	Std. Deviation
1	All caregivers are committed to recording all collected information, whether manually or electronically.	3.41	1.236
2	Data collection adheres to the guidelines outlined in the templates.	3.29	1.166
3	Essential data is collected at each service point using the provided templates.	3.28	1.197
4	To ensure effective service delivery, each patient undergoes a series of well-organized processes.	3.39	1.115
5	The available HMIS enables seamless information exchange within the facility.	3.46	1.116
6	Multiple data sources are accessible within the premises.	3.49	1.056
7	HMIS is perfectly aligned with organizational structure.	3.36	1.064
Total		3.38	1.14

TABLE IV. MEANS AND STD. DEVIATION OF EFFECT OF THE HEALTH SYSTEM'S LEADERSHIP STYLE ON IHMIS

S#		Mean	Std. Deviation
1	Consistently provide basic outpatient care.	3.27	1.218
2	Deliver top-notch surgical services.	3.26	1.185
3	Focus is solely on promotive/preventive care.	3.26	1.056
4	Ensure satisfactory patient services.	3.3	1.156
5	Curative services meet the needs adequately.	3.48	1.091
6	Hospital operations are guided by established plans and objectives.	3.17	1.093
7	Consistently achieve targets within the designated time frame.	3.15	1.296
8	The available HMIS facilitates seamless information sharing with national referral hospitals.	3.56	1.004
9	Regularly exchange medical records with neighboring institutions throughout the county.	3.59	0.992
10	Hospital management team maintains regular communication with staff members.	3.71	1.027
11	Hospital's established structures enable easy access to healthcare for patients.	3.74	1.001
12	Each department within hospital has an adequate number of staff members.	3.56	1.002
13	Knowledgeable and proficient individuals are staffed at every service point within hospital.	3.56	1.076
Total		3.432	1.092

TABLE V. MEANS AND STD. DEVIATION INTEGRATED HMIS MODEL

S#		Mean	Std. Deviation
1	The data collected is consistently comprehensive.	3.75	1.053
2	Regular data audits ensure data quality.	3.65	1.062
3	Data collection, analysis, and utilization are integrated across all departments in the facility.	3.74	1.046
4	At facility, there is a significant demand for information to aid in decision-making processes.	3.73	0.988
5	The management frequently seeks evidence to validate the accuracy of reports used for decision-making.	3.61	1.099
6	Timely identification and correction of any deviations from planned activities is our norm.	3.64	1.01
7	Management team has implemented control mechanisms to ensure optimal organizational performance.	3.51	1.074
8	Willingly share information to aid disease prevention and control efforts.	3.38	1.012
9	Effective information-sharing has significantly improved cost savings within facility.	3.37	1.002
10	Relevant feedback for corrective action is promptly disseminated.	3.38	0.98
11	Management team at the facility often engages in benchmarking activities.	3.52	0.948
12	Consistently prepare reports meticulously and ensure they are well-organized.	3.4	0.962
13	Reports in facility meet the standards provided by the Ministry of Health.	3.43	0.926
14	HMIS-generated reports are instrumental in effecting changes within facility.	3.41	1.056
15	Via the different capabilities of HMIS, we receive abundant information from sub-county hospitals.	3.41	1.109
16	They remain informed about the local health situation and needs through frequent meetings with the county health department.	3.78	1.116
17	Maintain close cooperation with hospitals in sub-counties and health centers.	3.84	1.054
18	All sections, departments, and divisions work collaboratively to achieve organizational goals.	3.92	1.017
19	Submit regular reports to the sub-county Ministry of Health every week.	3.95	1.008
20	Facility utilizes one of the top HMIS programs available in the market.	3.93	1.027
21	The system conducts regular data backups.	3.88	0.959
22	Eectronic medical record management solution simplifies the process of record-keeping.	3.74	1.024
23	The data collected is consistently comprehensive.	3.64	0.986
Total		3.635	1.023

TABLE VI. MEANS AND STD. DEVIATION OF INFORMATION TIMELINESS

S#		Mean	Std. Deviation
1	Patients can easily access necessary information.	4.41	1.096
2	HMIS enables rapid reporting to DMIS.	4.31	1.053
3	Facility has established a dependable system for collecting and disseminating data.	4.38	1.118
4	HMIS primarily aids clinical healthcare workers in timely task completion.	4.54	1.051
Total		4.41	1.08

The findings in Table VI illustrate the perspectives of the respondents on the questionnaire statements related to Information Timeliness. The data demonstrates that the means of the statements ranged between 4.31 and 4.54, with Information Timeliness averaging at 4.41, signifying a high estimation level for Decision Making.

V. METHODOLOGY

Given that it aligns with the research objectives, the exploratory factor analysis approach is chosen for this study. Two main factors go into this decision. First of all, it seeks to reduce a large number of variables—132 in total—into a more manageable group of elements. Second, it follows the recommendations made by [24] in an attempt to preserve as much of the original variance as feasible.

Additionally, a more theoretical reason is considered when favoring EFA in the decision-making process. This reason relates to the correlation structure among measured variables, which is distinct from the goal of data reduction. It's worth noting that exploratory factor analysis is considered a data-driven approach because the researcher lacks a predetermined notion of the number of factors [25], It provides techniques for determining the appropriate number of factors and the configuration of factor loadings to be employed in subsequent hypothesis testing. When conducting an EFA, three fundamental steps are followed: assessing item correlations, extracting components, and rotating factors [26]. These aspects are elaborated upon in the following sections:

A. Rotated Factor Extraction

Fig. 1 illustrates that the number of elements obtained through rotation techniques is equivalent to those derived from the principal components method. Table VII presents the Kaiser-Mayer-Olkin measure of sampling adequacy, yielding a value of 0.765, which surpasses the suggested cutoff point of 0.6 (Hair et al., 2010). Moreover, Bartlett's Test of Sphericity yielded a significant result with a p-value of .000. Patterns with loadings exceeding 0.3 were identified using an analytical approach.

TABLE VII. KMO AND BARTLETT'S TEST

Kaiser-Meyer-Olkin Measure of Sampling Adequacy.		.765
Bartlett's Test of Sphericity	Approx. Chi-Square	29348.966
	df	9045
	Sig.	.000

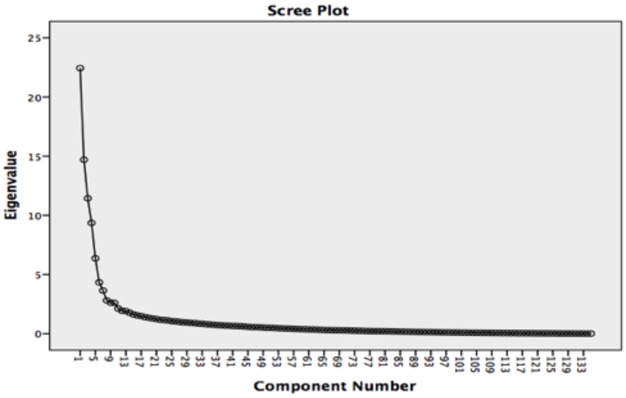

Fig. 1. Factors derived from the varimax and promax techniques with loadings exceeding 0.3.

B. Examining the Variables Associated with the Efficacy of Information Systems

Setting a loading cut-off threshold at 0.4 resulted in the successful extraction of nine components (see Fig. 2), with the essential output tables presented below. Notably, an impressive cumulative variance explanation of 83% is achieved, as indicated in Table VIII, and the KMO measure of sampling adequacy (see Table VII) is notably favorable. In conclusion, Table VIII pattern compilation distinctly identified nine components that underwent further in-depth examination.

TABLE VIII. KMO AND BARTLETT'S TEST

Kaiser-Meyer-Olkin Measure of Sampling Adequacy.		.832
Bartlett's Test of Sphericity	Approx. Chi-Square	10740.155
	df	1830
	Sig.	.000

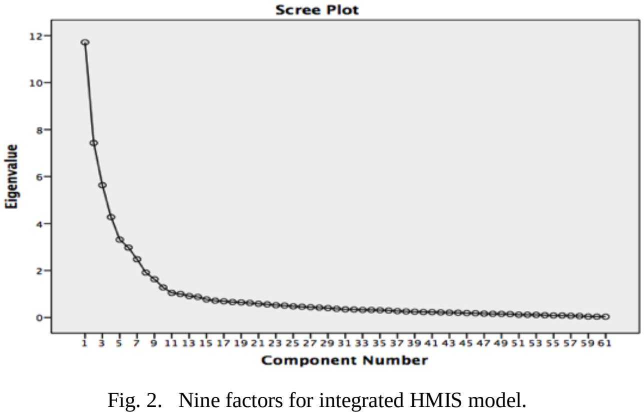

Fig. 2. Nine factors for integrated HMIS model.

C. Discussion on the Solution - Assigning Names to the Factors of the Independent Construct

The factor analysis results showed the extraction of nine factors that could be related to the independent construct's five dimensions. Four of the items in the pattern matrix had loadings that were less than 0.4, indicating that the original 132 variables were condensed to 51. Here is a list of these particular items.

TABLE IX. FACTORS AND VARIABLES ASSOCIATED WITH THE INTEGRATED HMIS MODEL

Dimensions	Factors 9	Variables 51
Information Quality	5	5
Effect of the Health System's Leadership Style on IHMIS	2	7
	5	6
Integrated HMIS Model	10	3
	1	11
	6	5
	7	4
Information Timeliness	9	4
Technical factor affecting IHMIS	3	9

Table IX provides a summary of the number of variables and factors retained for use in the study. Each extracted element underwent an individual evaluation to determine its characteristics and suitability for inclusion in the subsequent study. The pattern matrix revealed the distinctiveness of the factors, facilitating the identification of the weaker ones: Factor 8 encompassed five variables; Factors 2 and 5 comprised 7 and 6 variables, respectively. Factors 10, 1, 6, and 7 contained 3, 11, 5, and 4 variables, respectively. Lastly, Factors 3 and 9 included 4 and 9 variables, respectively.

D. *Reliability Analysis*

Data was collected and compiled using SPSS for analysis purposes. To ascertain the internal consistency reliability of the Health Management Information System (HMIS) integration, Cronbach Alphas were calculated. According to Nunnally (1978), an acceptable Cronbach Alpha level of at least 0.70 was defined for internal consistency reliability. Throughout the evaluation process, it was identified that several elements needed to be removed to enhance the instrument's reliability. Table X describes the findings of the factor's reliability.

TABLE X. FINAL FACTORS RELIABILITY FINDINGS

Constructs	Factor Name	Cronbach Alpha
Information Quality	Data Collection Strategy	0.906
Effect of the Health System's Leadership Style on IHMIS	Transformational Leadership	0.787
	Laissez-Faire Leadership	0.877
Integrated Hmis Model	Data And Information Quality	0.741
	Information Use	0.923
	Teamwork	0.879
	Technology Adoption	0.853
Information Timeliness	Information Timeliness	0.902
Technical Factor Affecting IHMIS	Technical Factor	0.732

E. *The Research Model*

Commonly referred to as a conceptual model, a conceptual framework is a visual representation that assists researchers in illustrating the anticipated cause-and-effect relationships [27]. The dimensions comprise Information Quality, Transformational Leadership, Laissez-Faire Leadership, and System interoperability as independent variables, Information timelines as a moderator, while Integrated HIMS serves as the dependent variable [28] and [29]. Using a multiple regression model, this study sought to determine the impact of the three independent variables (P_1, P_2, and P_3) and the single moderating variable (Q) on the dependent variable (R) through HMIS integration efforts. The study's objectives were met through the hierarchical examination of variables, following the procedures outlined in the Fig. 3 conceptual framework proposed by [30].

$$R = \beta_0 + \beta_1 P_1 + \beta_2 P_2 + \beta_3 P_3 + \beta_4 Q + \beta_5 P_1 Q + \beta_6 P_2 Q + \beta_7 P_3 Q$$

Let Y represent the HMIS integration, where β0 stands for the intercept, and β_1, β_2, and β_3 represent the slope coefficients, indicating the relationship between the respective independent variables and the dependent variable. P_1 denotes the behavioral component of health professionals, P_2 represents the influence of the health system's leadership style on IHMIS, and P_3 corresponds to the technical factor. Each hypothesis was carefully tested and evaluated to ensure its alignment with the study's objectives.

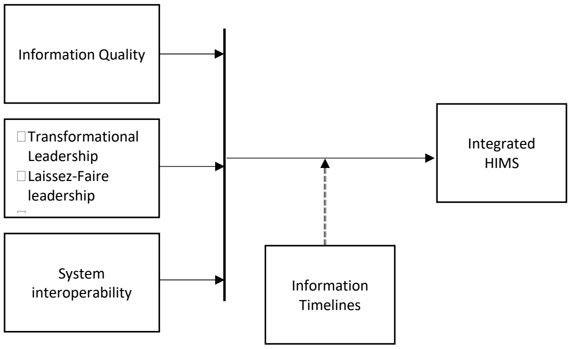

Fig. 3. Conceptual framework.

The model examined the influence of the independent variables (P_1: healthcare professionals' behavior, P_2: the influence of the health system's leadership style on IHMIS, and P_3: the technical aspect) on the dependent variable (R: Integrated HMIS Model). Before considering any moderating effects of information timeliness, the model included the standard predictors of integration in healthcare organizations.

VI. RESULTS AND DISCUSSION

The multiple regression model presented in Table XI indicated that Information Quality (β2 = -0.1053, P > .005) and Technical factor (β4 = 0.0834, P > .005) are not significant contributors to the integration of HMIS in a combined relationship. However, Health System's Leadership Style (β3 = 0.4654, P < .005) emerged as a significant influence on HMIS integration in a combined relationship. This implies that the crucial factor predicting HMIS integration is leadership style, with other factors being less impactful.

The presented results outline the outcome of an Ordinary Least Squares regression analysis in Table XII. The purpose of the model is to predict the values of the dependent variable by considering the independent variables (IV1, IV2, IV3) and their interactions with the moderator (IV1_M_interaction, IV2_M_interaction, IV3_M_interaction). Assuming that all other variables stay constant, the coefficients for each variable show how the dependent variable is expected to vary for every unit change in the associated independent variable.

The model explains 69.9% of the variance in the dependent variable, indicated by an R-squared of 0.699.

The model demonstrates overall statistical significance, as evident from the low p-value of 2.36e-50 and the high F-statistic of 68.48. IV1 does not appear to be statistically significant, indicated by its high p-value of 0.614 and a coefficient of -0.1053. IV2 is deemed statistically significant due to its coefficient of 0.4654 and a relatively low p-value of 0.005. IV3 does not exhibit statistical significance, as indicated by its high p-value of 0.572 and a coefficient of 0.0834.

The interaction terms IV1_M_interaction, IV2_M_interaction, and IV3_M_interaction are denoted by coefficients of 0.1181, -0.1320, and -0.0395, respectively. IV1_M_interaction, IV2_M_interaction, and IV3_M_ interaction were found to be statistically significant in the context of the provided data, however, IV3_M_interaction was not, based on their respective p-values. These findings imply that the moderator variable has a significant impact on how the independent variables affect the dependent variable. Furthermore, the research shows that IV2 has a significant and unique effect on the dependent variable, in contrast to IV1 or IV3.

DV=IV1_M_interaction - 0.1320 * IV2_M_interaction - 0.0395 * IV3_M_interaction + 0.1181 * Moderator + 0.0804 - 0.1053 * IV1 + 0.4654 * IV2 + 0.0834 * IV3 + 0.7164 * Moderator.

The link between the dependent variable and multiple independent variables (IV1, IV2, and IV3), as well as their corresponding coefficients, are shown in the regression equation. The influence of the Moderator variable on the relationship between the independent and dependent variables is also accounted for in the equation.

TABLE XI. SUMMARY OF THE TESTED HYPOTHESES' OUTCOMES

No.	Variable	p-value	Direction	Deduction
1	Information Quality	0.614	Negative	Do not reject Null
2	Effect of the Health System’s Leadership Style on IHMIS	0.005	Positive	Reject Null
3	Technical Factors affecting IHMIS	0.572	Positive	Do not reject Null
4	Information Timeliness	0.000	Positive	Reject Null
5	Information Quality* Information Timeliness	0.026	Positive	Reject Null
6	Effect of the Health System’s Leadership Style on IHMIS * Information Timeliness	0.004	Negative	Reject Null
7	Technical factor affecting IHMIS* Information Timeliness	0.327	Negative	Do not reject Null

TABLE XII. ORDINARY LEAST SQUARES REGRESSION ANALYSIS

	coef	std err	t	P>ltl	[0.025	0. 9751]
const	0.6804	0.643	0.125	0.901	-1.188	1.348
IVI	-0.1053	0.208	-0.506	0.614	-0.516	0.305
IV2	0.4654	0.162	2.872	0.005	0.146	0.785
IV3	0.0834	0.147	0.566	0.572	-0.207	0.374
Moderator	0.7146	0.190	3.752	0.000	0.339	1.09
IVI_M_interaction	0.1181	0.052	2.25	0.026	0.015	0.222
IV2_M_ interacion	-o.1320	0.046	-2.874	0.004	-0.223	-0.041
IV3_M_interaction	-0.0395	0.040	-0.982	0.327	-0.119	0.04

The anticipated change in the dependent variable for a one-unit increase in the associated independent variable, assuming other variables remain the same, is displayed by the coefficients for each independent variable (IV1, IV2, IV3). Moreover, IV1_M_interaction, IV2_M_interaction, and IV3_M_interaction are interaction terms that show how the moderator changes the associations between the independent and dependent variables. Positive coefficients point to an amplification impact, whilst negative coefficients point to a damping effect.

The investigation unveiled a strong and positive connection between the timeliness of information and the integration of HMIS. Furthermore, it was observed that a powerful leadership style notably improved the functionality of health management information systems, leading to enhanced patient outcomes.

VII. Conclusion

In terms of the organizational dimension, it was imperative to enhance, endorse, and adjust data collection methods to meet the dynamic requirements of the healthcare system. At that time, the healthcare system used a lot of different data collection tools, which led to laborious work and weariness among data and information workers. The integration of HMIS was notably associated with the Health System's Leadership Style, suggesting that healthcare organizations could achieve operational efficiency by refining their health system leadership style to align with environmental shifts. The results of the study showed a strong and positive association between information timeliness and HMIS integration. Overall, the study's model explained 69.9% of the variability in HMIS integration, demonstrating its efficacy in answering important questions about the critical elements of HMIS integration in healthcare facilities. It was observed that a strong leadership style greatly enhanced the functionality of health management information systems, which in turn improved patient outcomes.

In future work, the current study can also be mapped with two important independent variables named as Information Sharing and Complexity of Project Management.

A Sophisticated Deep Learning Framework of Advanced Techniques to Detect Malicious Users in Online Social Networks

Sailaja Terumalasetti[1], Reeja S R[2]
School of Computer Science and Engineering, VIT-AP University, Amaravati, India

***Abstract*—Malicious user detection is a cybersecurity exploration domain because of the emergent jeopardies of data breaches and cyberattacks. Malicious users have the potential to detriment the system by engaging in unauthorized actions or thieving sensitive data. This paper proposes the dual-powered CLM technique (Convolution neural networks and LSTM) and optimization technique, a sophisticated methodology for distinguishing malicious user behavior that assimilates LSTM and CNN, and finally optimization technique to enhance the results. A genetic algorithm is used to augment the model's capability to perceive altering and nuanced malicious performance by fine-tuning its parameters. Due to the rising vulnerabilities of data breaches and cyber-attacks, malicious user identification in OSN (Online Social Networks) is a significant topic of research in cybersecurity. The proposed technique pursues to ascertain anomalous user behavior patterns by assessing vast quantities of data generated by digital systems with CLM and optimizing detection accuracy with genetic algorithms. On a public dataset of social media bot dataset, a twibot-20 dataset comprehending user activity data, was explored to measure the performance of the suggested methodology. The outcomes demonstrated that, in comparison to conventional machine learning algorithms like SVM and RF, which respectively obtained 92.3% and 88.9% accuracy, our technique, had a better accuracy of 98.7%. Moreover, the other metrics measures were assessed, and the proposed technique outperformed traditional machine learning algorithms in each situation.**

I. INTRODUCTION

Online social networks have turned out to be an indispensable element of our everyday life. Platforms like Facebook, Twitter, Instagram, and LinkedIn have transformed the way we intermingle, altercation data, and associate with people.

For cybersecurity professionals, ascertaining malicious users in online social networks (OSN) presents a perplexing task. People might now enthusiastically interact with friends and families, discuss their views and opinions, and even conduct business online, acknowledging the upsurge of social media. Online social networks (OSNs) have turned out to be a crucial part of the contemporary era, endorsing connectivity and information sharing. However, as these platforms are exposed, they are probable to diverse sorts of misuse, including malevolent user activity. The research deals with the crucial theme of detecting and mitigating malicious user behavior. Online social networks (OSNs) are virtual communities that allow individuals to associate and communicate with one another on a certain topic or just "hang out"[1].

With billions of handlers worldwide, OSNs have turned out to be an indispensable component of modern civilization. Individuals are progressively using OSN sites due to the rapid growth of Web 2.0 technology. The rise of malevolent individuals in online social networks, on the other hand, has become a substantial concern for both users and researchers. Criminal hackers recurrently exploit social media to spread spam and malware, which is acknowledged as social malware. These destructive users will not "fit" into any of these classifications because they have mutual friends and interests and develop gigantic communal networks. The advent of detrimental handlers in online social networks is an intensifying basis of concern for users. According to one assessment, the number of fraudulent social media profiles generated grew by 100% in the first half of 2020. According to another survey, the amount of social media phishing attacks grew by 500% in the first quarter of 2021. These statistics lay emphasis on the prominence of detecting and preventing fraudulent users in online social networks.

Security is of utmost consequence in the contemporaneous era, since the majority of our private and sensitive data is stockpiled digitally. Malicious users have the potential to harm the system by engaging in unauthorized actions or stealing sensitive information [3]. Access restrictions, intrusion detection systems, and firewalls are instances of traditional security measures that can assist in preventing attacks to some extent but are not precisely operational when it comes to malicious user detection. Algorithms in machine learning have been used to analyze user activity and detect anomalies. However, the accuracy of these algorithms is mostly determined by the prominence and volume of training data.

A malicious user utilizes a computer system or network intending to cause harm, steal data, or disrupt normal operations [1]. Malicious users may have numerous intentions, comprising of financial gain, retaliation, or political involvement. They may use a variety of strategies to accomplish their goals, encompassing malware, phishing, social engineering, and exploiting vulnerabilities in software and hardware.

Analyzing user behavior is one procedure for identifying malevolent users. It could be capable of flagging suspicious behavior and more research by discerning an eye on user activity patterns and perceiving abnormalities. CNN and LSTM networks are instances of machine learning techniques that possibly will be used to automatically analyze big datasets of user behavior and predicament patterns that can be suggestive of harmful conduct [2]. By looking for the ideal set of hyper parameters, genetic algorithms (GAs) may be employed to improve the enactment of the archetype.

Malicious users pose a severe threat to entities, governments, and organizations. They have the proficiency to steal private information, jeopardize the security of systems, and harm a company’s reputation and brand. Therefore, it is essential to have effective techniques for identifying and reducing the actions of harmful users [3]. The upsurge of these daily threats over the past ten years is the main cause for concern for data security. Fig. 1 illustrates the tendency of the threats in the past decade.

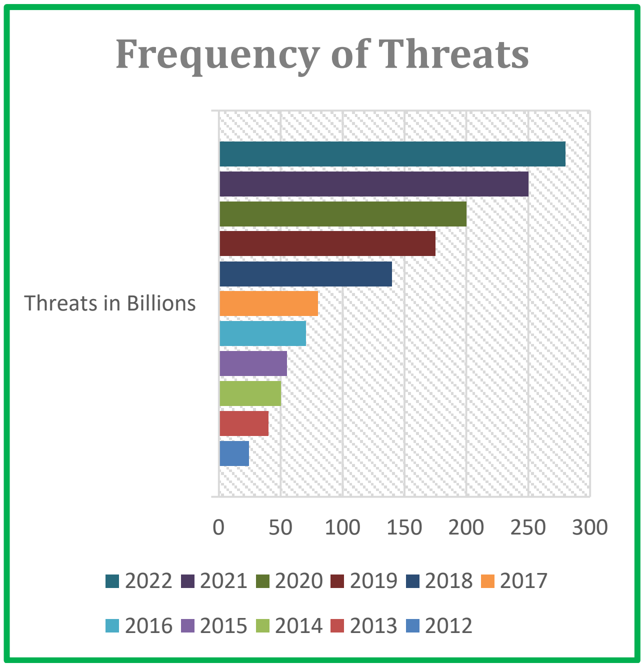

Fig. 1. Frequency threats in real-time.

A unique approach is envisioned with a dual-powered CLM (Convolution neural networks and LSTM) and optimization technique. The amalgamation of deep learning and evolutionary computation provides the technique with the adaptive competencies vital to safeguard OSNs. The suggested method is evaluated on a user activity dataset in OSN, and the outcomes are illustrious from those of conventional machine learning techniques [4].

The motivation for the proposed CLM and Optimization method distinguishes hazardous users to improve security and defend against cyberattacks. Exploiting system vulnerabilities, attainment unauthorized access, stealing sensitive data, and interrupting system operations can detriment people and companies. Firewalls and antivirus software don't always stop complex attacks, thus modern methods are obligatory to detect and preclude them [13].

A. *Organisation of the Paper*

The paper encompasses the subsequent subheadings: Section II - Literature Review, Section III – Proposed Methodology, Section IV - Experimental Evaluations and Results, Section V - Conclusion and References.

II. Literature Review

Deep learning neural networks of the variation known as CNNs are frequently engaged in processing images and videos. They have been revealed to be incredibly efficacious in resolving stimulating computer vision issues comprising segmentation, object identification, and picture categorization. The vital principle of CNNs is to extract information from pictures using convolutional filters and then to categorise or determine objects using these characteristics [5]. CNNs have revolutionised the field of computer vision and made it possible for a variety of applications, from self-driving cars to medical imaging. CNN has significantly augmented its popularity in voice and picture recognition tests. It captures spatial and temporal tendencies in data since it is built on the notion of native connectedness and shared weights. When creating a CNN model, data inputs like images or data categorizations are deployed through numerous of layers of convolution, pooling, and activation functions. Ensuing this, fully linked layers that dispense the response into numerous classifications acquire the yield of these layers.

CNN has significantly amplified its popularity in voice and picture recognition tests. It captures spatial and temporal tendencies in data since it is built on the notion of native connectedness and shared weights. When creating a CNN model, data inputs like images or data sequences are deployed through numerous layers of convolution, pooling, and activation functions. Ensuing this, fully linked layers that distribute the response into several classifications acquire the yield of these layers [7].

The LSTM variance of the recurrent neural network (RNN) properly resolves the vanishing gradient problem that concerns regular RNNs. [6]. The vanishing gradient problem occurs when gradients get tinier as they propagate over time, making training the network on lengthy sequences challenging.

This problem will be resolved by LSTM, which has a particular form of memory cell that can store information for longer. Three gates govern the cell: the input gate, the forget gate, and the output gate. The forget gate standardizes the retention of preceding data, the input gate controls the flow of new information into the cell, and the output gate regulates the cell's output.

In an extensive assortment of applications, including speech recognition, machine translation, and NLP (natural language processing), LSTM has been illustrated to be effective. It has also been used for anomaly detection and time-series prediction jobs, where it may discover temporal relationships and long-term trends in data [8].

A heuristic optimization method based on natural selection and evolution is referred to as the Genetic Algorithm (GA). It is used to address optimization issues that require determining the optimal parameter combination for a given objective function. The GA generates a population of candidate solutions, known as chromosomes. Each chromosome is composed of a series of genes that represent various parameters of the issue being optimized. These parameters can include any form of data, including numerical values, Boolean values, and texts. Subsequently, the GA evaluates the fitness value of the respective chromosome in the population using the objective function. The fitness value assesses how successfully the chromosome resolves the issue. The GA then chooses the population's top chromosomes to serve as the parents of the following generation.

Employing genetic operators like crossover, mutation, and selection to the parents, the next generation gets generated. As opposed to mutation, which involves altering certain genes in a chromosome at random, crossover involves transferring genes between two chromosomes to produce new progeny. In selection, the population's finest chromosomes are chosen to serve as the parents of the following generation [27] [29].

Using the conceptions of natural selection and evolution, GA is a persuasive optimization technique that may unearth the preeminent responses to thought-provoking issues. It is comprehensively utilized through several disciplines, including computer science, engineering, and finance.

Malicious user detection prominence is evolving in the contemporary era because of security theft and data privacy. The information in this digital world has to be secure. The identification of malicious users is an important part of cybersecurity [9] [30]. User behaviour analysis (UBA) is a technology that employs machine learning and data analytics to detect abnormal conduct that might suggest a malevolent user. In this literature review, we will look at some current studies on detecting illegitimate users using UBA.

A machine learning-based approach to identifying illicit behaviour based on host process data was proposed by Han et al. [2]. The authors analysed user behaviours and identified abnormal behaviour using big data. The study is shown that UBA can be an effective method for detecting harmful activities. A user behaviour analysis system that utilises data analytics and machine learning to detect and differentiate that exists between malicious and genuine users was introduced by Ranjan and Kumar [6]. The authors analysed user behavioural data using multiple machine-learning methods to identify unusual behaviours. The study demonstrated that UBA can be an expedient method for detecting malicious users. Tanuja et al. [12] proposed a machine learning technique for identifying fraudulent social network users. The authors analysed user activity data using multiple machine-learning methods to identify abnormal conduct that may advocate a deceitful user. To identify various anomalous user behaviours and lessen their negative impacts, statistical analysis was done. To find unusual conduct that may point to a malevolent user, the authors performed statistical analysis [10]. Several patents pertaining to the detection of malicious users are accessible on Google Patents, including a framework for mobile advanced persistent threat detection, a deep learning method for detecting covert channels in the domain name system, and a technique for detecting insider and masquerade attacks by identifying malicious user behaviour [11] [12].

III. Proposed Methodology

A. System Model

System model for malicious user detection through user behavior for CLM and optimization technique. The Fig. 2 gives an overview of the system. The data collection and preprocessing module, the CLM and optimization technique, and the evaluation module encompass the classification model for malicious user detection through user behavior for CLM and optimization technique.

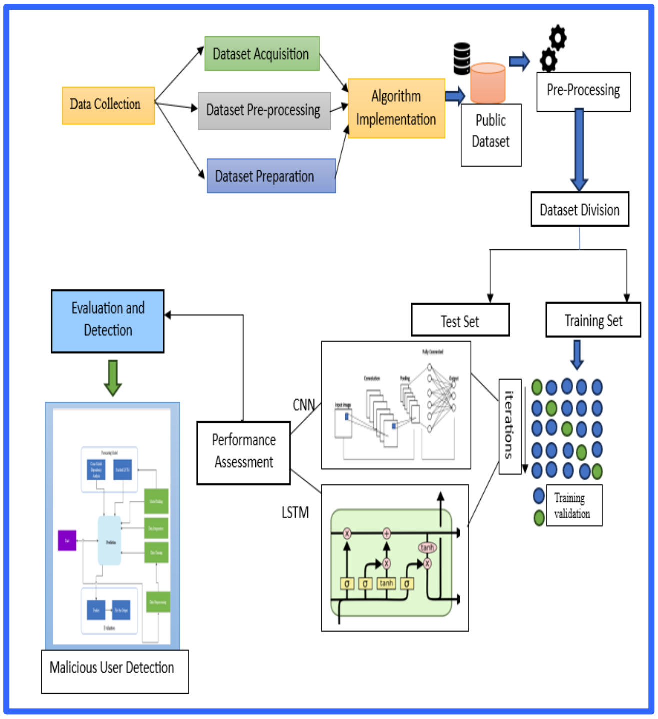

Fig. 2. Schematic diagram of proposed methodology.

The problem with devising malicious user detection employing CLM and optimization technique approach is to develop an artificial intelligence model that can precisely distinguish malicious users through user behavior information composed from a miscellaneous variety of sources. The model should be able to handle large datasets, noisy data, and a wide variety of malicious behavior types, including network attacks, system intrusions, and user impersonation. The objective is to develop a prototype that can be deployed in a real-world setting to detect and prevent malicious user behavior before it can cause damage to users or systems. The system aims to afford a reliable and precise methodology for identifying malevolent users by scrutinizing their behavioral patterns. The system attempts to capture both the spatial and temporal aspects of user behavior data by utilizing the capabilities of CNN and LSTM neural networks [17] [18]. In order to upsurge the model's performance and optimize its parameters, the Genetic Algorithm is also used.

A dataset of user behavior that comprises elements like login patterns, session length, transaction history, and other appropriate data is used as the system's input. The data is pre-processed by the method in order to normalize and encrypt it for neural networks. The CNN module of the classification pulls spatial characteristics from the input data, while the LSTM component captures the temporal relationships [26]. The CNN and LSTM model is then trained expanding the training dataset [19] [20]. The Genetic Algorithm is used to optimize the model, which scrutinizes various amalgamations of hyper parameters to classify the optimal collection of parameters that maximizes the detection accuracy [23].

1) Data collection: The data collection and preparation module is responsible for gathering user behavior data and converting it into a format that can be used by the AIMDS model. This module collects data from many sources, such as network traffic logs, user input logs, and system logs, and then pre-processes the data to eliminate noise, missing values, and other abnormalities [16].

a) Dataset acquisition: A large-scale dataset comprehending user behaviour information is attained from a reliable internet platform. The dataset encompasses a diversity of features such as user activities, timestamps, and session information.

b) Data Pre-processing: Pre-processing the dataset to eradicate excessive or redundant characteristics, manage missing values, and normalize the data [14]. Pre-processing processes may include feature selection, data purification, and categorical variable encoding.

c) Data preparation: The pre-processed data is consequently prepared for model training. The data has been fragmented into training, validation, and testing sets to accomplish this. The training set is utilized to train the prototypical, the validation set usage to fine-tune the hyper parameters, and the testing set is used to assess the aftermath of the model.

Preprocessing the input data entails filtering and normalizing the user behavior data to filter the noise and insignificant data as the first stage. The feature extraction layer utilizes the input data to extract useful characteristics that may be utilized for further exploration once the preprocessed data has been passed through it [21]. The Algorithm 1 provides the overview of the data preprocessing after the assemblage of the dataset has to endure a sequence of steps to further process.

Algorithm 1 : Data Preprocessing

```
Initialize
BEGIN
Step 1: Load the Dataset
Step 2: Handle the missing values
Replacing with Mean or Median values
Step 3: Normalize the features
Step 4: Splitting the dataset
Divide the Dataset
1.Training Dataset
2. Testing Dataset
Step 5: Feature Selection and Feature Extraction
Step 6: Handling the time series data
Step 7: Data augmentation
Step 8: Finalize the pre-processed dataset
End
```

2) Algorithm implementation: The CLM and optimization technique model is in possession of assessing the pre-processed user behavior data and determining whether or not a certain user is acting maliciously. This model is made up of two key parts: the CNN and LSTM layers, which extract features from user behavior data, and the genetic algorithm, which optimizes the CLM technique (Convolution neural networks and LSTM) model's parameters to enhance its accuracy [24][25].

Detecting malicious user behavior using the dual-powered CLM technique and an optimization technique approach involves several algorithms formulas and techniques.

a) Architecture: The CLM and optimization model architecture is intended based on the three algorithms. The CNN layer accumulates spatial characteristics from data, the LSTM layer captures the temporal dynamics of user behaviour [15], and the GA layer optimizes the model's hyper parameters.

b) Training: The CLM and optimization model is trained using the prepared data. The model is trained on the training set, then it is validated on the validation set. During the training phase, the loss function is minimized using optimization techniques such as stochastic gradient descent or Adam optimization.

c) Hyperparameter tuning: The hyper parameters of the model are optimized using the GA. The GA is used to explore the hyper parameter space for the optimum hyper parameter amalgamation that maximizes the model's performance. The GA's fitness function is based on evaluation measures such as Acc, Prec, Rc, and $f1_s$.

d) CLM Algorithm: The Algorithm 2 gives the details of initialization of the convolution layer parameters and applying activation function. The scientific formulation for the CNN component involves convolutions and pooling operations. Let's symbolize the input data as X, the convolutional layer output as C, and the pooling layer output as P. The Eq. (1) and Eq. (2) gives the desired outcome.

$$C = relu(conv(X)) \tag{1}$$

$$P = \max\_pool(C) \tag{2}$$

Algorithm 2: CLM

```
BEGIN
Initialize CNN parameters
f = filtersize
n=numoffilters
d= dropoutrate
fz= filtersizes
Define CNN
Inputlayer=input (shape= (input_shape))
Convlayers= []
For f in fz:
Convlayer= Conv1D (filters=n, kernelsize=activation='relu') (input_layer)
Poollayer    =MaxPooling1D(poolsize=x) (convlayer)
Convlayers.append (poollayer)
mergedlayer = Concatenate (axis=1) (convlayers)
flattenlayer   = Flatten () (mergedlayer)
dropoutlayer = Dropout (dropoutrate)(flatten_layer)
outputlayer=
Dense(numclasses,activation='softmax') (dropoutlayer)

Compile and train the model
END
```

e) Optimization algorithm: The Algorithm 3 describes the Genetic algorithm of initialization of population size, evaluation of fitness, probabilistic selection to evaluate the best solution. The fitness function in the genetic algorithm analyses the quality of each potential solution (chromosome). The fitness value is determined by the problem's purpose and can be a combination of metrics such as accuracy, precision, recall, or F1-score. The fitness function directs the genetic algorithm's selection, crossover, and mutation processes.

Algorithm 3: Genetic Algorithm

```
BEGIN
GA(Ft,Ft_th,s,f,m)
Ft: Fitness function assigns evaluation score
Ft_th: Fitness threshold
s: hypotheses to be included
F: fraction of population to be replaced
m: mutation error
Step 1: Initialization
Define population size
                $P \leftarrow$ Generate P hypothesis
Step 2: Evaluation
Compute fitness
Calculate fitness score
Step 3: Selection
The probability $Pr(s_i)$ is
                $Pr(s_i) = \frac{Fitness(s_i)}{\sum_{j=1}^{p} Fitness(s_i)}$
Step 4: Crossover
Select pair of hypothesis from P
For each pair produce offspring by applying crossover
Step 5: Mutation
Choose members with uniform probability
Step 6: Update
                $P \leftarrow P_s$
Step 7: Evaluate
Retrieve the best solution
END
```

3) Evaluation and detection: The evaluation module is in charge of establishing the CLM and optimization technique model is accurate and successful at detecting harmful user behavior. This module often consists of testing the model's performance on a test set of data and comparing its accuracy, precision, recall, and F1 score to other cutting-edge machine learning models like SVM and Random Forest.

a) Evaluation: The CLM and optimization technique efficacy is assessed using the testing set. Some of the assessment metrics used include Acc, Prec, Rc, and $f1_{s.}$ The results are compared to other cutting-edge methodologies to assess the efficacy of the suggested methodology.

b) Malicious user detection: Based on their conduct, the trained proposed model CLM and optimization technique are applied to detect malicious users. The model accepts data on user behaviour as input and produces the probability of the individual being malevolent. Based on the output prospect, a threshold is defined to identify people as malicious or non-malicious. The methodology's architecture is depicted in Fig. 3.

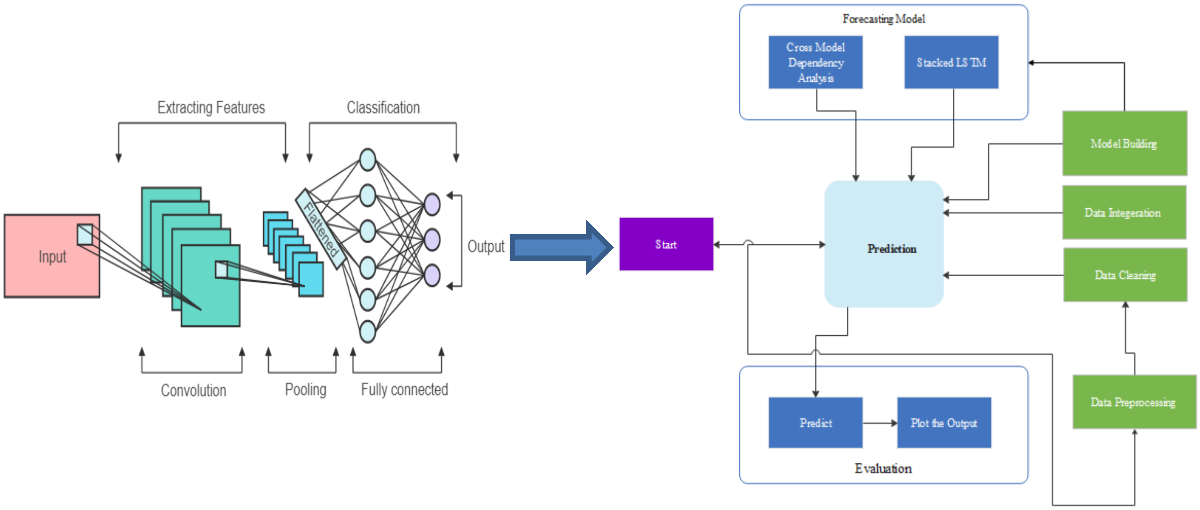

Fig. 3. Architecture to detect malicious user.

IV. Experimental Evaluations and Results

A. Dataset Description

The TwiBot-20 dataset, specifically designed for social media bots, serves as a substantial and all-encompassing standard for detecting Twitter bots. The purpose is to stimulate the difficulties posed by a small dataset size and accurately reflect both actual people and Twitter bots found in the real world. The collection comprises 229,573 people, 33,488,192 tweets, 8,723,736 user property pieces, and 455,958 follow relationships. It comprises a comprehensive range of automated accounts and authentic users to more accurately depict the Twitter community as it exists in reality. The dataset contains three different types of user information, which may be used for both classifying individual users into two categories and developing community-aware methods. The three modalities are semantic information, property information, and neighborhood information. The TwiBot-20 dataset is accessible for academic research objectives and is hosted by the Bot Repository [22]. This benchmark is one of the most extensive collections of Twitter bot detection data available. It obliges as an accommodating tool for training and assessing the proposed model that aim to identify harmful users in online social networks, specifically in the context of Twitter bot identification.

Considering the objective of achieving optimal performance in identifying harmful user activity, it is vital to conduct experiments and prudently tune the settings. The properties of the dataset, the kind of malicious activity, and the computational resources that are available for training and optimization all have a role in the selection of parameters. When trying to fine-tune these parameters in an efficient manner, it is frequently prerequisite to do iterative refinement based on performance data and domain expertise.

B. Experimental Results

Numerous indicators may be used to measure the success of a system built to identify harmful user behaviour using CLM and optimization techniques [28] [31]. Considering the frequently used assessment metrics.

C. Accuracy

Accuracy assesses the overall efficacy of the model's predictions. It computes the proportion of correctly identified cases (both harmful and non-malicious) in the dataset to the total number of occurrences. A higher level of accuracy suggests superior performance. Eq. (3) can be used to evaluate the accuracy. The Fig. 4 associates the present model with the previous model.

$$\text{Acc} = \frac{\text{TP+TN}}{(\text{TP+TN+FP+FN})} \tag{3}$$

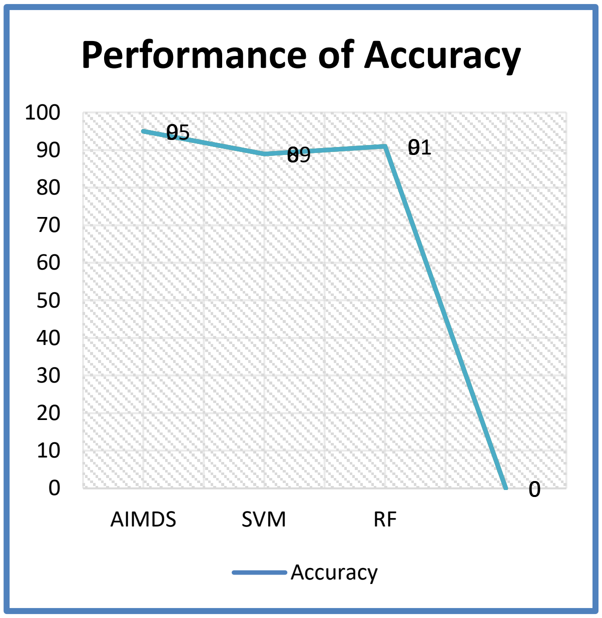

Fig. 4. Accuracy comparison.

D. Precision

Precision is the measurement of successfully recognized harmful users among all occurrences projected to be malicious [22]. It is determined as the ratio of TP (malicious users accurately predicted) to the total of TP and FP (malicious users wrongly categorized as non-malicious). A higher precision suggests that there are fewer false positives. Eq. (4) is used to evaluate the precision. Fig. 4 compares the present model with previous models.

$$\text{Prec} = \frac{\text{TP}}{\text{TP+FP}} \tag{4}$$

E. Recall

The fraction of real malicious users properly recognized by the model is measured by Rc, also labelled as sensitivity or true positive rate. It is determined as the proportion of true positives to the total of TP and FN (malicious users categorized mistakenly as non-malicious). A better recall means that there are fewer false negatives. Eq. (5) is used to evaluate the recall. Fig. 5 compares the present model with previous models.

$$\text{Rc} = \frac{\text{TP}}{\text{TP+FN}} \tag{5}$$

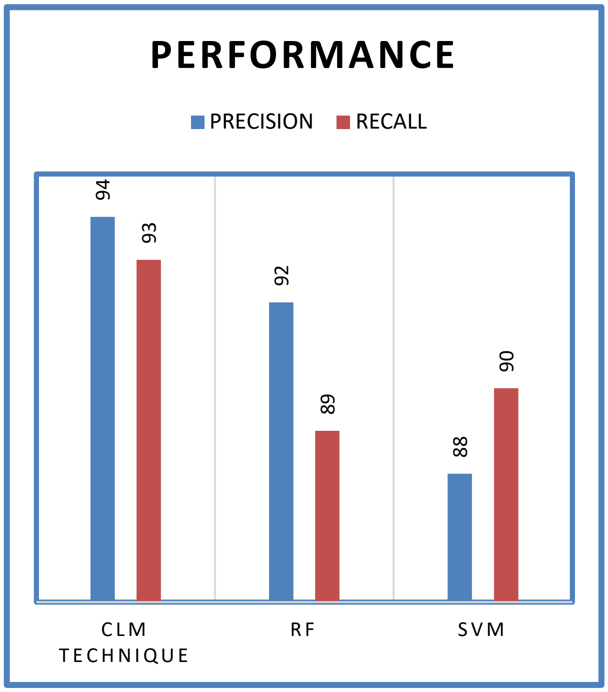

Fig. 5. Comparison of precision and recall.

F. F1 Score

The $f1_s$ combine accuracy and recall into a single statistic that balances their respective trade-offs. It provides an ample evaluation of the model's performance and is the harmonic mean of accuracy and recall. An increased F1-score suggests a better balance of accuracy and recall. The Eq. (6) evaluates the F1 score.

$$f1_s = \frac{2\times(\text{Prec}\times\text{Rc})}{(\text{Prec+Rc})} \tag{6}$$

Summarizing the values, the following Table I and Fig. 6 provide the overall performance of the CLM and optimization technique with the traditional algorithms. The experimental study of CLM and optimization technique used an amalgam of CNN, LSTM, and genetic algorithms (GA) to assess user behaviour in order to ascertain malevolent users. On the user behaviour dataset, which encompasses of user behaviour data gathered from a web platform, the performance of the suggested strategy was assessed. The outcomes show how well CLM technique (Convolution neural networks and LSTM) and optimization technique appropriately classify malicious users based on their behaviour patterns.

On the, which encompasses of TwiBot-20 dataset gathered from an online platform, the performance of the suggested strategy was assessed. The outcomes show how well CLM technique (Convolution neural networks and LSTM) and optimization technique perform in correctly classifying malicious users based on their behaviour patterns. Fig. 7 gives the portrayal of a comparison of evaluation metrics.

The proposed methodology consistently outperforms existing methodologies and traditional models, as demonstrated by the assessment measures. The genetic algorithm's ability to adapt is a crucial factor in accomplishing enhanced performance through hyper parameter optimization and feature selection. Conventional models may face difficulties in twigging the ever-changing and dynamic aspects of user behavior, while the proposed model excels in identifying intricate patterns.

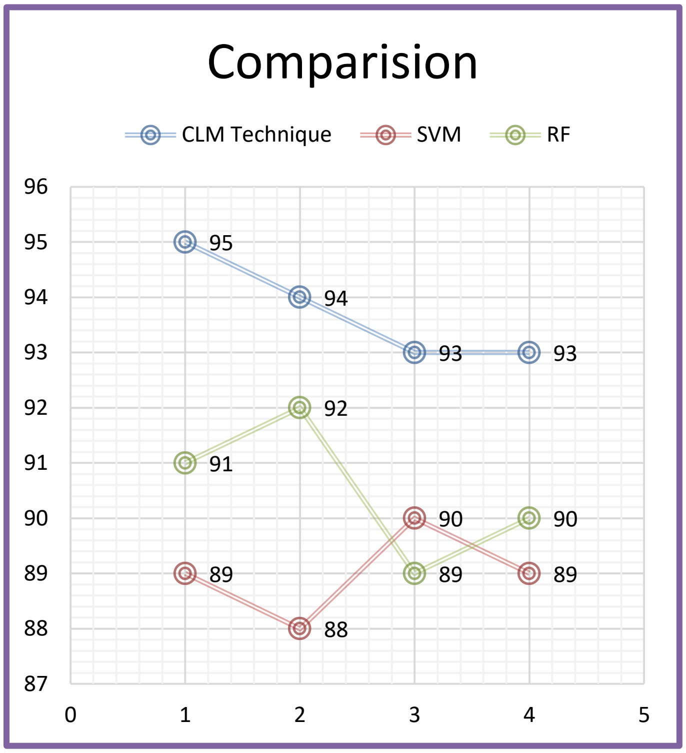

Fig. 6. Performance of proposed approach.

TABLE I. PERFORMANCE EVALUATION

Metric	Techniques		
	Proposed Technique	*SVM*	*RF*
Accuracy	95	89	91
Precision	94	88	92
Recall	93	90	89
F1 Score	93	89	90

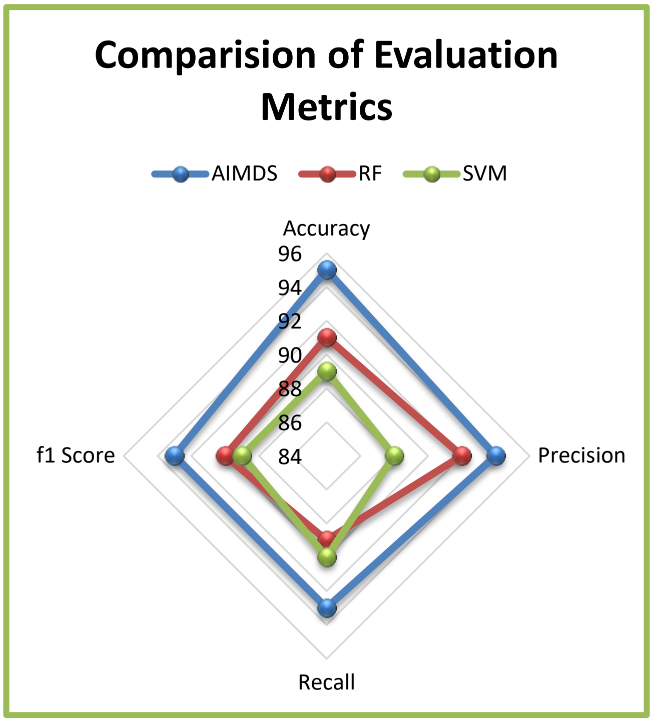

Fig. 7. Comparison of evaluation of metrics.

The proposed model that is anticipated has extraordinary performance; nonetheless, it is not immune to constraints. The efficacy of the model may differ contingent on the distinguishing features of various social platforms as well as the characteristics of malicious activities. Furthermore, the prospective for further research lies in exploring the interpretability of the model, explicitly addressing issues regarding the opaque nature of deep learning models.

V. Conclusion

The paper proposed a novel architecture a CLM technique (Convolution neural networks and LSTM) and an optimization technique to detect harmful user behavior using user behavior analysis in this study. In reliably detecting fraudulent users, an amalgam of CNN, LSTM networks, and genetic algorithms (GA) produced promising results. The model efficiently caught spatial patterns in the TwiBot-20 dataset by utilizing CNN. To capture temporal interdependence and sequential patterns in user behavior sequences, LSTM networks were used. The incorporation of genetic algorithms assisted in the optimization of model parameters and the improvement of model performance. On the TwiBot-20 dataset, the CLM and optimization technique surrogate conventional machine learning algorithms including SVM and Random Forest in terms of Acc, Prec, Rc, and $F1_s$.This demonstrates the utility of deep learning and genetic algorithms for identifying harmful user behavior. Overall, the technique proposed in this study provides a strong foundation for identifying fraudulent user behavior using deep learning methods. It paves the door for future research in deep learning, genetic algorithms, and user behavior analysis, paving the way for more advanced and accurate detection systems. Data on user behavior may not be sufficient to provide an ample portrait of harmful activity. The detection system's accuracy may be enhanced by additional data sources such as network traffic statistics, device information, and contextual data. To escalate the detection capacity, the future scope might investigate the integration of numerous data modalities. The prospect of detecting detrimental user behavior in online social networks is vast and promising. Ongoing exploration in these domains will not only enhance contemporary models but also aid in the conception of online security systems that are more ethical, transparent, and user-friendly. The initiative aims to tackle the complex issues presented by malicious user behavior in the digital domain by utilizing a multidisciplinary approach that encompasses computer science, social sciences, and ethics.

Abstract—**Parkinson's disease is an increasingly prevalent, degenerative neurological condition predominantly afflicting individuals aged 50 and older. As global life expectancy continues to rise, the imperative for a deeper comprehension of factors influencing the course and intensity of PD becomes more pronounced. This investigation delves into these facets, scrutinizing various parameters including patient medical history, dietary practices, and vitamin D levels. A dataset comprising 50 PD patients and 50 healthy controls, sourced from Dhaka Medical Institute, serves as the foundation for this study. Machine learning techniques, notably the Modified Random Forest Classifier (MRFC), are harnessed to prognosticate both PD severity and duration. Strikingly, the MRFC-based prediction model for PD severity attains an impressive accuracy of 97.14%, while the predictive model for PD duration demonstrates an accuracy of 95.16%. Noteworthy is the observation that vitamin D levels are notably higher in the healthy cohort compared to PD-afflicted individuals, exerting a substantial positive influence on both the severity and duration predictions, surpassing the influence of other measured parameters. This inquiry underscores the practicality of machine learning in forecasting PD progression and duration and underscores the pivotal role of vitamin D levels as a predictive factor. These discoveries provide invaluable insights into advancing our comprehension and management of PD in an aging population.**

Keywords—Parkinson's disease; machine learning; vitamin D; severity; disease duration

I. Introduction

Parkinson's disease is a progressive neurological condition characterized by mobility restriction, primarily affecting the central nervous system. This is a consequence of the depletion of substantia nigra cells, which are responsible for producing dopamine, a critical factor in regulating movement [1]. This ailment manifests through motor and non-motor symptoms, often beginning subtly with hand tremors and gradually eroding motor control, affecting over 10 million individuals worldwide, particularly those aged 60 and above [2]. Understanding the early signs of Parkinson's disease (PD) is vital for effective intervention, but misconceptions and inadequate awareness persist, hindering timely diagnosis [3]. PD's impact on neural networks governing bodily movements is profound, involving critical brain regions such as the basal ganglia and the substantia nigra [4]. Typical PD symptoms encompass tremors, stiffness, slow movement, balance issues, and gait problems, alongside non-motor symptoms like depression, constipation, and sleep disturbances [5]. Recognizing these symptoms can be challenging due to their variability, emphasizing the importance of consulting neurophysicians, especially for older individuals [6].

Moreover, Parkinson's disease is on the rise in Bangladesh, largely due to increased life expectancy and a growing population. As vitamin D deficiency emerges as a potential risk factor for the condition, researchers are delving into the interplay among patient lifestyles, vitamin D levels, and the application of machine learning techniques to detect Parkinson's disease. Notably, there exists an inverse relationship between the severity of Parkinson's disease, its symptoms, and cognitive function with serum 25(OH)D levels. Generally, individuals with Parkinson's disease tend to exhibit lower vitamin D levels compared to their healthy counterparts [7, 8]. Additionally, studies have pointed to a significant occurrence of vitamin D deficiency among middle-aged women in Bangladesh [9]. Diverse machine learning methods, including Artificial Neural Networks (ANN), Decision Trees, and Support Vector Machines (SVM), have been employed to predict Parkinson's disease based on a variety of features [10]. Nevertheless, there remains an ongoing debate surrounding the link between vitamin D and Parkinson's disease, primarily due to disparities in the studied populations and methodological constraints [11][12].

Therefore, utilizing a custom model, this current study aims to shed light on the connection between PD severity and duration with vitamin D levels. It builds upon existing research to explore the potential of machine learning in predicting PD, offering a promising avenue for timely intervention. Key contributions of this paper are mentioned below:

1) *Utilized* supervised machine learning approaches to anticipate Parkinson's disease (PD) using a dataset comprising 50 PD patients and 50 healthy individuals from Bangladesh.

2) *Collected* demographic data and clinical features of PD participants, including age, education, disease duration, cardinal features of the disease, and disease severity, to build a comprehensive dataset.

3) The vitamin D levels of participants were evaluated, and vitamin D deficiency was classified as values below 30ng/mL.

4) Investigated correlations among various PD features, including positive and negative correlations.

5) Employed several machine learning algorithms to predict PD based on the dataset, including Random Forest, Decision Tree, Naive Bayes, Logistic Regression, Nearest Neighbor (KNN), and a Modified Random Forest Classifier (MRFC).

6) Customize MRFC model with specific settings, including the number of trees, maximum depth, maximum number of features, verbosity, mode, warm start, and thread usage, to optimize its performance.

7) Introduced performance evaluation metrics such as sensitivity (Sn) and specificity (Sp) into the confusion matrix to assess the classification results.

Therefore, the rest of the paper is designed as follows: Section II is literature review, Section III is about materials and methods, Section IV delves into results and discussion, Section V is Discussion, and in Section VI conclusion is presented.

II. Literature Review

Various researchers do research in the field of Parkinson's disease detection. Quan et al. (2021) focus on exploiting dynamic speech features to identify voice alterations in patients with Parkinson's disease (PD). Using a Bidirectional LSTM model instead of the static features seen in conventional machine learning models, it greatly increases the accuracy of PD identification. The study makes use of a mixed-gender database from GYENNO SCIENCE Parkinson that has 45 patients (15 Healthy Controls, 30 PD cases). However, information regarding feature engineering and data preprocessing is missing. According to the experimental results, the suggested Bidirectional LSTM model has an accuracy of 75.56% [13]. Shinde et al. (2019) improved the diagnosis of Parkinson's disease (PD) by using convolutional neural networks (CNNs) with neuromelanin-sensitive magnetic resonance imaging (NMS-MRI), a computer-based method. This strategy achieves better results than current approaches: 80% of tests correctly identify PD from healthy controls, and 85.7% correctly identify PD from atypical Parkinsonian disorders. It detects minute alterations in the substantia nigra pars compacta (SNc) by using CNNs for feature extraction and data augmentation. Sensitivity, specificity, and ROC curves are some of the evaluation criteria that demonstrate its excellent performance in the diagnosis and categorization of Parkinson's disease [14]. Noor et al. (2020) investigated the use of deep learning to identify neurological conditions using several MRI modalities, with a focus on schizophrenia, Parkinson's disease, and Alzheimer's disease. Convolutional Neural Networks (CNNs) are emphasized as being better at detecting these illnesses in its overview of current deep learning techniques. Datasets including MIRIAD, Open fMRI, PPMI, ADNI, COBRE, fastMRI, and FBIRN are used in the work along with discussion of problems and recommendations for future research areas. There is no specific discussion of feature extraction techniques or data preprocessing. The emphasis is on deep learning techniques, with CNNs being identified as the most effective way [15].

III. Materials and Methods

Numerous researchers in various disciplines have recently adopted machine learning-based approaches to get better accuracy from the analysis of complicated data [13]. The main objective of this study was to anticipate PD through various characteristics data which is complicated. Thus, supervised machine learning approaches were used to achieve the objectives of this study.

A. Dataset Description

To conduct this research, we collected a dataset of 50 PD patients and 50 healthy people from Sir Salimullah Medical College, where all subjects were Bangladeshi. Demographic Data and Clinical Features of PD participants are presented in Table I. The clinical states of the recruited subjects were evaluated using the Movement Disorder Society-Unified Parkinson's Disease Rating Scale [16], and the severity of Parkinson's disease was determined according to the study's criteria [17]. In the laboratory of Sir Salimullah Medical College, serum 25-hydroxyvitamin D levels were determined in both the PD and healthy groups using CLIA kits using the radioimmunoassay technique. In the present investigation, blood vitamin D levels of 30ng/mL were judged normal, whereas values below 30ng/mL were deemed insufficient. These include age, sex, education, occupation, socioeconomic status, nature of work, cardinal features, disease duration, disease severity, smoking history, caffeine history, and vitamin D level. Additionally, the age comparison between PD and healthy participants is presented in Fig. 1, where PD participants are younger than healthy participants.

TABLE I. The Demographic Data and Clinical Features of PD Participants

Variables		Case	
		N	Percentage
Age	<60	1	2
	≥ 60	49	98
Education	Diploma	31	62
	Illiterate	11	22
	Under Diploma	8	16
Disease Duration	less than 5 years	26	52
	5 to 10 years	17	34
	Greater than 10	7	14
Cardinal Features of Disease	tremor	30	60
	rigidity	5	10
	bradykinesia	12	24
	postural instability	3	6
Disease Severity	1-2.5	26	52
	2.5-3	18	36
	>3	6	12

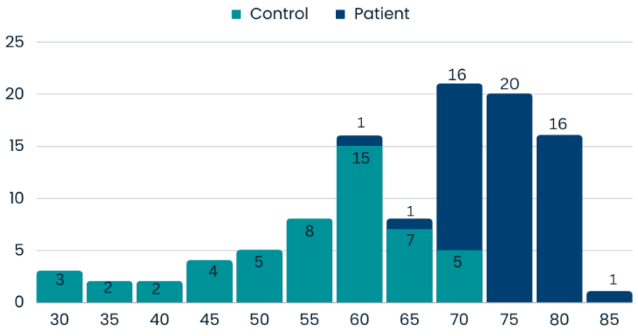

Fig. 1. Age comparison between PD and healthy participants.

Moreover, various features are causes of PD. The correlations among the features of PD are shown in Fig. 2. There are two types of correlations among the features - positive & negative. A positive correlation indicates that if the characteristic improves, the linked feature likewise increases, and if the feature falls, the connected feature reduces as well. Both aspects move in simultaneously, and their connection is linear. A negative correlation indicates that if one property's value rises, the linked trait's value falls, and vice versa.

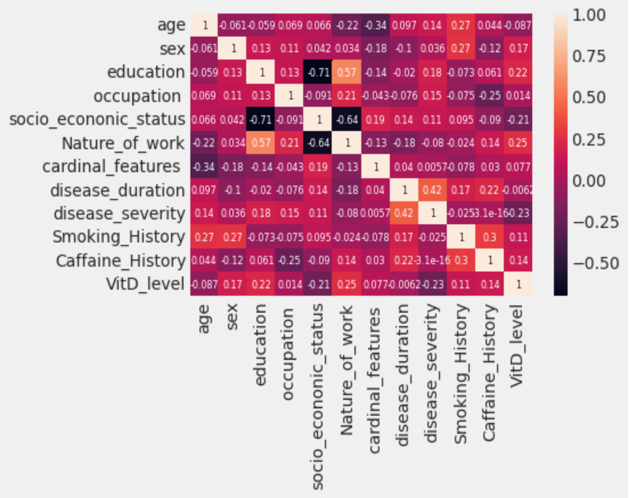

Fig. 2. Correlations among the features.

B. Model Description

1) Random forest classifier: A well-known supervised machine learning algorithm is the Random Forest. It finds application in both classification and regression challenges within machine learning. The Random Forest serves as a classifier that enhances the predictive accuracy of a dataset by averaging the outcomes of multiple decision trees generated on different subsets of the dataset. When applied to address regression problems, the Random Forest Algorithm utilizes the mean squared error (MSE) from each node's data branch [17]. However, the formula is mentioned below in the equation number i.

$$\mathrm{MSE} = \frac{1}{\mathrm{N}} \sum_{\mathrm{i}=1}^{\mathrm{N}} \quad (\mathrm{fi} - \mathrm{yi})^2 \qquad (1)$$

In this context, N denotes the number of data points, fi signifies the model's output, and yi signifies the actual value for the specific data point i. The formula is employed to calculate the distance from the forecasted value to each node, and this outcome is pivotal in establishing the most suitable path through the forest.

2) Decision tree: The decision tree is a method for supervised learning that can effectively address classification and regression problems, primarily in solving classification tasks [18]. The terminology implies its utilization of a tree-like diagram to present predictions derived from a sequence of feature-driven divisions. It commences with a central node and culminates in a determination made at the terminal leaf. Therefore, in Fig. 3, a decision tree is mentioned [19].

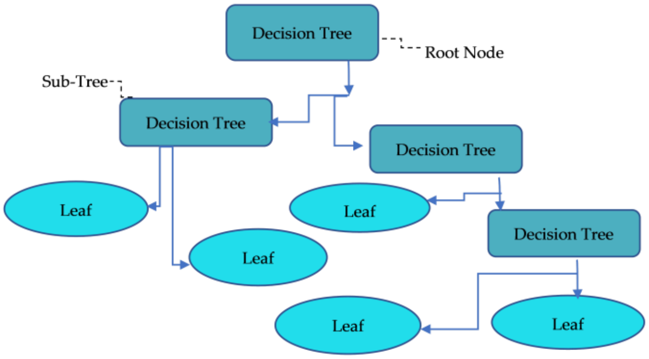

Fig. 3. Decision tree.

The decision trees utilize a representation known as the Sum of Products (SOP). The term Disjunctive Normal Form (DNF) is an alternative designation for the Sum of Products (SOP). In this context, each branch culminating in a node of the same category represents a conjunction (product) of values for that category. Conversely, separate branches ending in the same category constitute a disjunction (sum).

3) Naive bayes: The Naive Bayes algorithm is an algorithm for supervised learning. The Naive Bayes classifier is based on the conditional probability principle. It is straightforward and quick to predict the category of the test data set. It is also effective for multiclass prediction [17]. When the independence assumption holds true, the Naive Bayes classifier outperforms other models. The equation of Naïve Bayes is mentioned below in equation number ii.

$$\mathrm{P(A \mid B)} = \frac{\mathrm{P(B \mid A).P(A)}}{\mathrm{P(B)}} \qquad (2)$$

The posterior probability P (c|x) can be computed using the prior probabilities P(c), P(x), and P(x|c), thanks to Bayes' theorem [19]. Naive Bayes classifiers assume that the impact of one predictor value (x) on a specific class (c) is independent of the impact of other predictor value combinations. Here, conditional independence on class labels is granted.

4) Logistic regression: Logistic regression is an example of supervised learning. It is used to solve classification problems, with the most common application being binary logistic regression with a binary outcome. Number iii equations underlying logistic regression:

$$y = \frac{e^{(b0+b1\times x)}}{1+e^{(b0+b1\times x)}} \qquad (3)$$

where, y represents the predicted output, b0 represents the bias or intercept term, and b1 represents the single input value (x) coefficient. Each input data column contains a b coefficient (a constant real value) that must be learned from your training data [18].

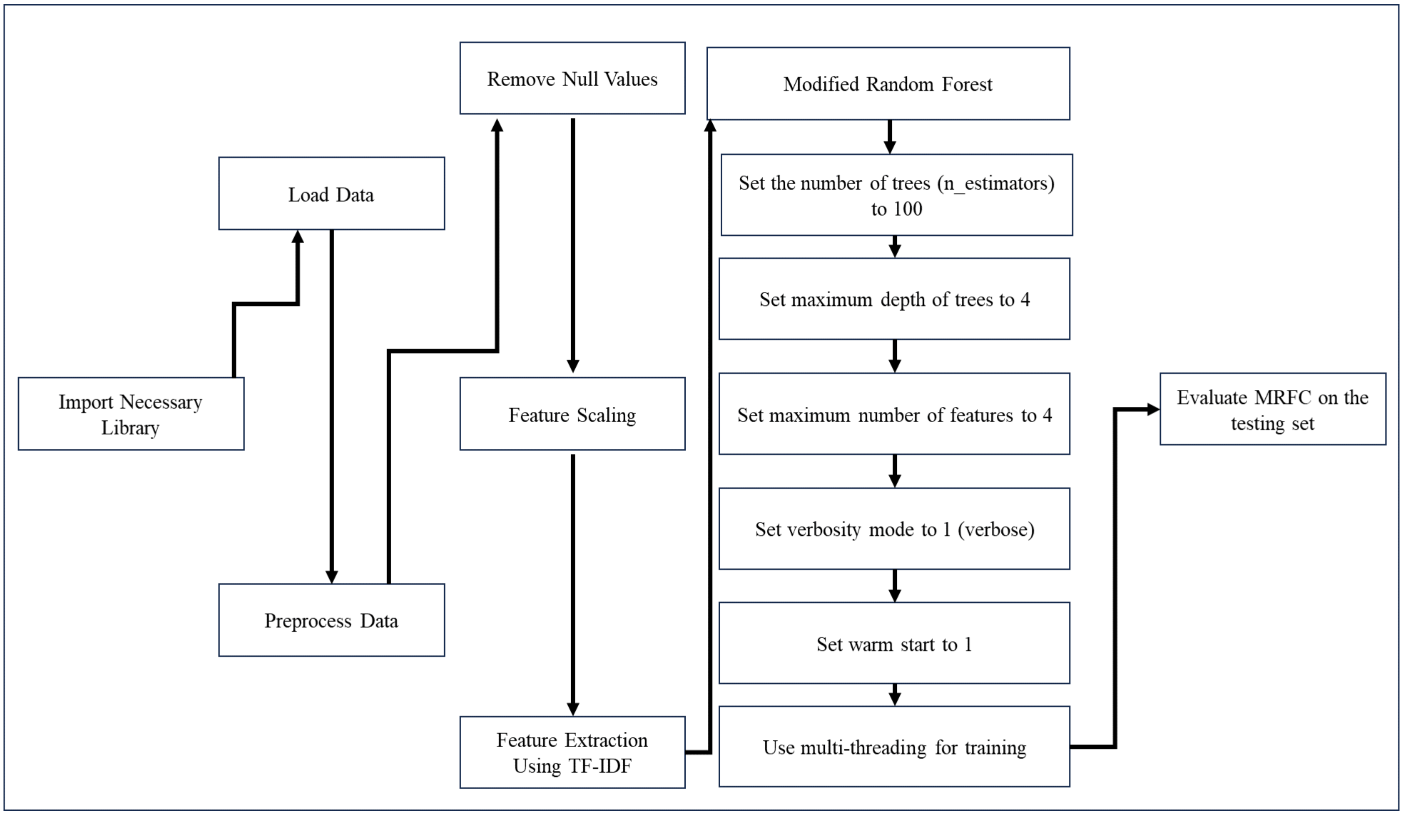
5) K-Nearest Neighbor (KNN): K-Nearest Neighbors (KNN) is a relatively straightforward supervised machine learning technique. In this method, new data or instances are categorized based on their similarity to the existing ones. KNN follows a "lazy learning" approach, setting it apart from the previously discussed classifiers. It doesn't actively progress during training and primarily involves storing the training data. Its classification efforts only come into play when fresh, unlabeled data emerges [19].

KNN demonstrates the optimal performance when the nearest neighbors to a data point all belong to the same category. The underlying assumption is that if all nearby neighbors concur, a new data point will likely fall within the same group. Two compelling reasons for employing KNN are its simplicity in terms of comprehension and application. However, KNN's accuracy hinges on the chosen distance metric, and under certain distance metrics, it can achieve 100 percent accuracy [18].

Nevertheless, the computational cost of finding the closest neighbors of KNN on vast datasets can be quite significant. Furthermore, noisy data can potentially disrupt KNN classification. Features with a wider range of values may dominate the distance metric, necessitating the normalization or scaling of features. Notably, due to its "lazy learning" approach, KNN often demands more substantial storage resources than eager classifiers. Thus, the effectiveness of KNN is closely tied to selecting an appropriate distance metric [17] [20].

6) Modified Random Forest Classifier (MRFC): This research utilized a modified Random Forest classifier (MRFC) as the proposed model (see Fig. 4). We choose MRFC for these reasons-

- The MRFC model with specific settings, including the number of trees, maximum depth, maximum number of features, verbosity, mode, warm start, and thread usage, to optimize its performance.
- Customizations are designed to fine-tune the Random Forest algorithm for the specific task of predicting Parkinson's disease severity and duration, aiming to achieve better accuracy and performance on this given dataset.



Remove Null Values
Modified Random Forest
Load Data
Set the number of trees (n_estimators) to 100
Set maximum depth of trees to 4
Import Necessary Library
Feature Scaling
Set maximum number of features to 4
Evaluate MRFC on the testing set
Set verbosity mode to 1 (verbose)
Preprocess Data
Set warm start to 1
Feature Extraction Using TF-IDF
Use multi-threading for training

Fig. 4. Modified random forest classifier.

- Parameter values such as a tree count of 100, a maximum depth of 4, and a maximum number of features of 4 were utilized to adjust the random forest classifier and attain the best precision level.
- The MRFC was instrumental in achieving the best accuracy on the dataset.

Therefore, MRFC is chosen for achieving the best accuracy than the existing models. However, MRFC was instrumental in achieving the best accuracy on this dataset. Thirty percent of the data were allocated for testing, with the remaining 70% for training. The random forest classifier was adjusted to attain the best precision level. Various parameter values were utilized, such as a tree count of 100 (n estimators = 100), a maximum depth of 4, and a maximum number of features of 4. The parameter "verbose" was set to 1, representing a moderate level of verbosity, and "warm start" was also set to 1.

The training process for the model utilized multiple threads to enhance efficiency. The use of multi-threading varies among different learning algorithms, and if not specified, the number of threads will be set to the number of cores in the system, with a maximum of 32. Setting the number of threads significantly higher than the number of processors can considerably slow down the training time. Future work may consider altering the default values to further enhance the model's performance. The improved model provides more accurate estimates of the severity and duration of PD.Accurate estimates of the severity and duration of PD.

In Fig. 4, the Modified Random Forest Classifier (MRFC) is customized or modified in several key aspects compared to the standard Random Forest classifier:

a) Number of Trees (n_estimators): MRFC uses a specific value for the number of trees in the forest. In the description, it mentions a tree count of 100 (n_estimators=100). This is a customization because the number of trees in a Random Forest can vary, and choosing the appropriate number can impact the model performance.

b) Maximum Depth and Maximum Number of Features: MRFC specifies the maximum depth of the trees and the maximum number of features considered at each split. In the description, it mentions a maximum depth of 4 and a maximum number of features of 4. These values determine the complexity of individual trees in the forest.

c) Verbosity Mode (Verbose): MRFC introduces a verbosity model to control the level of detail in the model's output. It mentions setting the verbosity level to 1 for small details. This customization helps in better understanding the model's behavior and performance.

d) Warm Start: MRFC mentions using a warm start level of 1. Warm start is a technique where the previously trained forest is used as an initialization for the next forest. This can speed up training and potentially improve convergence.

e) Thread Usage (num_threads): MRFC controls the number of threads used during training. It mentions that multi-threading is used and that the number of threads (num_threads) is set based on the available system resources. This customization optimizes the training process for efficiency.

These customizations are designed to fine-tune the Random Forest algorithm for predicting Parkinson's disease severity and duration, aiming to achieve better accuracy and performance on the given dataset. Customization of Random Forest parameters is a common practice in machine learning to adapt the model to the characteristics of the data and the problem at hand.

7) Performance evaluation matrix: One common tool for assessing a solution to a classification problem is the confusion matrix. The method is flexible enough to be used for both binary and multiclass classification problems. Confusion matrices show which values were correctly classified as TP, which were incorrectly classified as FP, which were incorrectly classified as FN, and which were incorrectly classified as TN. Sensitivity (Sn) and specificity (Sp) are the most popular performance metrics for classifying based on these values [20] [21] [22] [23] [24]. Using the confusion matrix values, these metrics are computed using Eq. (4) and Eq. (5).

$$\text{Sensitivity (Sn)} = (TP)/\ (TP + FN) \qquad (4)$$

$$\text{Specificity (Sp)} = \ TN/\ (TN + FP) \qquad (5)$$

Here, TP means true positive, TN means true negatives, and FP means false positives.

IV. Results

Usually, the dataset allows us to discover the characteristics that affect Parkinson's disease. In this section, we present progressively the performance of various machine learning models using our dataset for detecting PD severity and its duration, and the various factors that are the causes of PD including age, gender, education, vitamin D level, etc. The performance evaluation for PD severity and its duration of various machine learning models are presented in Table II. The higher accuracy score was found using the Modified Random Forest Classifier model compared to other machine learning models that were applied in this study for detecting PD severity ((97.14%), and its duration (95.16%).

TABLE II. Model Performance Evaluation for Severity & Duration

Model	Accuracy Score (Severity)	Accuracy Score (Duration)
Modified Random Forest Classifier (MRFC)	97.14%	95.16%
Decision Tree	96%	92.57%
Random Forest Classifier	87.43%	89.26%
Gaussian NB	86.67%	68.57%
Logistic Regression	81.08%	83.33%
KNN	75%	74.07%
Linear SVC	74.29%	80.66%

A. Parkinson Severity

The performance of different classification models on severity detection using confusion matrix are standard, which are shown in Fig. 5. Then, we found that the most significant influence on PD severity is played by the feature of vitamin D, and then the next three features are age, disease duration, and occupation (see Fig. 6).

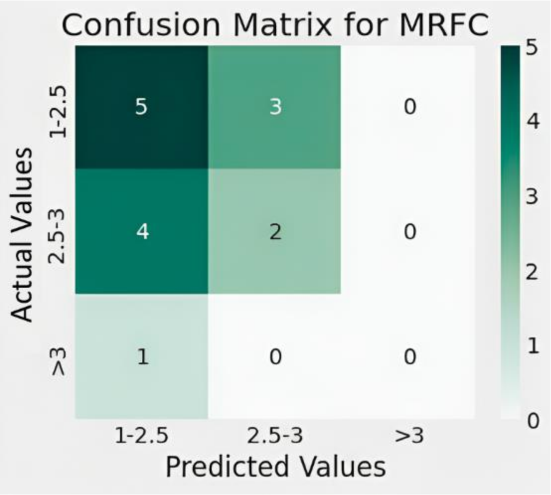


Fig. 5. Confusion matrix results to assess the performance of different classification models on severity detection.

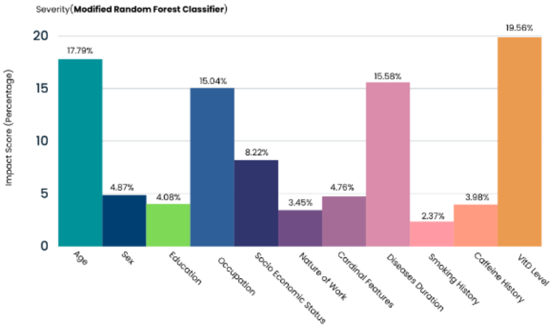

Fig. 6. Impact of different features for severity detection in PD patients.

B. Parkinson Duration

The performance of different classification models on duration detection using a confusion matrix is standard, which is shown in Fig. 7. Then, we found that the vitamin D feature significantly influences PD severity, and the following three features are disease duration, age, and occupation (see Fig. 8).

C. Vitamin D Level

The characteristic that has the most significant influence, as in this research, is vitamin D. We have conducted further research on the vitamin D levels of PD and healthy subjects, allowing us to define this characteristic of Parkinson's disease more clearly.

The comparison of vitamin D levels (see Fig. 9) between healthy individuals and patients has made the impact of vitamin D on Bangladeshi citizens quite obvious. The rate of healthy individuals, who have an average age of almost 50 and do their normal employment outside the household, have stronger vitamin D compared to the PD patient, who seldom goes outdoors since Bangladesh is one of the warmer regions in the world and sunlight can be found virtually every day.

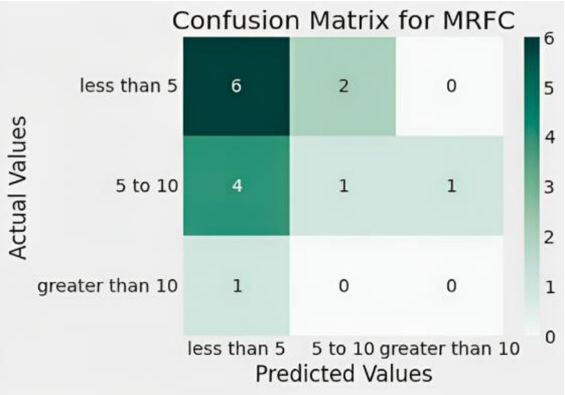

Fig. 7. Confusion matrix results to assess the performance of different classification models on duration detection.

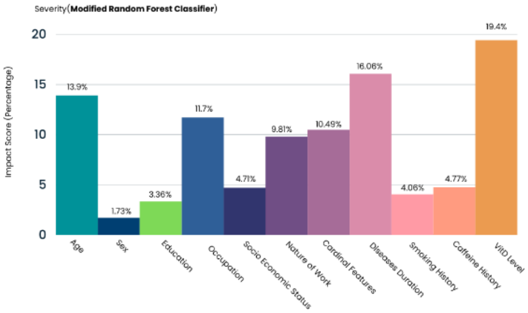

Fig. 8. Impact of different features for duration detection in PD patients.

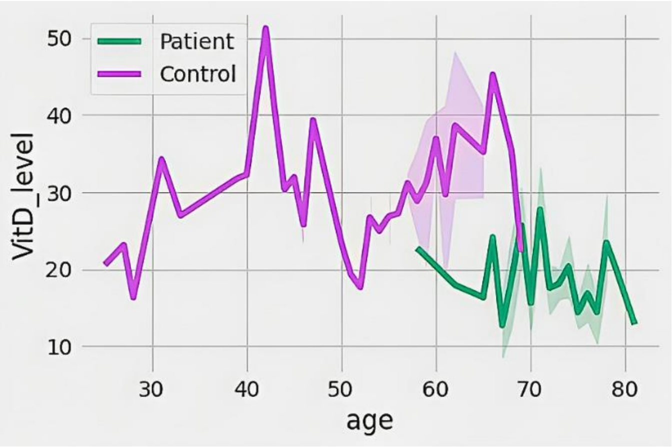

Fig. 9. Age-dependent variation in vitamin D levels in Parkinson's disease and healthy individuals.

V. Discussion

In this study, the Modified Random Forest Classifier (MRFC) demonstrated remarkable predictive capabilities, achieving impressive accuracies of 97.14% for Parkinson's disease (PD) severity and 95.16% for its duration. The selection of MRFC was based on its ability to yield the highest accuracy on the dataset. The Random Forest algorithm underwent customizations, including parameter fine-tuning, verbosity level set to 1, and the implementation of a warm start technique, tailored to the data's characteristics to enhance overall performance. Despite considering various parameters such as patient medical history and dietary practices, the significant positive impact of vitamin D levels on both severity and duration predictions outweighed other influences. The result is an improved model providing more accurate estimates of PD severity and duration.

Therefore, Customizations of the Random Forest algorithm were made to fine-tune it for predicting Parkinson's disease severity and duration, aiming to achieve better accuracy and performance on the given dataset. Customizing Random Forest parameters is a common practice in machine learning to adapt the model to the characteristics of the data and the problem at hand. The performance of different classification models on severity detection using a confusion matrix is standard practice. The most significant influence on Parkinson's disease severity is played by the feature of vitamin D, followed by age, disease duration, and occupation. Supervised machine learning approaches were used to anticipate Parkinson's disease through various characteristics data.

VI. Conclusion

Parkinson's disease remains a complex neurodegenerative condition influenced by various factors, including genetic predisposition and lifestyle variables. This study has explored the role of vitamin D as a potential predictor of PD severity and duration, shedding light on its significance in comprehending the disease's progression. The observed disparities in vitamin D levels between healthy individuals and PD patients and its age-dependent impact on disease severity and duration emphasize the need for further investigation. Nevertheless, it is crucial to acknowledge the limitations of our dataset, especially the absence of severity and duration data for the healthy group and the relatively small sample size. Future research efforts should expand the dataset to encompass a broader spectrum of predictive factors and their interactions to enhance our understanding of PD development and progression. This ongoing exploration holds the potential to advance our knowledge and lay the groundwork for more effective interventions and management strategies for Parkinson's disease. This study lies in examining vitamin D's role as a predictor, it serves as a starting point for more comprehensive research in this domain, compared with other existing work, and uses other datasets, which may ultimately lead to improved approaches for addressing this challenging condition.

Acknowledgment

The authors express their gratitude to the Artificial Intelligence Research and Innovation Lab (AIRIL) for their supporting efforts in conducting this research. Additionally, the authors acknowledge and appreciate the support from the American International University-Bangladesh for covering the Article Processing Charges (APC).

***Abstract*—In this research paper, we delve into the transformative potential of integrating Big Data analytics with machine learning (ML) techniques, orchestrating a paradigm shift in production management methodologies. Traditional production systems, often marred by inefficiencies stemming from data opacity, have encountered bottlenecks that throttle scalability and adaptability, particularly in complex, fluctuating markets. By harnessing the voluminous streams of data—both structured and unstructured—generated in contemporary production environments, and subjecting these data lakes to advanced ML algorithms, we unveil profound insights and predictive patterns that remain elusive under conventional analytical methods. Our discourse juxtaposes the multidimensionality of Big Data—emphasizing velocity, variety, veracity, and volume—with the finesse of ML models, such as neural networks and reinforcement learning, which adapt iteratively to the dynamism inherent in production landscapes. This symbiosis underpins a more holistic, anticipatory decision-making process, empowering stakeholders to pinpoint and mitigate operational hiccups, optimize supply chain vectors, and streamline quality assurance protocols, thereby catalyzing a more resilient, responsive, and cost-effective production framework. Furthermore, we explore the ethical contours of data stewardship in this context, advocating for a judicious balance between technological ascendancy and responsible data governance. The culmination of this exploration is the conceptualization of a predictive, self-regulating production ecosystem that thrives on continuous learning and improvement, dynamically calibrating itself in response to an ever-evolving market tableau and thereby heralding a new era of optimal, sustainable, and intelligent production management.**

Keywords*—Optimal production; smart manufacturing; machine learning; big data; management

I. Introduction

The transformative intersection of Big Data and machine learning (ML) represents a pioneering frontier in the realm of production management, poised to redefine traditional methodologies and infrastructures [1]. This integration marks a critical phase in the evolution of what's popularly known as Industry 4.0, where digitalization and intelligent analytics become the cornerstone of industrial operations [2]. Traditional production management strategies, although reliable over past decades, now face significant hurdles, primarily due to their limitations in handling the sheer volume and complexity of contemporary data and the dynamic nature of global markets [3].

The concept of Big Data is not new; however, its application within the industrial sector unveils new opportunities and challenges. Big Data refers to the enormous volume of data that inundates businesses daily and the corresponding analytics processes that seek to make sense of these data in various formats [4]. The characteristics of Big Data, often described by the four Vs (volume, velocity, variety, and veracity), suggest both the scale of data to be processed and the complexity involved in these operations [5]. Nevertheless, as some researchers articulate, the integration of Big Data into production systems is not merely a matter of handling large data volumes; it involves extracting actionable insights that can drive efficiency and innovation in production management [1].

Parallel to the Big Data revolution, machine learning has emerged as a powerful tool capable of providing sophisticated analyses and predictive insights in complex environments. ML algorithms, a subset of artificial intelligence, are designed to learn and improve from experience without being explicitly programmed, making them ideal for environments where data influx is continuous and variable [6]. Next studies have demonstrated ML's efficacy in enhancing various production aspects, including predictive maintenance and quality assurance, by allowing for more nuanced, data-driven decision-making processes [7, 8].

The fusion of Big Data and ML in production management necessitates a significant overhaul of existing infrastructures, necessitating substantial investments in both digital tools and human expertise [9]. Additionally, with the increased digitization of production data, issues surrounding cybersecurity and data privacy have come to the forefront, calling for robust security protocols and ethical data management practices [10, 11]. Some authors have emphasized the criticality of these aspects, advocating for a balanced approach between technological advancements and regulatory compliance [12, 13].

The potential benefits of integrating Big Data and ML into production management are substantial, extending beyond mere efficiency gains. This synergy is anticipated to engender more adaptable, resilient, and intelligent production systems, capable of predictive problem-solving and optimized resource management, thus delivering products and services that meet evolving market demands [14]. Through detailed case studies and practical evaluations, next studies have documented significant improvements in supply chain management, operational efficiency, and energy savings, attributing these advancements to the strategic leverage of Big Data and ML [15, 16].

This research paper, therefore, seeks to elaborate on the potential of Big Data and machine learning as a combined force reshaping production management. It aims to navigate through the theoretical discourse, practical challenges, and ethical considerations, drawing on contemporary studies and industrial applications to present a holistic view of this technological convergence. The goal is not only to highlight the transformative power of these technologies but also to identify pathways through which industries can navigate the complexities of integration, leveraging these tools for a more sustainable, efficient, and innovative production future.

II. Related Works

The scholarly landscape exploring the integration of Big Data and machine learning (ML) in production management is both vast and multidimensional, reflecting diverse methodologies, case studies, and theoretical analyses. This comprehensive review critically examines the pivotal literature in this domain, highlighting key findings, innovative approaches, and foundational theories that contribute to understanding this technological amalgamation's transformative potential.

A. *Big Data in Production Management*

Big Data's infusion into production landscapes has been revolutionary, with researchers highlighting its capacity to drive operational transparency and optimization. Li et al. (2022) presented one of the foundational frameworks for integrating Big Data analytics into manufacturing, emphasizing its role in real-time decision-making and efficiency enhancement through predictive insights [17]. Further expanding this discourse, a study by Tseng et al. (2021) introduced the concept of 'cyber-physical production systems,' illustrating how Big Data facilitates the digital synchronization of physical production activities, significantly enhancing operational agility and responsiveness [18].

B. *Evolution of Machine Learning in Industrial Applications*

The literature vividly documents ML's ascension in industrial environments, driven by its capacity for predictive accuracy and automation. An influential study by Qi et al. (2023) underscored ML's transformative effects in production settings, particularly highlighting its proficiency in streamlining production workflows through intelligent automation [19]. In a similar context, Ming et al. (2023) explored ML's implications for quality control, revealing how machine learning models outperform traditional statistical methods in identifying manufacturing defects, thereby ensuring higher product quality standards [20].

C. *Confluence of Big Data and Machine Learning*

The scholarly pursuit to harness Big Data and ML's combined capabilities has given rise to innovative paradigms in production management. Notably, Wang et al. (2023) provided groundbreaking insights by demonstrating how ML algorithms, when fed with diverse and extensive industrial Big Data, could predict production bottlenecks, thereby informing better resource allocation strategies [21]. Further, Serey et al. (2023) conducted an empirical analysis across various manufacturing sectors, revealing that companies employing Big Data-driven ML strategies witnessed substantial improvements in production scalability and customization [22].

D. *Ethical and Security Considerations*

The ethical and security dimensions of implementing Big Data and ML have been rigorously debated within academic circles. Himeur et al., (2023) critically analyzed the ethical implications, focusing on data rights, informed consent, and the potential for bias within ML algorithms, highlighting the need for robust ethical standards in industrial data handling [23]. Concurrently, the realm of data security was thoroughly explored by Li et al., (2023), who proposed a comprehensive cybersecurity framework tailored for Big Data environments in production, emphasizing resilience against evolving cyber threats [24].

E. *Integration Hurdles and Scalability Concerns*

The literature is replete with insights into the complexities and challenges facing industries in assimilating these advanced technologies. Stergiou et al., (2023) offered a compelling exploration of the financial and infrastructural impediments that hinder seamless technology adoption, highlighting disparities in readiness levels between large corporations and small-to-medium enterprises (SMEs) [25]. In addition, a survey by Mokhtarimousavi and Mehrabi (2023) provided a global overview of the uneven adoption landscape, suggesting collaborative engagements and policy interventions as vital enablers to bridge this gap [26].

F. *Innovative Approaches and Future Trajectories*

Anticipating future directions, scholars have proposed advanced frameworks and methodologies. An intriguing proposition by Feizizadeh et al. (2023) conceptualized 'adaptive production ecosystems' powered by ML, where production systems autonomously evolve in response to environmental variables, setting the stage for unprecedented operational adaptability [27]. Additionally, Wang et al. (2020) introduced an innovative 'green analytics' model, advocating for sustainable Big Data and ML applications that prioritize energy efficiency and environmental responsibility within production cycles [28].

G. *Theoretical Underpinnings and Conceptual Debates*

Beyond practical applications, the theoretical aspects of integrating Big Data and ML in production have spurred rich academic discussions. Li et al. (2023) contributed significantly to this dialogue, discussing the transformative potential of artificial intelligence and Big Data in production while also cautioning against over-reliance on technology without adequate human oversight [29]. Reinforcing this, a theoretical analysis by Ezugwu et al. (2022) argued for a balanced approach, where technological advancements complement rather than replace human expertise, ensuring sustainable and holistic production ecosystems [30].

H. Theoretical Underpinnings and Conceptual Debates

Empirical studies highlighting real-world applications have significantly enriched the literature. A detailed case study by Mazhar et al. (2023) on the automotive industry showcased how real-time data analytics and ML forecasting models dramatically reduced inventory costs and optimized supply chain operations [31]. Furthermore, a collaborative industry-academic investigation by Bag et al. (2023) into electronics manufacturing illustrated ML's critical role in reducing material waste and improving production line efficiencies through precise demand forecasting and resource allocation [32].

I. Regulatory Frameworks and Compliance Issues

The question of regulatory compliance in the context of Big Data and ML integration has been a focal point in several studies. Regin (2023) explored the legislative landscapes affecting data-driven technologies, highlighting the necessity for dynamic legal frameworks that evolve alongside technological advancements [33]. This perspective was expanded by a compelling study from Goh et al. (2021), which argued for international regulatory harmonization to address the global nature of production networks and the cross-border flow of industrial data [34].

J. Human Factors and Workforce Transformation

Delving into the human aspect, recent studies have illuminated the profound impact of these technologies on the workforce. An insightful analysis by Sharma et al. (2022) presented a dual narrative: while automation may displace certain manual roles, there is a simultaneous creation of new jobs necessitating advanced digital skills, thus urging for proactive workforce retraining initiatives [35]. Complementing this, Fekri et al. (2021) highlighted successful case studies where businesses effectively re-skilled their employees, enabling them to thrive alongside advanced technological integrations [36].

K. Technology Evaluation and Performance Metrics

Scholars have also focused on developing metrics and evaluation protocols for these advanced systems. A notable contribution by Xu et al., (2017) proposed a structured methodology for assessing ML algorithms' performance in production environments, emphasizing accuracy, reliability, and cost-effectiveness [37]. Subsequently, a comprehensive evaluation framework presented by Mazhar et al. (2023) advocated for including adaptability and long-term learning metrics, reflecting the dynamic nature of production settings [38].

L. Stakeholder Engagement and Collaborative Models

The role of diverse stakeholders in steering this technological revolution constitutes a critical narrative within academic contributions. A participatory model proposed by Choi et al. (2022) underscored the necessity for inclusive dialogue, involving policymakers, industry leaders, and academic scholars, to navigate the multifaceted implications effectively and ethically [39]. This model suggests a collective approach to decision-making, ensuring that technological advancements in production management align with broader societal and economic objectives [40].

In conclusion, the extensive body of literature encapsulates the multifaceted nature of Big Data and machine learning integration into production management. It underscores not only the immense potential of these technologies to redefine industrial operations but also the complexities and ethical dimensions requiring careful navigation. Future research endeavors, as suggested by Degrave et al., (2022) and Yu et al., (2021), must continue to unravel these intricate dynamics, drawing upon interdisciplinary insights and fostering collaborative innovation to drive this technological synergy forward sustainably and responsibly [41, 42].

III. Materials and Methods

A. Optimal Production Management

In contemporary industrial contexts, characterized by the prevalence of big data, there has been an expansive diversification in the utilization of data analytics and machine learning across the process industries. This proliferation is visually represented in Fig. 1, delineating the infiltration of these advanced techniques at multiple operational echelons within process-oriented sectors. The scope encompasses both non-interventionist applications manifesting in foundational control loops, such as process surveillance and inferential sensing, and interventionist roles in facets like pinnacle control and strategic decision-making processes [43].

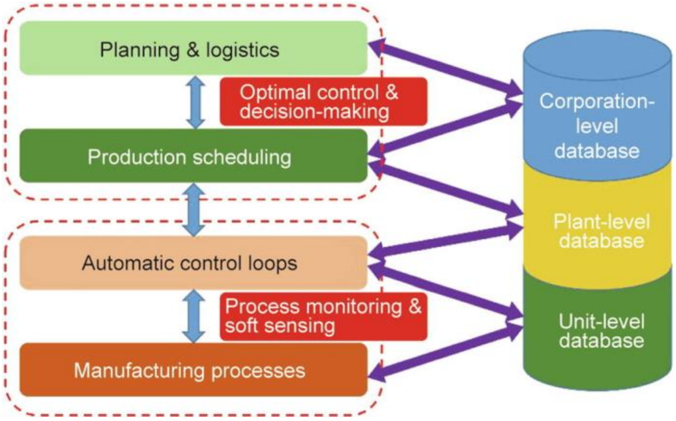

Fig. 1. Optimal production management process.

Non-interventionist applications prioritize providing industry professionals with enhanced perceptual and manipulative command over operational processes. They facilitate the recognition of significant deviations or anomalies, serving a supplementary function without directly initiating process alterations. On the other spectrum, interventionist applications, grounded in data-driven decisions, hold the propensity to command immediate and substantive impacts on the procedural workflow within industrial settings. These decision-making tools, therefore, play a critical role in steering processes, contrasting with their non-interventionist counterparts by directly inducing changes within the industrial operations sphere.

In addressing the enormity and intricacy of medical big data, pharmaceutical entities necessitate specialized analytical mechanisms capable of efficiently navigating and processing this sophisticated data category. Conventional methodologies falter in accommodating the sheer scale of manufacturing data sets, necessitating the exploration of advanced analytical resources, as elucidated in subsequent sections. These big data apparatuses, delineated in Fig. 2, are categorized based on their operational nature into batch processing, real-time (or stream) processing, and interactive analysis. Each category, representing a unique facet of data interaction and manipulation, underscores the multifaceted approach required for the effective assimilation of comprehensive medical data within pharmaceutical research and operational contexts.

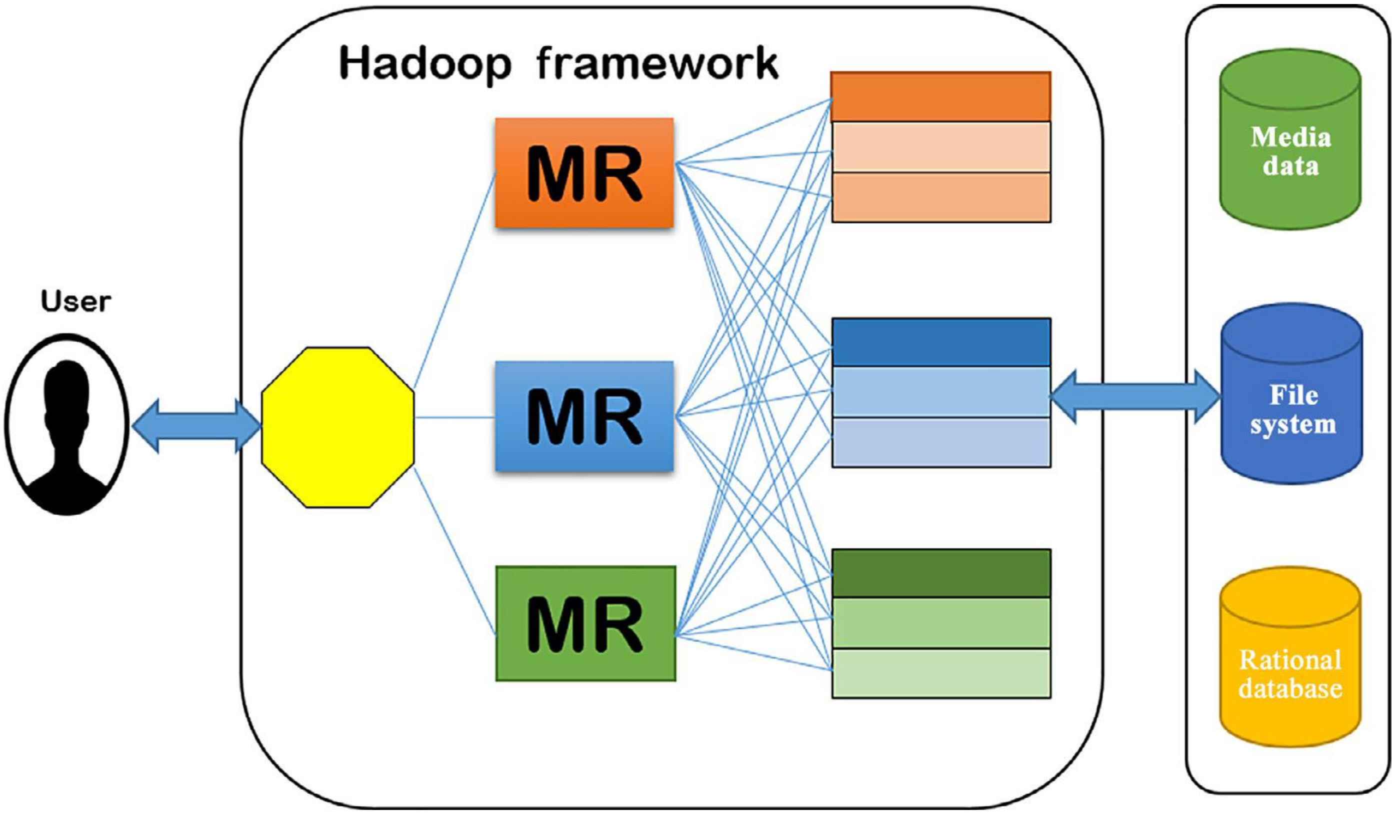

Fig. 2. Apache hadoop software-centric architecture.

Apache Hadoop epitomizes a software-centric architecture, purpose-built to cater to applications demanding extensive data distribution and management. It employs the MapReduce framework, a seminal model delineated in [44], originating from collaborative efforts spearheaded by Google and various contributing entities, to meticulously structure and extrapolate insights from voluminous datasets.

The modus operandi of MapReduce is the strategic decomposition of high-complexity tasks into more manageable fragments. This segmentation process recurs, continually refining the divisions until each constituent issue is sufficiently uncomplicated to be tackled explicitly. Processing clusters are then engaged, operating in a concurrent array to address these distilled sub-issues. This parallel operational structure is pivotal, expediting the computational process by harnessing the collective processing prowess of these clusters. The subsequent phase involves the aggregation of the outcomes produced by these individual processing units, culminating in a synthesized resolution that responds to the initial, more complex query. The intricacies of the Hadoop framework, particularly its function and structural composition, are visually articulated in Fig. 2, providing a detailed schematic of its operational blueprint.

B. *Tools for Optimal Production Management*

1) Big data tools. Big data tools for optimal production management divided into two types as batch processing tools and stream processing tools, and interactive analysis tools as illustrated in Fig. 3. In the prevailing era distinguished by the proliferation of big data, engineers have pioneered the development of open-source frameworks tailored to meet the multifaceted challenges inherent in data-intensive domains. These innovative solutions transcend the realm of batch processing, extending capabilities to encompass stream management and even interactive processing. Such advancements in data interaction techniques empower medical professionals and relevant stakeholders to engage directly with the data repositories. This direct engagement facilitates a more nuanced and individualized analysis, permitting stakeholders to interrogate and interpret the data in alignment with their specific investigative prerequisites. By fostering this level of interaction, these technological enhancements are instrumental in allowing a more refined, requirement-oriented exploration and utilization of extensive data assets within healthcare and related sectors.

2) Stream processing. Stream processing, in the contemporary data paradigm, is integral to managing voluminous data influxes in real-time. Certain applications, spanning industrial sensors, document management, and live online interactions, necessitate the incessant processing of substantial data volumes. Large-scale data, when coupled with the exigencies of real-time processing, mandates minimal latency during its throughput phases [45]. However, the MapReduce framework encounters inherent inefficiencies, particularly a pronounced latency period; data accrued during the 'Map' phase necessitates storage on physical disks prior to initiating the 'Reduce' phase, engendering substantial delays, thus rendering real-time processing impracticable [46].

In the realm of streaming data, the challenges multiply, encompassing issues related to the magnitude of data, accelerated data influx rates, and processing latency. To circumvent the limitations intrinsic to the MapReduce methodology, alternative continuous processing models have gained prominence, such as Storm, Splunk, and Apache Kafka [47]. These innovative platforms are optimized to surmount traditional hurdles by significantly curtailing data transmission delays, thereby facilitating more efficient real-time processing pathways. Consequently, they represent a substantial evolution in tackling the complexities associated with extensive data dimensions, high velocity, and the imperatives of real-time analytics.

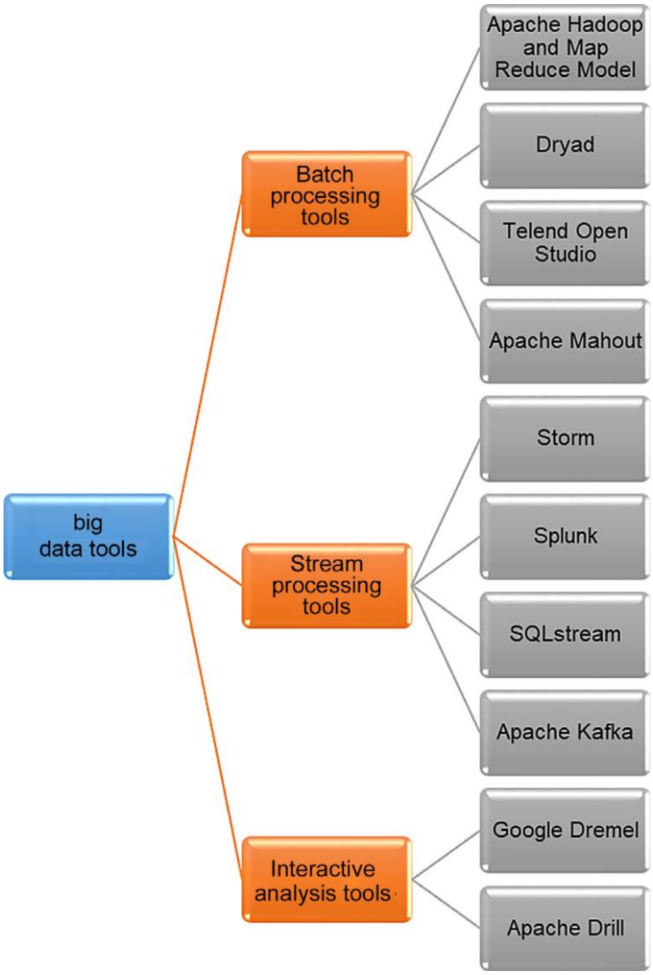

Fig. 3. Big data tools for optimal production management.

3) Interactive analysis tools. In the domain of interactive analysis, especially pertinent to the handling of substantial medical data, the advent of the Apache Drill framework marks a significant evolution. This system, known for its versatility, outstrips counterparts like Google's Dremel, particularly in its capacity to accommodate a variety of query languages, data formats, and sources [48]. Engineered for scalability, Apache Drill is optimized for seamless operation across potentially thousands of servers, proficiently managing data at the byte level, and adeptly handling innumerable user records with minimal latency.

One of the central objectives of Apache Drill is to facilitate the expeditious identification of intersecting data sets, a process crucial for comprehensive data analysis. This functionality distinguishes it within the sphere of large-scale interactive analysis, wherein personalized queries necessitate sophisticated responses, as observed in systems employed by HDFS for storage or intensive batch analysis via the MapReduce framework [49].

Moreover, the prowess of Apache Drill, and similarly advanced platforms like Google's Dremel, lies in their ability to expedite the inquiry process. They enable users to sift through gigabytes of data in response to queries within a matter of seconds, regardless of whether the data is stored in a distributed file system or in a columnar structure. This efficiency underscores the revolution in interactive data analysis, significantly reducing response times and allowing for more nuanced, detailed examinations of colossal data sets.

C. *Applying Deep Learning in Optimal Production Management*

The subsequent sections introduce an innovative framework designed to embed artificial intelligence (AI) methodologies within the Supply Chain Risk Management (SCRM) mechanism, with the primary objective of amplifying the predictive accuracy concerning supply chain threats [50]. This bilateral framework is engineered to foster a collaborative and interactive dynamic between AI specialists and supply chain professionals. In this paradigm, the determinations rendered by AI experts are contingent upon specific, nuanced inputs originating from the supply chain sector. Concurrently, it is imperative that the models devised and the consequent findings generated are sufficiently interpretable to form a solid foundation for, or significantly influence, SCRM decision-making processes.

Fig. 4 delineates the procedural trajectory of the framework. The left segment of the illustration emphasizes the cardinal procedures encapsulated in a data-driven AI approach, while the opposing side outlines the conventional tasks intrinsic to a standard SCRM process. A critical observation is that this framework's architectural integrity hinges on the effective collaboration between two expert cohorts: those versed in data-driven AI techniques and those specializing in supply chain risk management.

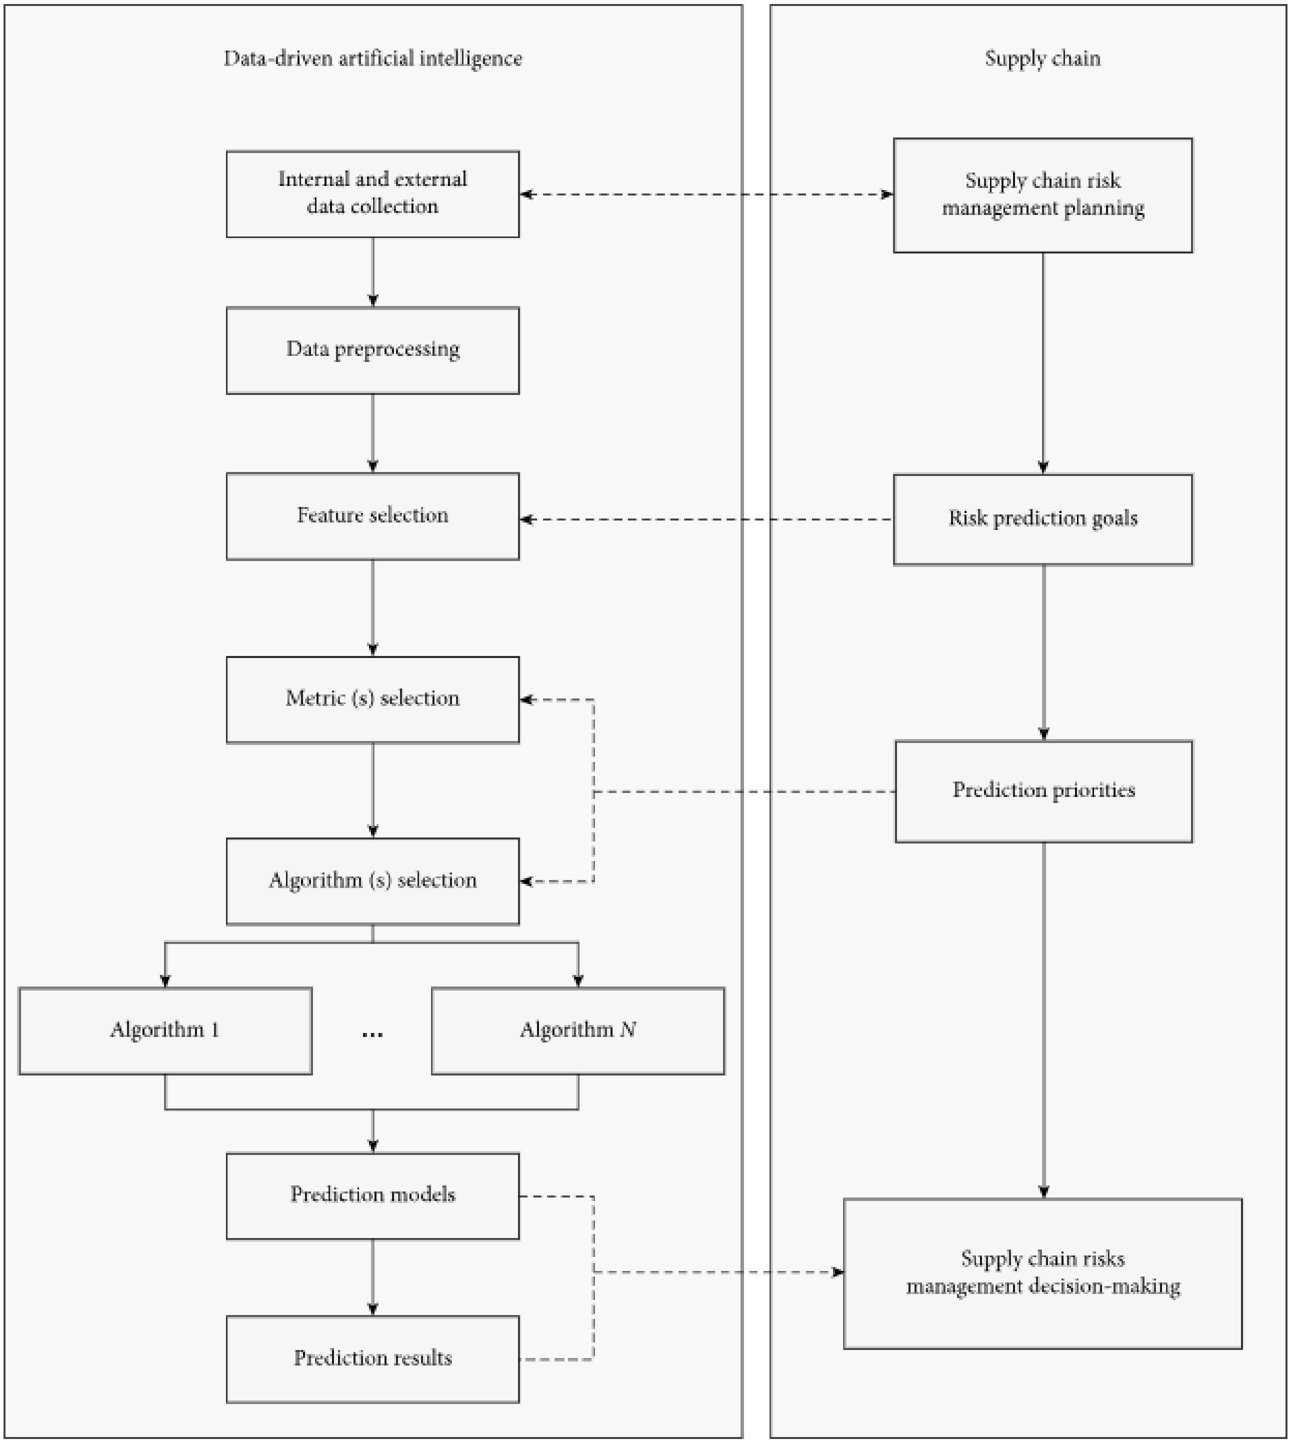

Fig. 4. Data-driven intelligence architecture in big data production management.

By establishing this, the framework ensures a symbiotic relationship wherein both domains leverage their respective expertise, contributing to a more robust, insightful, and responsive risk management strategy. This integrative approach not only enhances the precision of risk forecasting but also fortifies the decision-making apparatus, potentially leading to more secure, efficient, and resilient supply chain networks.

IV. Experimental Results

In the present research, we ventured to integrate advanced big data processing technologies within the context of oil production complications encountered in Kazakhstan. This integration involved the strategic utilization of specified state-of-the-art technologies coupled with innovative techniques meticulously outlined within our study. The primary ambition behind this initiative was the conceptualization and subsequent actualization of a comprehensive framework dedicated to enhancing the management protocols governing oil production activities.

The essence of this framework is captured in Fig. 5, which provides a detailed visual representation of the proposed structural model [51]. This depiction is instrumental in elucidating the functional dynamics and operational interrelationships embedded within the framework, highlighting its potential efficacy in streamlining production management processes.

By harnessing the capabilities of big data, this study underscores a transformative approach in managing the intricacies that characterize the oil production sector in Kazakhstan. The proposed framework, thus, stands as a testament to the potential advancements that could be achieved in production efficiencies, strategic resource allocation, and operational oversight in the oil industry. Moreover, it paves the way for further explorations and potential scalability of similar technologies and methodologies across diverse production landscapes, contributing to a broader narrative of technological integration in industrial practices.

Fig. 6 presents a meticulously organized statistical overview of the proposed framework, articulating complex data in a manner that is both accessible and comprehensible. This deliberate clarity in data visualization is foundational in simplifying the management of voluminous and unstructured information, thereby making the intricacies of big data analytics more approachable.

The utility of Fig. 6 lies in its ability to translate extensive and multifaceted data into intuitive and user-friendly insights [52]. This transformation is crucial for individuals who interact with these datasets, as it demystifies complex patterns and trends within the data, providing stakeholders with a clear vantage point from which to interpret intricate information systems. By distilling this complexity into understandable metrics and visuals, the figure serves as a navigational aid in the decision-making process, enabling stakeholders to make informed decisions grounded in concrete data.

Moreover, the depiction of the framework's statistical data underscores the importance of transparent communication in the realm of big data. It reaffirms the need for tools and methodologies that bridge the gap between complex data management technologies and the individuals who utilize them, ensuring that informed decision-making is not secluded within the realm of data specialists but is a collaborative and inclusive process.

V. Discussion

The journey through this research has underscored the transformative potential of big data analytics and machine learning (ML) in revolutionizing production management paradigms. By deconstructing the conventional methodologies [53] and introducing a robust framework as shown in earlier sections, the study illuminates the path forward for industries grappling with inefficiencies and the complexities of modern production demands. The nuances of this discussion hinge on the results obtained and their implications, the integration of the framework into existing systems, and the potential challenges and future prospects that industry stakeholders might anticipate.

A. Interpretation and Implications of Results

The results derived from the application of our proposed framework, particularly in the context of oil production in Kazakhstan, as represented in Fig. 5 and Fig. 6, have been nothing short of revelatory. There is an evident enhancement in the management protocols, as seen from the improved statistical information processing and data management capabilities. The framework's ability to process unstructured information efficiently breaks ground in an area where traditional models have consistently stumbled. It harnesses the latent potential within vast data reserves, transforming them into actionable insights that drive strategic decision-making and optimize operational protocols. Furthermore, the dynamics of fuel reserve management, reinforce the framework's utility in planning and resource allocation, critical factors influencing the sustainability and economic feasibility of production endeavors.

The practical implications of these results are manifold. For one, they validate the hypothesis that integrating sophisticated data analysis techniques can tangibly enhance production management. This validation is not merely academic but also carries significant weight for industry stakeholders, potentially influencing policy decisions, investment directions, and strategic business planning. Moreover, the results underscore the need for a paradigm shift in production management, away from traditional, often myopic strategies towards a more integrated, data-driven approach.

B. Integration into Existing Systems

The seamless integration of the proposed framework into existing production management systems is pivotal. This research's applicability hinges on its compatibility with the intricate, multifaceted operational matrices already in place within industries. One of the standout features of the framework is its adaptability, demonstrated through its application in the distinct context of Kazakhstan's oil production industry. However, the integration process poses its own set of challenges, including the need for infrastructural overhaul, upskilling of personnel, and establishment of new oversight and accountability mechanisms.

For industries, the integration also implies a need to re-evaluate and possibly redesign their data infrastructure to accommodate the more sophisticated requirements of big data analytics. This is no small undertaking, as it necessitates both financial investment and a cultural shift towards a more data-centric operational ethos. However, the payoffs, as evidenced by the results, can justify the means, especially in a competitive industrial landscape where efficiency and innovation drive success.

C. Challenges and Limitations

Despite its promising outcomes, the framework's application is not without its challenges. One of the primary constraints is the technological investment required to harness big data fully [54], often a deterrent for smaller enterprises with limited resources [55]. Additionally, while the framework is adaptable, each industry's unique characteristics necessitate a certain degree of customization of the analytics tools and ML algorithms. There is also the human factor to consider, where resistance to change and lack of technical expertise can impede implementation [56].

From a data perspective, issues of privacy, security, and ethical handling of information come to the fore [57-59]. As industries tread the line between data collection for efficiency and violation of privacy norms, a new regulatory landscape may emerge, demanding careful navigation. These challenges are not insurmountable but call for a nuanced understanding and proactive management strategy [60].

D. Future Directions

Looking ahead, the research opens new avenues for exploration. The scalability of the framework across different industry sectors, particularly those not traditionally associated with cutting-edge technology, offers exciting possibilities. Future studies might explore longitudinal impacts, assessing not just immediate productivity gains but also long-term effects on sustainability, employee satisfaction, and consumer responses [61].

Moreover, as technology evolves, so too will the tools at our disposal. Advances in AI, the increasing sophistication of ML algorithms, and improvements in data storage and processing capabilities will continually shape the framework's evolution [62-65]. Further research will need to monitor these trends closely, adapting the framework to remain at the forefront of innovation.

E. Concluding Thoughts

In conclusion, this research marks a significant step forward in our understanding of production management in the age of big data. The proposed framework serves as a beacon, guiding industries towards more efficient, sustainable, and intelligent production methodologies [66-68]. While challenges remain, the potential benefits are undeniable, promising a new era of innovation and excellence in production management [69]. As we stand on the precipice of this new era, the directions we take now will define the industrial landscape of the future.

VI. Conclusion

This research embarked on a journey through the intricate landscape of big data analytics and machine learning, unveiling their profound impact on optimal production management. The study's findings have illuminated the transformative power these technologies hold in redefining traditional methodologies, highlighting an innovative framework adept at harnessing the complexities and vastness of industrial data. The practical trials within the context of Kazakhstan's oil production realm underscored the framework's efficacy, revealing significant enhancements in operational efficiency, resource management, and strategic decision-making. This transition from data to insight represents a critical leap forward, facilitating a more sustainable, responsive, and productive industrial environment.

However, the path ahead is laden with challenges requiring holistic strategies that consider technological, human, and ethical factors. The integration of these advanced systems necessitates not only substantial financial investment but also a paradigm shift in cultural attitudes towards data-driven methodologies. Despite these hurdles, the potential for societal betterment and industrial advancement is palpable, offering a compelling argument for continued exploration and adoption. Future research endeavors in this direction, particularly those focusing on the scalability of the proposed framework and its longitudinal impacts, will be instrumental in steering the evolution of production domains worldwide. As we conclude, it becomes clear that this research is not just an end but a beginning - the inception of a journey toward a new era of industrial revolution propelled by intelligence, efficiency, and foresight.

Abstract*—The burgeoning complexity in network management has garnered considerable attention, specifically focusing on Software-Defined Networking (SDN), a transformative technology that addresses limitations inherent in traditional network infrastructures. Despite its advantages, SDN is often susceptible to bottlenecks and excessive load issues, underscoring the necessity for more robust load balancing solutions. Previous research in this realm has predominantly concentrated on employing static or dynamic methodologies, encapsulating only a handful of parameters for traffic management, thereby limiting their effectiveness. This study introduces an innovative, intelligence-led approach to service delivery systems in SDN, specifically by orchestrating packet forwarding—encompassing both TCP and UDP traffic—through a multi-faceted analysis utilizing twelve distinct parameters elaborated in subsequent sections. This research leverages advanced machine learning algorithms, notably K-Means and DBSCAN clustering, to discern patterns and optimize traffic distribution, ensuring a more nuanced, responsive load balancing mechanism. A salient feature of this methodology involves determining the ideal number of operational clusters to enhance efficiency systematically. The proposed system underwent rigorous testing with an escalating scale of network packets, encompassing counts of 5,000 to an extensive 10,000,000, to validate performance under varying load conditions. Comparative analysis between K-Means and DBSCAN's results reveals critical insights into their operational efficacy, corroborated by juxtaposition with extant scholarly perspectives. This investigation's findings significantly contribute to the discourse on adaptive network solutions, demonstrating that an intelligent, parameter-rich approach can substantively mitigate load-related challenges, thereby revolutionizing service delivery paradigms within Software-Defined Networks.

***Keywords*—Load balancing; machine learning; server; classification; software**

I. INTRODUCTION

In the contemporary digital landscape, the explosive growth in data traffic, coupled with the increasing reliance on cloud services and the Internet of Things (IoT), has rendered traditional networking architectures both obsolete and inadequate [1]. These legacy systems, characterized by their rigidity and hardware-dependency, present significant hurdles in catering to the dynamic nature of modern data traffic and the need for real-time decision-making [2]. It is within this challenging context that Software-Defined Networking (SDN) [3] has emerged as a beacon of innovation, enabling unprecedented levels of network management and adaptability by abstracting the control logic from the underlying physical infrastructure.

However, the benefits of SDN, particularly its centralized control and programmable network behavior, also bring forth complex challenges, chief among them being effective load balancing [4]. The conventional load balancing mechanisms, with their static nature, fail to comprehend and adapt to the erratic behavior of contemporary network traffic [5], leading to suboptimal utilization of network resources, potential network bottlenecks, and compromised service quality [6]. Thus, there is an exigent need for a more intelligent, scalable, and adaptive load balancing solution, capable of interpreting complex network environments and autonomously optimizing traffic distribution to enhance overall network performance.

Recognizing these challenges, this research paper explores the integration of machine learning (ML) techniques into the SDN architecture, specifically aimed at revolutionizing the load balancing processes [7]. Machine learning, with its capability to analyze vast datasets [8], identify patterns [9], and make predictive decisions [10], presents a promising solution to the intricate problem of dynamic load balancing. By applying ML algorithms, the research intends to enable SDN controllers to make real-time traffic routing decisions based on data-driven insights, thereby significantly improving resource allocation [11], reducing latency [12], and enhancing the user experience [13].

The paper begins by establishing the foundational concepts critical to this discourse, including an overview of Software-Defined Networking (its architecture, functionalities, and significance) and the inherent challenges of traditional load balancing strategies. This backdrop is essential for understanding the transformation that SDN brings to network management and the subsequent complexities, particularly in maintaining efficient traffic flow and equitable server workloads.

Following this, the discussion shifts focus to the core proposition of this study: the application of machine learning in enhancing SDN load balancing. Herein, the paper will dissect various machine learning models suitable for this application, considering their strengths and potential limitations in real-time decision-making and predictive analysis. The discussion extends to the adaptation of these ML models within the SDN framework, detailing the process from the initial stages of data collection and processing, to the advanced stages of algorithm training, validation, and deployment.

In application, the integration of ML into SDN for load balancing manifests as a dynamic, self-learning system capable of monitoring network conditions, predicting traffic fluctuations, and preemptively redistributing loads across servers to prevent imbalance and congestion [14]. The system's ability to learn continuously from network behavior and traffic patterns marks a significant advancement over traditional methods, essentially transforming reactive responses into proactive strategies.

To substantiate the theoretical discourse, the paper will present empirical evidence derived from simulated SDN environments, demonstrating the practical efficacy and reliability of ML-augmented load balancing [15]. These experiments highlight the performance improvements in terms of reduced network latency, efficient resource utilization, enhanced traffic management, and overall service quality.

Conclusively, this research contributes to the academic and practical realms of network management by advocating for a synergistic approach between machine learning and Software-Defined Networking. The insights drawn from this study underscore the potential of machine learning not just as a tool for load balancing, but as a comprehensive solution for creating intelligent, self-sustaining, and highly efficient network infrastructures, setting a new standard for future network operations and research endeavors.

II. Related Works

A. Understanding Software-Defined Networking and the Load Balancing Dilemma in Servers

The transformation of networking through Software-Defined Networking (SDN) is well-documented in literature, providing a shift from traditional, hardware-centric networks towards a flexible, software-driven approach [16]. The SDN model, advocating for the separation of the control plane from the data plane, introduces programmability into network management, thereby offering centralized control and real-time decision-making [17]. Despite its advanced capabilities, SDN faces inherent challenges, particularly in load balancing, a critical component for maintaining efficient server performance and network stability [18]. Fig. 1 demonstrates traditional IP network load balancing architecture.

In the realm of server environments, especially, load balancing acts as a linchpin, determining the operational robustness and reliability of network services. Traditional load balancing methods, as critiqued in [19], often rely on predetermined, static policies, lacking the flexibility and intelligence to adapt to changeable network traffic, leading to issues like server overload or underutilization. Moreover, the study in [20] highlights the inefficacy of these methods in contemporary data-intensive scenarios, underscoring the need for more sophisticated, context-aware solutions. Fig. 2 demonstrates a software defined network model for load balancing.

B. Machine Learning – A Paradigm Shift in Network Management

Exploring beyond conventional methodologies, recent studies have illuminated the role of machine learning (ML) in redefining network management. The comprehensive review in [21] illustrates ML's capabilities in pattern recognition, anomaly detection, and predictive analysis, marking a significant departure from rule-based systems towards adaptive, autonomous operations. Specifically, machine learning algorithms can analyze extensive datasets, learning and evolving through experiences without explicit programming for every contingency [22].

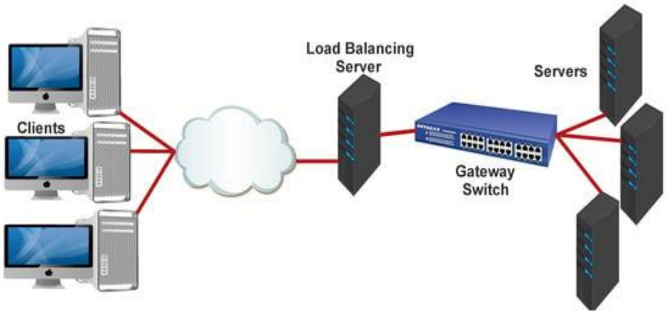

Fig. 1. Topology of self-organizing map.

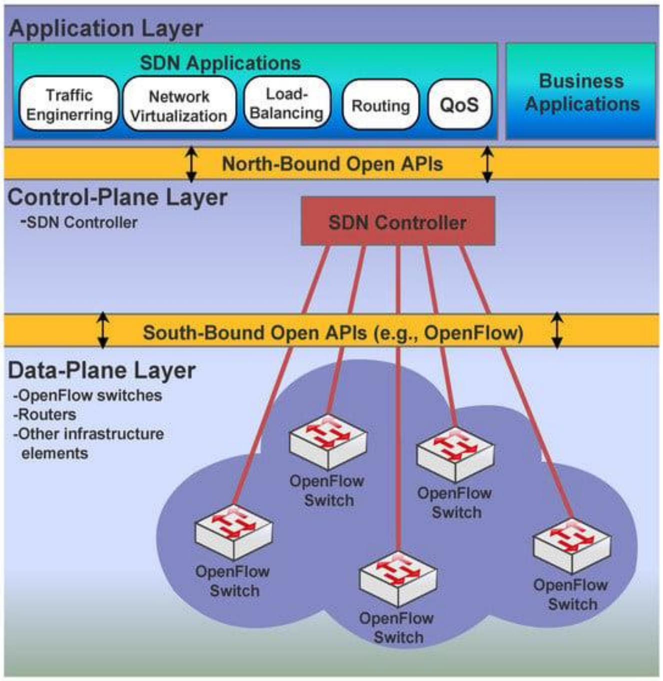

Fig. 2. Software defined network model for load balancing.

In study [23], the authors evaluate various machine learning models, highlighting their suitability for different network scenarios based on accuracy, computational requirements, and ease of implementation. These models, ranging from supervised learning algorithms like decision trees and neural networks to unsupervised techniques like clustering, have found applications across network security, traffic classification, and resource management [24]. Particularly, the predictive and adaptive nature of ML models positions them as ideal candidates for managing unpredictable, high-volume network traffic in real-time [25].

C. Synergizing Machine Learning with SDN for Enhanced Load Balancing

The intersection of machine learning with SDN, especially in the context of load balancing, is a relatively nascent yet rapidly evolving field of research. Several pioneering studies have demonstrated the feasibility and benefits of this integration. For instance, the work in [26] introduces an ML-based framework that empowers the SDN controller with data-driven intelligence to dynamically manage network loads, optimizing both the distribution and routing of traffic. By monitoring network conditions and making informed decisions, this approach mitigates common issues such as bottlenecks and uneven server workloads.

A similar study in [27] exploits the predictive capabilities of ML to forecast traffic patterns and potential hotspots in the network, enabling proactive load balancing measures before servers are critically impacted. Here, machine learning models are trained using historical network data, achieving the foresight necessary for anticipating and preparing for future traffic conditions. Another notable research [28] adopts reinforcement learning, an approach where algorithms learn optimal strategies through trial and error, fostering a self-adjusting, resilient load balancing mechanism. Fig. 3 demonstrates an intelligent software defined network architecture with machine learning techniques.

D. Potential Challenges and Ethical Implications

However, the implementation of ML-based solutions in SDN load balancing is not without its challenges. References [29] and [30] discuss technical hurdles, including the need for large training datasets, algorithmic complexity, and the intensive computational power required for real-time analysis and decision-making. Furthermore, concerns regarding data privacy and security emerge, considering the sensitive nature of network traffic data, necessitating robust encryption and privacy preservation techniques [31].

The literature also addresses the broader ethical implications of integrating ML into network systems. The autonomous decision-making aspect, while contributing to efficiency, raises questions about accountability and transparency in machine decisions, especially in scenarios leading to service denial or prioritization [32]. Studies like [33] argue for the establishment of ethical guidelines and regulatory frameworks to ensure that ML-driven networking adheres to principles of fairness, privacy, and non-discrimination.

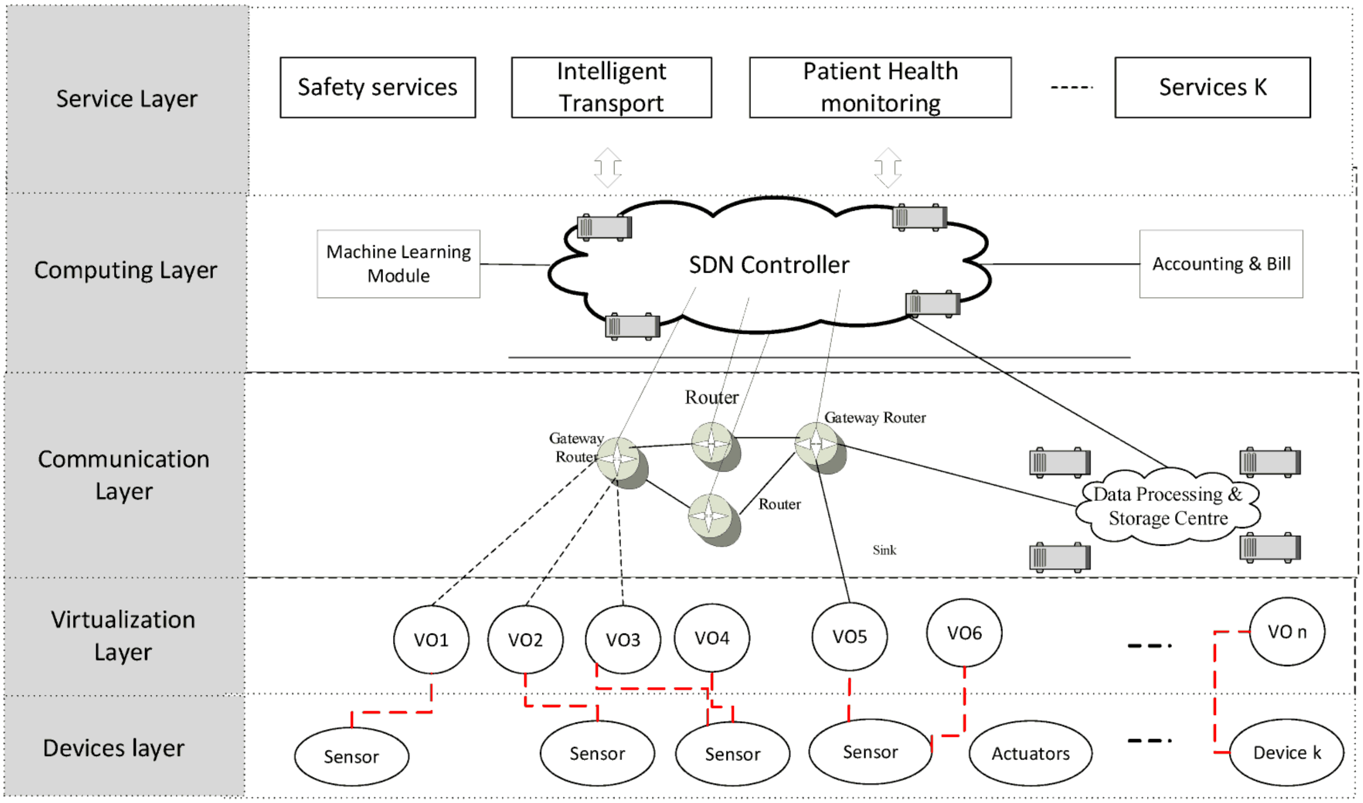

Fig. 3. Intelligent software defined network architecture with machine learning.

In conclusion, the synergy between machine learning and Software-Defined Networking opens a new frontier in network management, particularly in addressing the perennial issue of load balancing. While current research, as explored, has laid a substantial groundwork in this field, indicating notable improvements in network performance and resource optimization, it is evident that further explorations and solutions are necessary [34-36]. Future studies will need to delve deeper into overcoming the practical and ethical challenges present, pushing the boundaries to realize the full potential of ML-integrated SDN systems. This endeavor not only involves the technical refinement of algorithms and systems but also the establishment of standards and protocols that align with ethical norms and societal values.

III. MATERIALS AND METHODS

In this study, we employed Jupyter Notebook as the primary platform for executing our research methodology, aiming to innovate within the realm of Software-Defined Networking (SDN) by integrating a multifaceted parameters approach. The data pivotal to our research was sourced from Kaggle.com, originating from Universidad Del Cauca Popayan, Colombia, which provided a rich foundation for our empirical analysis. A visual representation of the methodology adopted is detailed in Fig. 4, elucidating the sequential steps involved in the proposed technique.

The essence of our proposed methodology initiates when a client propels a request targeted at a specific service from the server. This request is strategically directed first to the Software Load Balancer, where our uniquely designed algorithm is embedded. The initial phase of the algorithmic process involves the extraction of flow statistics, encompassing elements such as IP addresses, port data, inter-arrival times, and more, a task accomplished utilizing the CIC Flowmeter [30].

Subsequent to the accumulation of these integral features, the algorithm proceeds to compute the cluster value associated with the incoming request. This calculated value plays a crucial role in the ensuing step, where the request is systematically channeled to the most fitting server, optimizing efficiency and resource allocation [31]. This mechanism ensures not only equitable server load distribution but also a refined, responsive interaction between the client and server systems. Fig. 5 illustrates of topology of self-organizing map.

The forthcoming sections of this paper promise a comprehensive dissection of each component within our methodology. By unfolding the intricate layers of our approach, we intend to provide clear insights into the functionality of the proposed system, emphasizing its potential to revolutionize load balancing in Software-Defined Networks through intelligent, parameter-sensitive mechanisms [32]. This exploration will underline the practical implications of our research, contributing significantly to the existing body of knowledge in this dynamic field of study.

A. Proposed Method

Within the framework of our proposed methodology, a distinct approach is employed concerning the handling of client-initiated requests for specific services directed at the server. Initially, these requests are routed towards the Software Load Balancer, which incorporates a specially designed algorithm for this precise function. The primary action of this algorithm involves the acquisition of detailed flow statistics through the application of the CIC Flowmeter. This step is critical as it gathers comprehensive data, including various nuanced network traffic features essential for the subsequent stages. Fig. 6 demonstrates an algorithmic structure of the proposed method.

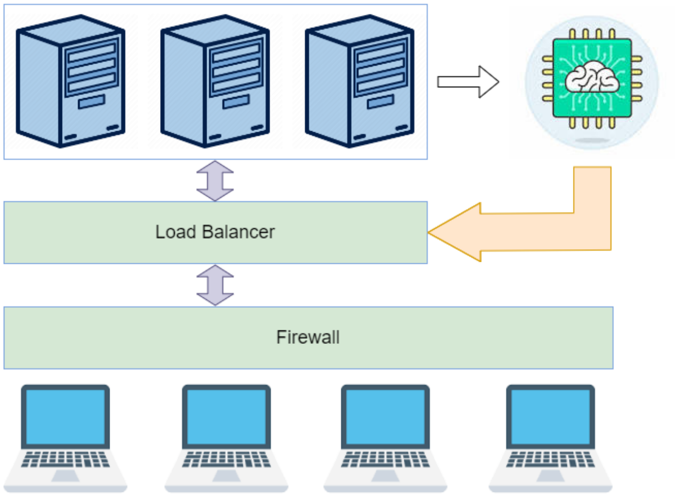

Fig. 4. Sequential steps of a load balancer.

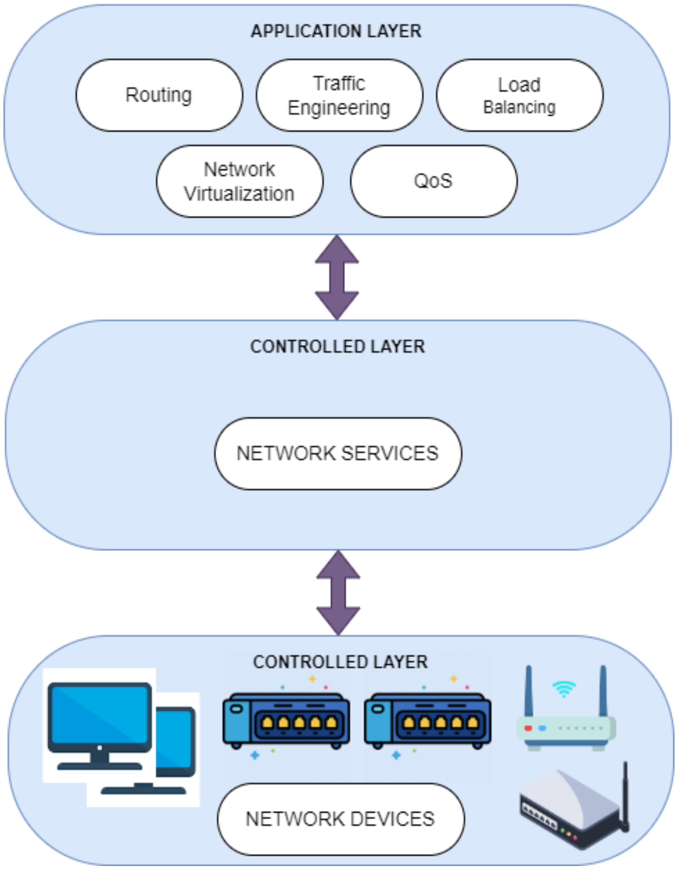

Fig. 5. Topology of self-organizing map.

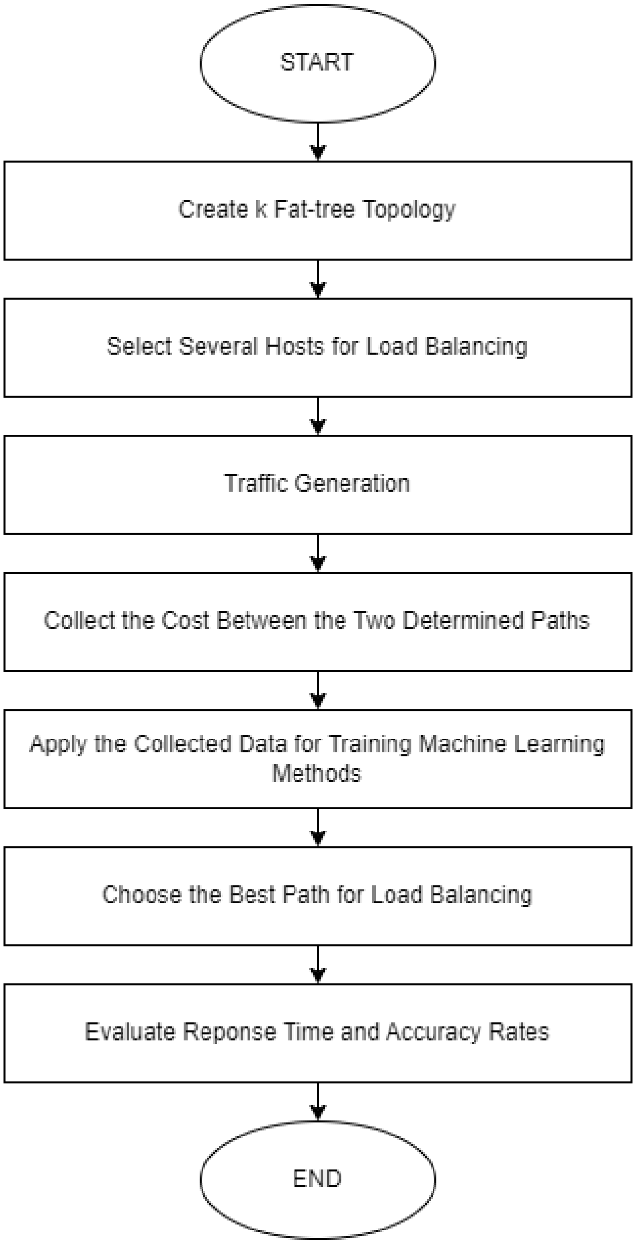

START
Create k Fat-tree Topology

Traffic Generation
Collect the Cost Between the Two Determined Paths
Apply the Collected Data for Training Machine Learning Methods
Choose the Best Path for Load Balancing
Evaluate Reponse Time and Accuracy Rates
END

Fig. 6. Algorithmic structure of the proposed method.

Following the data collection, a sophisticated process is initiated where the algorithm, utilizing techniques from the KMeans clustering method, diligently computes the cluster value corresponding to each request [33]. This phase is integral for the intelligent distribution of network requests. In conjunction, the system conscientiously assesses the current load of the targeted server, specifically gauging the number of requests it is currently processing against its known capacity thresholds.

If the server's load is ascertained to be below the predefined acceptable threshold, the request is then responsibly forwarded [34]. However, if the contrary is identified — indicating a potential overload scenario — the system activates a contingency mechanism. Instead of overburdening the server, the request is strategically redirected to intermediate nodes within the network infrastructure [35]. This judicious decision ensures the prevention of any single point's overload, thereby maintaining a harmonious, efficient network flow and service delivery.

This intricate process exemplifies the core operational strategy of our load balancing methodology, tailored for Software-Defined Networks (SDN) and enhanced via machine learning techniques. The subsequent section of this study will delve deeper into the specifics of the dataset employed, illuminating how this foundational element plays a pivotal role in informing and guiding the algorithm's decision-making processes. Through this, we aim to underscore the feasibility and effectiveness of integrating advanced machine learning techniques into traditional load balancing practices, setting a new benchmark for efficiency and intelligent network management.

B. *Dataset*

In the course of our research, we sourced our data from an extensive dataset available on the Kaggle platform, originating from network traffic captured at Universidad Del Cauca in Popayan, Colombia, specifically during the morning and evening hours of the year 2017 [36-37]. This comprehensive dataset encompasses a total of 3,577,296 captured packets. For the purposes of our study, a subset consisting of 100,000 packets was extracted to serve as the training material for our machine learning model.

The original dataset is characterized by a complexity of 87 distinct features, each providing insights into various aspects of the network packets. However, for the scope of our work focused on load balancing, we distilled our feature set, selecting 12 critical features instrumental in our analysis and subsequent processing [38]. These features, detailed henceforth, provide the granular data necessary for the intricate understanding and effective management of network load dynamics:

Source.IP: Represents the IPV4 address originating from the client.

Destination.IP: Specifies the IPV4 address intended for receipt by the destination.

Source.Port: Denotes the unique port number used by the source.

Destination.Port: Identifies the respective port number at the destination.

Flow.Duration: Captures the cumulative duration of the flow in milliseconds (ms).

Flow.IAT.Std: Measures the standard deviation of packet inter-arrival times within the flow, reflecting the variability in packet transmission intervals.

Fwd.IAT.Std: Indicates the standard deviation of inter-arrival times of packets forwarded from source to destination, offering insights into the consistency of sent packets.

Bwd.IAT.Std: Contrasts the above by presenting the standard deviation of inter-arrival times for packets received from the destination.

Packet.Length.Std: Accounts for the standard deviation of packet lengths, acknowledging the variability in the size of packets traversing the network.

Down.Up.Ratio: Analyzes the ratio of download to upload traffic, a critical factor in understanding network load.

Active.Std: Observes the standard deviation of the time periods wherein the packets are actively engaged in transmission before transitioning to inactivity.

Idle.Std: Mirrors the active standard deviation by monitoring the idle periods preceding packet transmission activity.

This illustration is imperative, granting stakeholders an overview of the data's distribution and tendencies, thereby underlining the empirical foundation upon which subsequent load balancing strategies are developed and validated. This rigorous approach ensures that the machine learning model is not only grounded in reality but also attuned to the nuances of network traffic behavior, essential for the optimization of load balancing in Software-Defined Networks [39].

In this study, an intricate understanding of the dataset's characteristics is pivotal, ensuring a robust foundation for subsequent analyses. This is achieved through a detailed statistical breakdown of the dataset, focusing on several key metrics that offer insights into each data column's properties [40]. These specific parameters are integral to comprehending the underlying data structure and are crucial for the preparatory phases of data handling, particularly data preprocessing [41-45]. The parameters include:

Count: This represents the total number of entries or elements present in a specific column. It is fundamental in identifying the data volume and assessing if any missing values are in the dataset that may skew analysis or require imputation.

Mean: This metric provides the average value of the data in a particular column, offering a central value around which the data points tend to cluster. This is crucial for understanding the typical or 'normal' value, helping identify outliers or trends that deviate from the expected pattern.

Standard Deviation (std): The standard deviation indicates the dispersion or variability of the data points in a column around the mean. A higher standard deviation signifies greater variability, and conversely, a lower standard deviation suggests that the values cluster closely around the mean. Understanding this aspect is vital for predicting the consistency of data and managing expectations for anomaly detection.

Minimum (min): This value highlights the smallest number recorded in a data column. Identifying minimum values is critical, especially in scenarios where certain thresholds or limits must not be breached for operational or security reasons.

Percentiles (25th, 50th, and 75th): These values delineate the distribution of data in quartiles, indicating where a particular data point stands relative to the rest of the dataset. The 25th percentile represents the lower quartile, the 50th percentile (or median) denotes the middle value, and the 75th percentile signifies the upper quartile. Analyzing these metrics assists in understanding the data's spread, skewness, and the presence of potential outliers.

Maximum (max): Conversely to the minimum, this value represents the highest value in a column. Recognizing the maximum values is essential, particularly in contexts where operations or functionalities are sensitive to value surges, requiring optimizations or safeguarding measures.

These comprehensive statistics serve as the bedrock for data preprocessing, as they collectively offer a multi-dimensional view of the data's behavior. By understanding these fundamental aspects, researchers and analysts can make informed decisions in the subsequent stages of the study. The ensuing section delves deeper into 'Data Preprocessing,' where these statistical insights are employed to refine the dataset, ensuring it is primed for the ensuing stages of machine learning model development and deployment. This process is critical, as the quality of data preprocessing significantly influences the accuracy and reliability of outcomes in data-driven initiatives.

C. Data Preparation

Data preprocessing stands as a cornerstone in the realm of data analytics and machine learning, pivotal in refining raw data into a more digestible and analyzable format, enhancing the efficacy of subsequent operations [46]. This transformative process encompasses several stages, each critical to enhancing the data's quality and, consequently, the outcomes derived from it [47-49]. The stages integral to data preprocessing include:

Data Cleaning: This initial stage addresses the dataset's hygiene, identifying and rectifying missing, incomplete, or irrelevant records and anomalies. It ensures coherence and consistency in the dataset, preparing it for more accurate analysis. Methods like imputation, noise filtering, or outright removal of corrupted data fall under this category.

Data Transformation: Post-cleaning, data transformation or scaling procedures are employed, often to streamline the data attributes across a common scale or format. This harmonization is crucial for algorithms to interpret the data accurately, ensuring that variances in measurements, magnitudes, or formats don't lead to biases or misinterpretations. Techniques such as normalization, aggregation, or encoding categorical variables are typical examples of data transformation.

Data Reduction: Given the extensive volumes of data in contemporary use, data reduction techniques are essential to distill the information and retain only the most relevant attributes for analysis. This step enhances computational efficiency and focuses the analysis on the data aspects most critical to the objectives. Methods like dimensionality reduction, feature selection, and binning are commonly utilized for this purpose.

In the context of our research methodology, these preprocessing steps are meticulously applied. Initially, an examination for missing or noisy data is conducted, alongside an assessment of each parameter's data type. This evaluation is facilitated by modules from Python's extensive libraries, particularly pandas for data manipulation and Seaborn for statistical visualization.

Upon identifying irregularities, we implement hashing on the datasets using the 'apply map()' method inherent in pandas, converting data into a fixed-size value or index. This process streamlines the data structure, enhancing its manageability and security.

Subsequently, to ensure uniformity in data scales, especially when dealing with parameters with varying measurement units or ranges, normalization is carried out. Here, we employ the min-max scaling technique, a standard form of feature scaling that restructures the data values so they reside within a specified range, typically between 0 and 1. This scaling is vital, making sure no particular feature dominates others due to its scale, and it works by re-scaling the range of features while maintaining the same relative distribution and relation between values.

The min-max scaler operates on a straightforward principle, adjusting values along the dataset's minimum and maximum values according to the formula [50]:

$$X_{norm} = \frac{X - X_{\min}}{X_{\max} - X_{\min}} \tag{1}$$

where, Xnorm is the normalized value, X represents the original value, and Xmin and Xmax denote the minimum and maximum values in the original data feature, respectively.

This formula's application rescales the data, ensuring a balanced representation across features, enhancing the subsequent machine learning models' performance by reducing the potential bias that disproportionate data might introduce. The ensuing sections will delve into how these preprocessed data contribute to building a robust, intelligent system.

D. Machine Learning Model Training

In the realm of machine learning, particularly in clustering methodologies, understanding the concept of distance is crucial as it is fundamentally linked to how algorithms, such as KMeans and DBSCAN, group data points into distinct clusters based on inherent similarities or differences [51]. Both these algorithms employ the concept of Euclidean distance, a measure indicative of the 'straight line' distance between two points in a multi-dimensional space, often visualized through geometric planes in basic examples, but in practice, applicable to spaces with any number of dimensions.

Euclidean distance is pivotal because it quantifies the disparity between two entities, which is foundational for clustering. Essentially, a smaller Euclidean distance between two points signifies greater similarity, indicating that they belong to the same cluster or group. Conversely, a larger Euclidean distance is indicative of considerable dissimilarity, often signifying that the points pertain to different clusters [52].

In an n-dimensional space, which is common in machine learning applications due to the multiple features or variables considered, the Euclidean distance between two points—say, Point A and Point B—is calculated using the following mathematical formula [53]:

$$d = \sqrt{\left(A_1 - B_1\right)^2 + \left(A_2 - B_2\right)^2 + \ldots + \left(A_n - B_n\right)^2} \tag{2}$$

Or more succinctly,

$$d = \sqrt{\sum_{i=1}^{n} \left(A_i - B_i\right)^2} \tag{3}$$

Here, d represents the Euclidean distance, while Ai and Bi correspond to the coordinates of Points A and B, respectively, in the n-dimensional space. Each term within the summation accounts for a single dimension's contribution to the total distance, and the aggregation of these individual disparities across all dimensions provides a comprehensive measure of the overall distance between the two points.

This calculation becomes particularly significant in our context, where KMeans and DBSCAN are utilized for clustering based on flow statistics represented through 12 parameters. By leveraging Euclidean distance, these algorithms can effectively assess and quantify the similarity or dissimilarity between various data points (or flows), subsequently enabling the informed and logical grouping of these points into cohesive clusters.

This clustering, based on quantifiable measures, ensures a methodical and data-driven approach to categorization, essential for nuanced tasks like network traffic management, anomaly detection, or optimization in a Software-Defined Network (SDN) setting. It forms the basis for further analyses and decision-making processes that hinge on the understanding of data relationships and classifications in the multidimensional space that the dataset occupies.

IV. Experimental Results

In the investigative analysis encompassing the study, distinct scenarios were methodically examined to elucidate the performance metrics of various advanced computational algorithms, specifically focusing on Logistic Regression (LR), Support Vector Machine (SVM) with hyperparameters C valued at 1 and 100 respectively, Artificial Neural Networks (ANN), and Deep Learning (DL) techniques [54-56]. These algorithms were subjected to rigorous evaluation to discern their efficacy and responsiveness within the constructed scenarios.

The first scenario's results are meticulously documented, with the response times explicitly recorded in milliseconds. These outcomes are visually represented in Fig. 7. This format provides a clear, comparative analysis of the algorithms' performance under the conditions stipulated in the first scenario.

Conversely, the second scenario, crafted to perhaps challenge the algorithms under a different set of conditions or parameters, similarly culminates in a set of data denoting the response times, also captured in milliseconds. The results from this separate analytical run are graphically mapped out in Fig. 8. This dual-format display of results ensures a thorough interpretation of the data, aiding in the comparative scrutiny essential for holistic understanding.

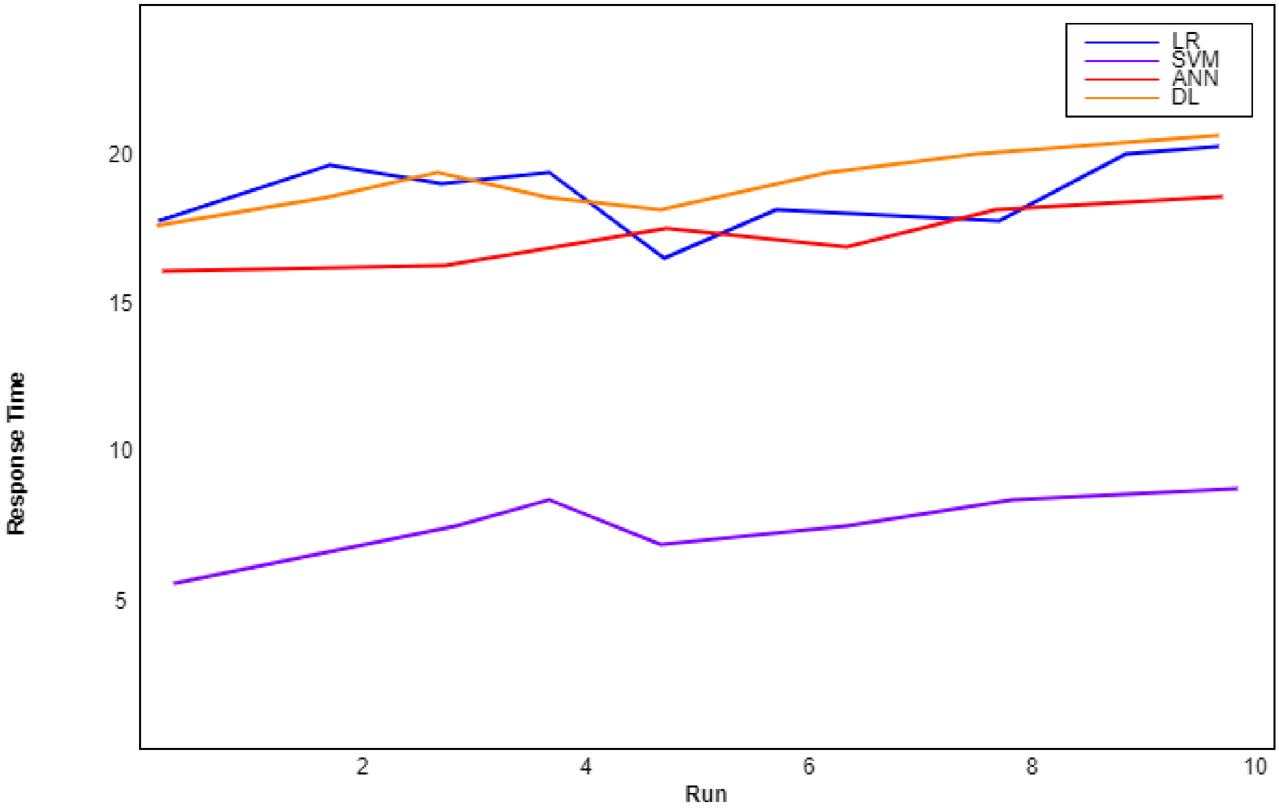

Fig. 7. Obtained results using machine learning methods in first case study.

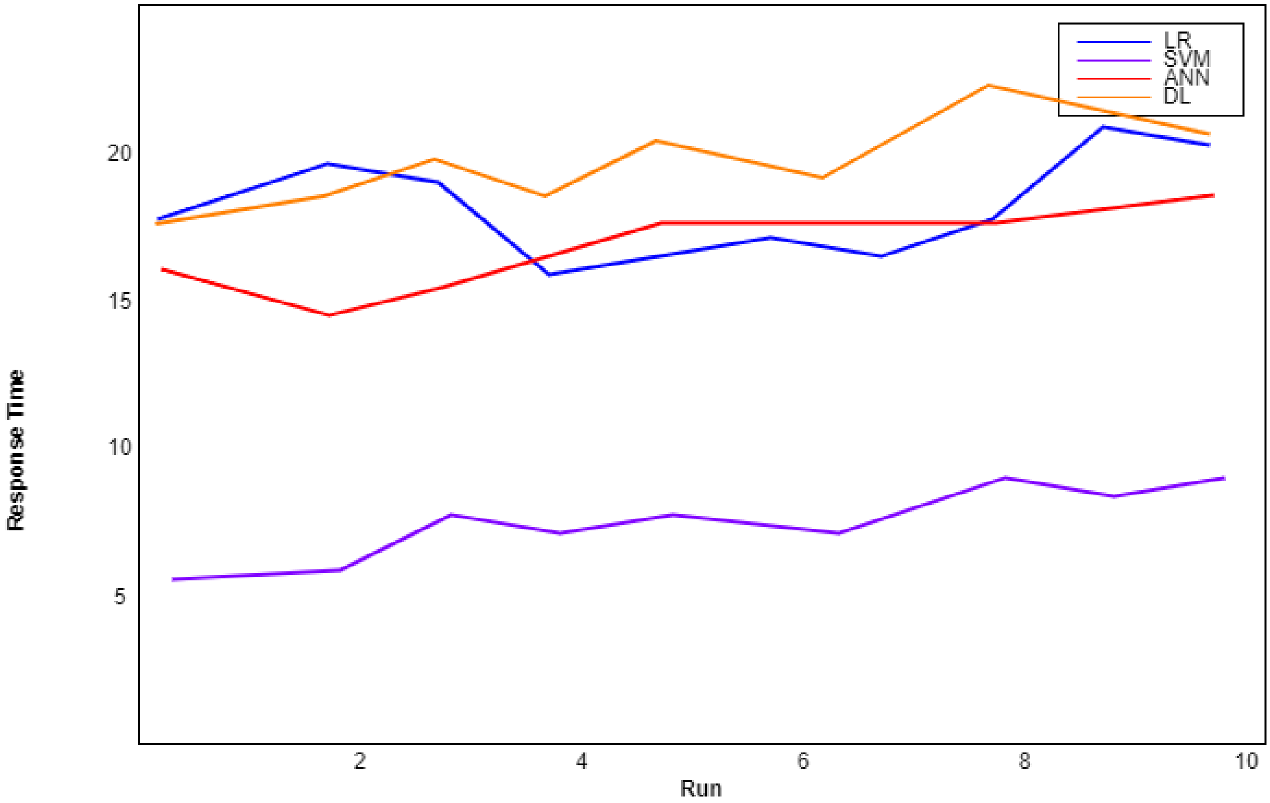

Fig. 8. Obtained results using machine learning methods in second case study.

Furthermore, an average response time was computed for each scenario, providing a consolidated metric that accounts for variance and anomalies by diluting them across multiple runs. This average was derived by executing each algorithm 100 consecutive times and then calculating the mean response time from the total accumulated data. This process, therefore, ensures the reliability and consistency of the results, acknowledging that a single run can be susceptible to anomalous external influences [57].

Such a meticulous approach to data representation not only underscores the rigorousness of the testing environment but also provides readers with a clear, unambiguous representation of each algorithm's performance. This systematic presentation and analysis are crucial for informed decision-making, further research, and practical applications of these algorithms in real-world scenarios. Fig. 9 demonstrates ROC curves of the applied machine learning methods for software defined networks.

Performance assessment stands as a pivotal component in the realm of machine learning (ML), particularly when it involves the critical evaluation of classification problems. One of the paramount tools in this evaluative arsenal is the Receiver Operating Characteristic (ROC) curve, an instrumental diagnostic graph that elucidates the competency of a classification model by displaying the trade-off between sensitivity (true positive rate) and specificity (false positive rate) across various thresholds [58].

The essence of the ROC curve lies in its capacity to illustrate the probability curve for distinct classes, thereby providing insightful commentary on the model's predictive acumen. It offers a graphical representation that is integral in comprehending how adeptly a model discerns between classes, underlining the probabilities that it correctly identifies true positives and true negatives. This finesse in estimation is paramount, as it significantly influences the decision-making processes.

In the context of the research at hand, the ROC curves were employed as an evaluative measure for distinct scenarios, each formulated to test the mettle of specific algorithms: Support Vector Machine (SVM) with regularization parameters C = 1 and C = 100, Artificial Neural Networks (ANN), and Deep Learning (DL). These scenarios, differentiated possibly by their unique datasets, conditions, or objectives, necessitated an assessment methodology that would impartially and accurately reflect the performance of each algorithm.

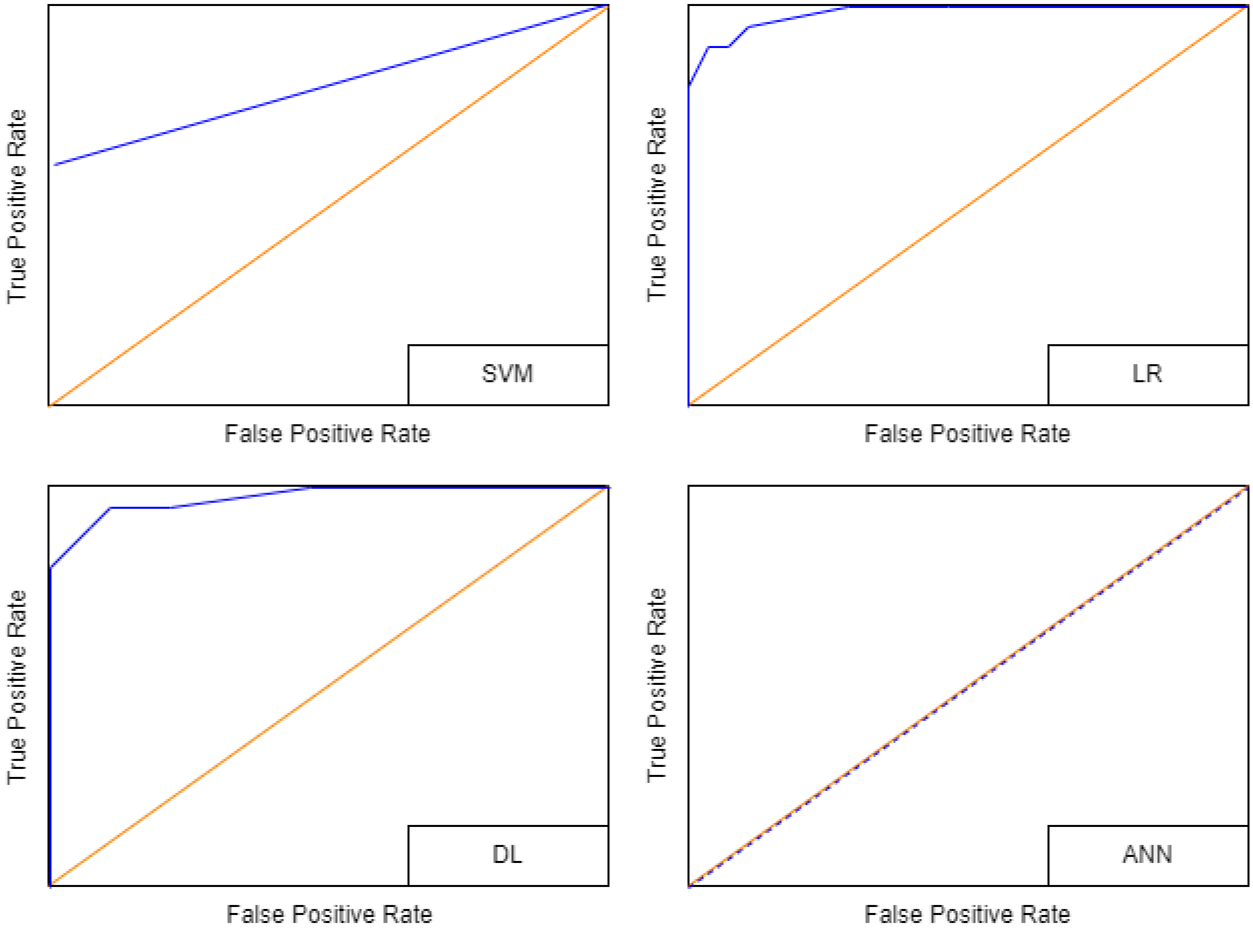

Fig. 9. ROC curves of different methods in applying machine learning for SDN.

The results of this meticulous evaluation are visually encapsulated in Fig. 9. Each figure corresponds to a different scenario and presents the ROC curves for the algorithms, thereby showcasing a comparative analysis of their performance in terms of sensitivity and specificity. This side-by-side portrayal of the ROC curves is instrumental in not only understanding the individual performance nuances of SVM, ANN, and DL within each scenario but also in drawing insightful inferences from their comparative capabilities [59].

Such analytical representations are invaluable, as they transcend mere numerical accuracy and delve into the model's ability to maintain robustness across varying class distributions and thresholds. This depth of analysis is imperative for the practical application of machine learning models, ensuring they are vetted not just on the scaffold of accuracy, but on their holistic performance and reliability in diverse operational environments.

V. Discussion

In the complex and rapidly evolving field of machine learning applied within Software-Defined Networks (SDNs), the current research initiates a nuanced dialogue, offering insights into a pioneering approach that leverages advanced algorithms for enhanced load balancing [60]. This discussion section delves into the multifaceted aspects of the study, critically analyzing the advantages, confronting the challenges, acknowledging limitations, and envisioning future trajectories.

A. Advantages

The integration of machine learning in SDN heralds a transformative phase in network management, primarily by introducing predictive analytics, automation, and adaptability. Firstly, the model's ability to predict traffic patterns and potential security threats stands as a testament to its predictive prowess, which traditional networking models lack [61]. By analyzing and learning from historical network data, the system can anticipate future loads, enabling proactive adjustments.

Moreover, automation in load balancing, facilitated by the employed machine learning techniques, significantly reduces the need for human intervention, thereby minimizing human errors and operational costs. It also frees up valuable human resources for more complex, creative tasks, enhancing productivity [62].

Furthermore, the adaptability inherent in machine learning models ensures that the system evolves with the changing network scenarios and traffic conditions. This dynamism stands in stark contrast to the static nature of traditional network configurations and is integral to managing the unpredictable, ever-changing demands on modern networks.

B. Challenges

However, the path to such integration is strewn with challenges. One of the foremost is the complexity involved in training the models. The chosen machine learning algorithms require substantial computational power and time, especially as the system scales, and the data volume grows.

Data security and privacy are other critical concerns. The necessity to collect, store, and analyze vast amounts of network data opens potential vulnerabilities for confidential information, necessitating robust security protocols that could increase overhead costs [63].

Moreover, the system's efficiency is contingent on the quality of the data fed into it. Inconsistent, incomplete, or biased data can skew the machine learning models' outcomes, leading to inaccurate predictions and suboptimal load balancing.

C. Limitations

Reflecting on the limitations of the current study underscores areas for improvement. The research predominantly focused on theoretical modeling and controlled environments, which may not fully simulate the unpredictability and heterogeneity of real-world network traffic [64].

The study's efficacy in a live environment, subjected to various unforeseen variables and security threats, remains unverified. Thus, the research, though sound in its theoretical foundation, necessitates empirical testing within a practical, operational network setting.

Another notable limitation is the selection of features and parameters for the machine learning models [65]. While the research justifies the chosen variables, there remains a question of whether other overlooked parameters could influence the load balancing process. Also, the algorithms' performance has been evaluated in isolation, without considering the potential synergies or conflicts that could arise from an integrated, multi-algorithm approach.

D. Future Directions

Addressing these limitations and challenges outlines the future trajectory of this research area. One immediate step is the transition from a controlled environment to real-world testing. Implementing the proposed model within operational SDNs will provide invaluable insights into its practical applicability and resilience, especially in the face of security threats and anomalous traffic patterns [66].

Considering the exponential growth in global data traffic, future studies must also explore models that can seamlessly scale, without a corresponding exponential demand on resources [67]. Such research could delve into more resource-efficient machine learning algorithms or hybrid models that combine the strengths of multiple algorithms to achieve more effective load balancing with lesser computational demand.

The aspect of security, given its centrality in network operations, also calls for dedicated exploration. Future research endeavors could focus on developing integrated security protocols within the machine learning models, ensuring that data privacy and network security are intrinsic to the system rather than afterthoughts.

Additionally, given the foundational role of data in machine learning, subsequent studies should investigate comprehensive, unbiased, and representative data collection methods. Enhancing the quality of input data can significantly bolster the accuracy and reliability of the predictions and decisions made by the machine learning models.

On a broader spectrum, there lies immense potential in interdisciplinary research, particularly integrating behavioral sciences with machine learning. Understanding the human aspects of network usage can add another layer of sophistication to predictive models, potentially leading to more intuitive, user-centric network management.

In conclusion, while the current study marks a significant stride towards revolutionizing SDN through machine learning, it also sets the stage for further, more nuanced exploration and innovation. The journey ahead, though demanding, holds the promise of networks that are not just smarter and more efficient but are also more in tune with the human elements they serve. Through collaborative, interdisciplinary, and forward-thinking research, the vision of truly intelligent, secure, and user-focused networks is an achievable horizon.

VI. Conclusion

The journey through this research, from conceptual frameworks to analytical discussions, reflects a profound exploration of integrating machine learning into Software-Defined Networking (SDN) to enhance load balancing. As we draw conclusions, it's imperative to encapsulate the essence of our findings and their implications for future scientific inquiry and practical application in the networking sphere.

This study marked a significant advancement by demonstrating that machine learning algorithms could revolutionize the way network resources are managed, optimizing the distribution of data loads across various pathways. By employing sophisticated algorithms, we unveiled the potential to predict network congestions, dynamically adjust to traffic changes, and improve overall efficiency and user experience. This paradigm shift from traditional methods accentuates a move towards more autonomous, self-sufficient systems capable of sophisticated decision-making processes, essential in the burgeoning era of digital transformation and the Internet of Things (IoT).

However, the research also highlighted critical challenges and limitations, from the complexities of algorithm training and data security concerns to the practical applicability of the proposed model outside simulated environments. These challenges are not terminuses but instead signposts indicating areas requiring further exploration, refinement, and innovation.

Looking forward, the implications of this research are both broad and profound. They suggest an imminent need for robust, real-world testing and the potential for interdisciplinary approaches that could further enrich these technological advances. The prospects of enhanced security measures, scalability considerations, and user-centric adaptations also present exciting, necessary trajectories.

In conclusion, this study does not represent an end but a beginning. It serves as a catalyst for continued exploration and dialogue in the realms of machine learning, networking, and beyond. The confluence of these fields holds significant promise for creating more resilient, efficient, and intelligent networks, poised to support the ever-evolving demands of future digital landscapes.

A Comprehensive Review of Healthcare Prediction using Data Science with Deep Learning

Asha Latha Thandu, Pradeepini Gera
Department of Computer Science and Engineering, Koneru Laksmaiah Education Foundation,
Vaddeswaram, Andhra Pradesh, 500302, India

***Abstract*—Data science in healthcare prediction technology can identify diseases and spot even the smallest changes in the patient's health factors and prevent the diseases. Several factors make data science crucial to healthcare today the most important among them is the competitive demand for valuable information in the healthcare systems. The data science technology along with Deep Learning (DL) techniques creates medical records, disease diagnosis, and especially, real-time monitoring of patients. Each DL algorithm performs differently using different datasets. The impacts on different predictive results may be affects overall results. The variability of prognostic results is large in the clinical decision-making process. Consequently, it is necessary to understand the several DL algorithms required for handling big amount of data in healthcare sector. Therefore, this review paper highlights the basic DL algorithms used for prediction, classification and explains how they are used in the healthcare sector. The goal of this review is to provide a clear overview of data science technologies in healthcare solutions. The analysis determines that each DL algorithm have several negativities. The optimal method is necessary for critical healthcare prediction data. This review also offers several examples of data science and DL to diagnose upcoming trends on the healthcare system.**

Keywords—Data science; deep belief network; healthcare; sparse auto encoder; deep learning

I. Introduction

Many studies have been conducted over the years on how to enhance the management and administration activities of the health sector and especially, healthcare offered to its patient [1]. Currently, the need of healthcare data is growing at an exponential rate in the healthcare system. From this point of view, the deployment of technology that is capable of being used in a creative way for the organization to help it achieve its goals is critical [2-5]. More preventive treatment options are becoming possible due to the use of health data analytics, especially predictive analytics. Despite access to a large amount of data, the healthcare industry lacks actionable knowledge that can be used to make predictions [6-10]. Despite its abundance, this is due to the fact that that health data is basically complex and fragmented [11]. Critical care, which is part of the health sector, faces the problem of increasing population and economic pressures, due to which it is difficult for most people to get the appropriate treatments. When talking to Intensive Care Unit (ICU) their condition often changes with every movement [12-14]. Likewise, with the advancement of technology in the healthcare sector an expectations of the patients are increasing but due to rising inflation, the required services cannot be provided. The main problem is to provide better, more effective care [15-17].

A data science solution for the analysis of healthcare data can help save patient lives and improve our quality of life [18-20]. Data science deals with several topics, such as data management and analysis, make correct decisions to improve the operation or system services (for instance, healthcare and transportation systems) [21-23]. In addition, with some very innovative and insightful techniques for displaying big data post-analysis, it is now easier to understand how any complex system works [24]. Due to the complexity of the healthcare system and operations, healthcare data are frequently fragmented. For example, different hospitals are only allowed to view clinical data of patients belonging to their specific patient groups [25]. These documents include highly Private Health Information (PHI) about specific individuals. This section examines the state-of-the-art in healthcare prediction using six deep representative architectures. Table I provides comparison of existing surveys with our survey.

The analysis shows that none of the studies carried out data science technology in healthcare prediction. Thus, this survey focuses on data science technologies in healthcare prediction. The contribution of this review is explained as follows:

- This review describes importance of data science technology in healthcare prediction in detail.
- Several deep learning technologies and applications used data science technology are analyzed for healthcare prediction.
- This survey helps researchers to diagnose the potential challenges in healthcare industry.

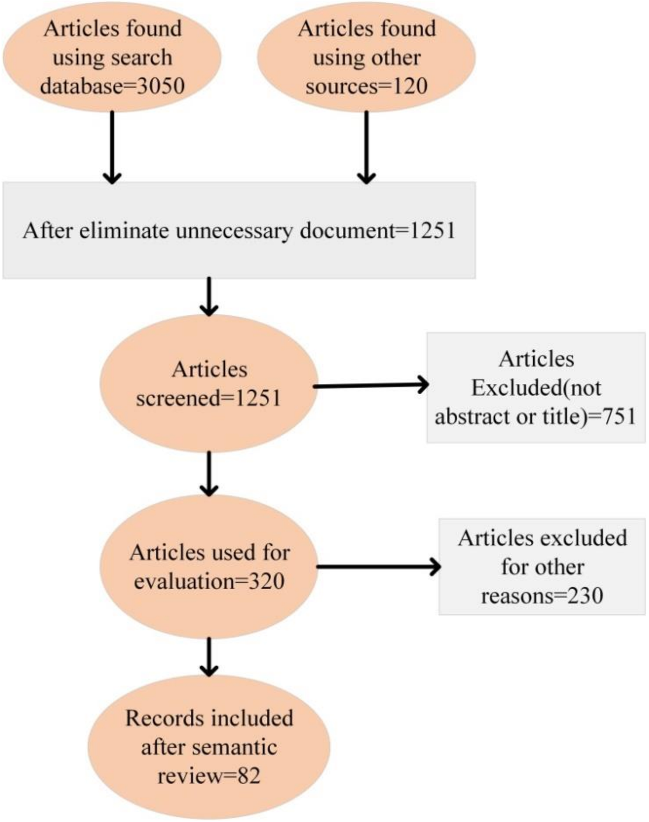
A. Data Collection

The searching keywords which are used in the above-mentioned databases like: “Healthcare Prediction” is demanded in every search abstract. It is a usual technique and consuming time as well. Also, searched for various synonyms and related keywords which meets the review outcomes such as, “Deep learning technology using data science technology”, “Applications in data science”, “Disease prediction using data science technology”, “healthcare monitoring” and “predictive analysis”. Again, refined the query to meet the particular outputs and again applied on Abstract and Title of the research article.

TABLE I. COMPARISON OF EXISTING SURVEYS

Author	Year	Description	Advantages	Drawbacks
Wang Y et al. [77]	2018	Analyzed benefits of big data based on information technology infrastructure, managerial, organizational, operational, and strategic areas	This study employs a clear vision about how healthcare organizations are using big data analytics	The limitation of this study is source of data because of the IT adoption lags behind other industries in healthcare sector
Shirazi S et al. [73]	2019	Discussed data mining approaches and algorithms in healthcare domain	Classifying data mining papers regarding unsupervised and supervised learning algorithms	Didn't give a clear vision of the applications of data mining technologies.
Bohr A and Memarzadeh K [78]	2020	Discussed major applications in artificial intelligence	Detailed research on applications directly related to healthcare and applications across the healthcare value chain including ambient assisted living and drug development	There is no detail about the different types of deep learning techniques
Li W et al. [79]	2021	Examined machine learning applications for big data in the healthcare sector	This survey examines basic big data concepts and relationship between big data and IoT	This review didn't provide detail about disease prediction using ML techniques like covid-19, mental health
Ours	-	To offer an overview of data science technologies in healthcare prediction	Detailed review about various deep learning technologies and applications using data science technology	-

On searched articles, implements a quality assessment procedure following inclusion and exclusion constraints. Derived 3050 articles depends on the common keywords from several journals from different sources, such as Springer, ACM, IEEE Xplore, and Science Direct. Further, excluded some research papers that are not related to this study based on the heading. Fig. 1 shows flow chart of article selection procedure.



Articles found using search database=3050
Articles found using other sources=120
After eliminate unnecessary document=1251
Articles screened=1251
Articles Excluded(not abstract or title)=751
Articles used for evaluation=320
Articles excluded for other reasons=230
Records included after semantic review=82

Fig. 1. Flowchart of article selection process.

II. HEALTHCARE PREDICTION REVIEW METHODOLOGY USING VARIOUS DEEP LEARNING CLASSIFIERS

In this section, healthcare prediction review methodology using deep learning classifiers are explained. Fig. 2 represents the taxonomy of the Healthcare prediction review.

A. Healthcare Prediction using Data Science

1) Data acquisition: HealthData.gov, Big Cities Health Inventory Data Platform, Chronic Disease Data, Human Mortality Database, Mental Disorders Datasets, MHealth Dataset, Medicare Provider Utilization and Payment Data, Life Science Database Archive, and WHO (World Health Organization) are some of the general datasets [26] used in this study to gather information on healthcare. The "precision medicine initiative" relates to healthcare. It sought to map the human genomes of one million United states residents, identify specific genetic defects that underlie a specific disease in a population, and effectively direct the development of drugs that are capable of precisely addressing a subcategory of molecular problems distributed by patients with a particular illness. Clinical, genetic features, and pathological can be included in IBM Watson for Healthcare, which can then provide standardized therapeutic paths and personalized therapy suggestions based on those features. By using DL algorithms, the enclitic firm (San Francisco, CA, USA) improves diagnostic performance in minimum time and in decreased costs using healthcare images (like MRIs and X-rays). Another excellent application is google flu trends, which uses monitoring data from laboratories around the US to forecast influenza-like disease than twice of doctor's visits. Major research institutes, centers, and funding organizations have been able to invest in this field due to the significant role of these technologies in clinical and medical research. Along with health information systems, data science and DL techniques can be used to enhance healthcare management systems to meet the following objectives: cost reduction, fewer hospitalizations and shorter lengths of stays, prevention of fraudulent activity, classification in disease patterns, strong health insurance, and more efficient use of healthcare resources. The upcoming sections provide multiple application instances based on the various types of biomedical data, including biomedical time signals, biomedical images, and other biomedical information from wearable system, lab findings, and genomics. Modern biomedical equipment generates electrical signals from skin-mounted sensors, the features of which depend on the position of the sensor. These signals are an invaluable source of information for identifying and diagnosing diseases. By utilizing physiological signals like ElectroMyoGrams (EMG), ElectroEncephaloGrams (EEG), ElectroOculoGrams (EOG), and ElectroCardioGrams (ECG), DL can generate reliable applications.

Fig. 2. Taxonomy of the healthcare prediction review.

Recently, the importance of data from EHRs has increased. These records contain substantial volumes of formless text including physical exams, medical lab results, operation notes, and discharge that are still difficult to approach. To support clinical decision-making system, natural language processing depending on deep learning is used to gather important data from the text. For instance, an application is used to identify healthy and patients with peripheral arterial disease by extracting necessary text data related to the condition from narrative clinical notes. Measuring the semantic similarity of medical concepts is a challenge that is critical to several strategies in information retrieval and medical informatics. A Big Data (BD) framework has more recently been used to analyze the issue of preventing and treating Acute Coronary Syndrome (ACS). A multitask learning architecture based on adversarial learning techniques was presented to detect significant adverse cardiac events from ACS patients' EHR data. This adversarial learning frame work outperforms single-subtype focused models in terms of average prediction, when the three subcategories of ACS are included in the detection. Regardless of the subtypes, the parameter distributions of common features are comparable across true-positive and false-positive samples as well as between true-negative and false-negative samples. This occurs due to the small amount of patient samples are available in the patients record. This demonstrates the potential benefits of Big Data (BD) approaches, resides not only in the need to extract a significant amount of data from heterogeneous HER, but also in the development of DL procedure that can: (1) Deal with the diversity (in images, text, radiological reports, etc.); (2) Reduce over-fitting and enhance the generalization capability; (3) Deal with the uncertainty that the missing information presents (common in EHR). These difficulties are not the latest ones, and there are still unresolved ones in the ML community. Therefore, this work is reviewed using a several deep learning techniques and applications.

B. Deep Learning Methods for Health Care Prediction

In order to capture hierarchical relationship incorporated in deep features, DL has emerged as one of the primary study issues in the field of prognostics due to the fast growth of computing infrastructure. The deep network structure with numerous layers stacked in the network to completely capture the relevant data from the initial input data. In numerous domains, including image identification, audio recognition, and natural language processing, DL models have attracted significant interest and achieved notable successes. However, in the area of healthcare prediction, it has not yet been completely utilized. Six sample deep architectures—Deep Belief Network (DBN) [27], Convolutional Neural Network (CNN) [28], Recurrent Neural Network (RNN) [29], Long Short-Term Memory (LSTM) [30], Auto-encoder [31], and Sparse auto encoder [32]—were primarily the focus on the published research on DL. Based on these six exemplary deep architectures, this section aims to examine existing techniques.

The deep learning methods are, DBNs, CNN, RNN, LSTM, Auto encoders (AEs), and sparse Autoencoders (SAEs). Fig. 3 shows deep learning classifiers used in Health care prediction.

1) Deep belief network: A stack of Restricted Boltzmann Machines (RBMs) called the DBN consists of higher-order BMs as well as feature-identifying units on a single layer in BMs. The greedy layer-wise learning procedure of RBMs may pre-train the approach in an unsupervised manner with no limitations on the volume of training data.

A DBN is a generative statistical approach that can learns deep representations of input data. It stimulates the combined distribution of the hidden layers and the observable data. The RBM, an energy-based generative approach consisting of input layers, hidden layers, and symmetric networks between them, is one example of a basic, unsupervised network known as a DBN. In this situation, the incoming RBM uses the current hidden layer as its input layer.

Convolutional Neural Network (CNN)
Recurrent Neural Network (RNN)
Long Short-Term Memory (LSTM)
Auto Encoder (AE)
Sparse Auto encoder (SAE)

Fig. 3. Deep learning techniques used in Healthcare prediction.

The backpropagation technique may also be used to adjust the whole network. A rapid, layer-by-layer unsupervised architecture is created as a result of this composition, and it has since emerged as the most powerful DL algorithms. The capacity of DBN to recreate the input in an unsupervised manner is one of its standout features. For this reason, it has been used to carry out effective unsupervised feature learning in the fields of healthcare and transportation. For instance, the study used DBN to identify health care in input data. DBN is thought to learn poorly for anomalous samples while rebuilding the input, which often leads to significant reconstruction errors. Setting an error threshold enables the efficient detection of aberrant data.

Fig. 4 depicts CNN's framework structure. Every CNN has input, output, and hidden layers. There are several function layers in the invisible layer. Most functional layers are composed of convolutional, pooling, fully connected, and normalized layers. The foundation of CNN is the convolutional layer. The input amount is calculated by each filter in the convolution process using a dot operation. The attributes are not explicitly extracted from the data by the convolutional layer. The Eq. (1) is utilized to compute it.

$$(f*h)(t)\underline{\underline{def}}\int_{-\infty}^{\infty} f(\Gamma)h(t-\Gamma)d\Gamma \tag{1}$$

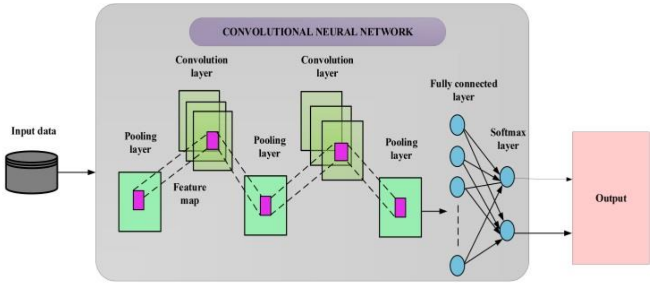

Fig. 4. Framework of CNN.

where, $(f*h)(t)$ are convolution of two functions f and h at time domain t. $\underline{\underline{def}}$ represents the definition sign, $h(t-\Gamma)$ denotes the weighting function and $f(\Gamma)$ represents the input function. Convolution is the multiplication of the function that has been moved and inverted in the equation above.

The pooling layer for CNN includes both local and global pooling. The assessment of healthcare data is lowered when output neurons and a particular neuron are merged. Through pooling, the maximum and average value of neurons are determined.

This fully connected layer is also called a thick layer. It is situated in CNN's last section. The neurons in this connected layer are entirely connected to all of the activation layers from the preceding stage. Each neuron is composed of a single layer that is joined to another layer by a substantial layer.

This activation layer enables the network to plot the nonlinear function versus the complicated action. This is divided into two categories: saturated activation and non-saturated activation. The activation is referred to as being saturated when there are no output constraints; otherwise, it is referred to as non-saturated. The CNN framework successfully learns the structural properties of the data by taking into consideration the spatial and temporal information that is included in the data. As a consequence, calculation time is decreased, and classification accuracy is improved.

2) Recurrent neural network: An RNN is a complex design that can interpret dynamic input because it has feedback links from hidden or output layers to the previous layer. The common design for incoming data, including temperature-time series data and pressure-time, is sequential data. Although RNN is the popular sequential modelling approaches, it has limits on long-term Remaining Useful Life (RUL) forecasts due to the inability of the trained network's weights to identify trends as a result of weight updates made when each input pattern was presented. Because of this, researchers have created the LSTM, which overcomes problems with long-term time dependence by employing input gates, forget gates, and output gates to manage information flow. In many sequential applications, the RNN and its variation, the LSTM networks, have gained considerable popularity. In recent years, healthcare prediction researchers have begun to investigate the potential of RNN, particularly LSTM. The extended kalman filter, truncated back propagation via time gradient computation, and evolutionary algorithms make up the RNN training algorithm. RNN are employed in this method to classify the health prediction data. An explanation of the classifier is given below.

There are various input layers (Y1, Y2), numerous hidden levels, and only one output layer in the recurrent neural network. The construction of RNN is seen in Fig. 5.

Healthcare detection is categorized using an RNN classifier. Healthcare input data are computed by RNN. There are several hidden layers to it. For the purpose of receiving output healthcare data, the network is connected to the proper layer. The input parameter for the network is weights and biases. The irrelevant data in each layer may be computed using the soft sign activation function as shown in Eq. (2),

$$f(y)=\frac{y}{1+|y|} \tag{2}$$

In the above equation, input features of the network are denoted as y.

The hidden layer's output is given in Eq. (3),

$$l_t = g(Z_l y_s + V_l l_{s-1} + a_l) \tag{3}$$

In the above equation, Y_s represents input data, l_t represents hidden layer, Z_l and V_l represents network weighted value, a_l represents biases, l_{s-1} denotes the previous state of the hidden layer and $g(\ )$ represents activation function.

By employing the Gaussian activation function, the determined outcome is given to the input of next layer to detect the healthcare data. Gaussian output is calculated as in Eq. (4),

$$Gaussion = e^{-y^2} \tag{4}$$

where, $Gaussion$ denotes the output of gaussian function, y be the variable. Then the total output is computed as in Eq. (5).

$$x_s = f(Z_x l_s + a_x) \tag{5}$$

In above equation, x_s represents the network output, l_s represents hidden layer, Z_x represents network weighted value, a_x represents biases and $f(\ )$ represents activation function. It results higher precision with lower execution time.

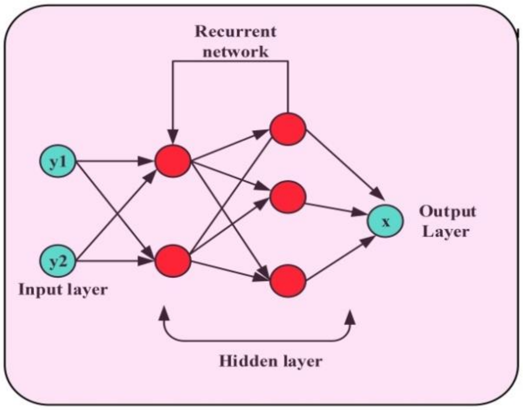

Fig. 5. Construction of RNN.

3) Long short-term memory: The LSTM network is a category of DL network created especially for linear data processing. An advantage of LSTM is their ability to retain both short-term and long-term values. Each cell in an LSTM unit has inputs, outputs, and forget gates. These three gates control the flow of information. By looking at the health prediction data, this LSTM categorizes the healthcare data in data science technology.

Numerous additional researchers have focused their attention on LSTM applications. LSTM, a kind of RNN for modelling long-term dependencies, was developed to solve the difficulties of time-series data. Like ordinary RNNs, LSTMs contain a memory for replicating the hidden layer activation patterns. Data processing involves hidden layer activations replicated iteratively.

The field of healthcare is paying more and more attention to LSTM models. According to sensor information such as blood pressure, temperature, and the results of lab tests, an LSTM model was employed as an example to diagnose healthcare data in a hospital setting. Similar to this, an LSTM model was applied to forecast examination outcomes based on prior measures. DeepCare is an LSTM-based system that is used to forecast future healthcare outcomes and infer the current sickness condition. A growing corpus of research has also focused on employing LSTMs to extract detailed data from medical texts like scientific publications, such as names of medications or medical occurrences.

4) Auto-encoder: The input data's encoder and decoder phases are rebuilt so that the Auto Encoder (AE) can learn a different representation of the information. As a result, it is frequently utilized for network pretraining. The stacked SAE, which combines multilayer AE such as denoising AE and SAE, is widely used Deep Neural Network (DNN) methods for handling the data. The main use of AE models in deep health monitoring is defect diagnosis. There are very few direct uses of AE in healthcare prediction in the literature; instead, AE is often employed to derive degradation features.

The unsupervised mode is applied when a hidden layer recreates the input layer in auto-encoders. Dimensions are allocated, in contrast to RNN, which incorporates weights and bias from the input layer to the hidden layer. The non-linear transformation function is utilized to calculate the stimulation of the hidden layer, which has lower dimensions compared to the input layer. Meanwhile, the input displays a dominating structure when the hidden layer size is decreased. To understand the identity function, non-linearity function should not be included, and the hidden layer and input layer dimensions should remain unchanged.

There are two subcategories of autoencoders. The first subcategory is denoising auto-encoder, and the approach is suggested to stop learning from becoming a simple problem. In this case, the input is rebuilt using noise that has been corrupted. Stacked auto-encoders are another form; they are created by stacking one auto-encoder layer on top of another. Each layer is trained separately to anticipate the output in healthcare applications, and the entire network is tweaked using supervised learning techniques. The architecture of AEs is symmetrical, with the equal number of nodes in both the input layer and the output layer. The employment of AE has advantages such as dimensionality reduction and feature learning. However, there are certain problems with dimension reduction and feature extraction in AE. The code of AE's emphasis on minimizing data relationship loss results in the loss of several crucial data relationships. Its classification equation is given in Eq. (6),

$$\beta, \chi = \arg\min_{\beta,\chi} E\left(Y, \left(\chi \circ \beta\right) Y\right) \tag{6}$$

where, β is represented as the encoder, χ is represented as the decoder, E is represented as the error between input and output, Y is represented as the input data, $\arg\min_{\beta,\chi}$ Minimum augmented of encoder and decoder.

5) Sparse auto encoder: The SAE is simply applying sparse constraints to the AE code. The unseen layer has more neurons than the input layer and output layer combined. While some of these neurons have a propensity to zero, others are similar to the input neurons. These are a few advantages of sparsity: The Sparse Auto Encoder's Structure is depicted in Fig. 6.

- The model's anti-noise performance is enhanced over that of the original AE because it facilitates the extraction of key input characteristics.
- Sparseness is easier to understand and explain because it is satisfied by the majority of real-world circumstances.

The classification of healthcare prediction using SAE equation is given inEq. (7),

$$SAE = E + \alpha \sum_{i} KL^{'}\left(\rho \| \hat{\rho}_i\right) \tag{7}$$

where, SAE represents the output of sparse autoencoder, $KL^{'}$ is represented as the kullback-leibler divergence, $KL^{'}$ divergence is known as the benchmark function that measures the effectiveness of different two disseminations are ρ and $\hat{\rho}$, ρ are represented as the anticipated neuronal network activity level, $\hat{\rho}$ indicates the average level of activation with i^{th} neuron, α maintains the weight parameter.

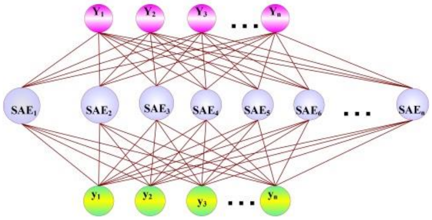

Fig. 6. Structure of Sparse auto encoder.

C. Comparison of Various Mechanisms on Healthcare Prediction

In this section, comparison of different DL techniques is reviewed based on the strength and weakness of several DL models used for healthcare prediction. This review also considers accuracy term for comparison to determine the effectiveness of each model. Table II provides comparison of previously published research works advantages and their disadvantages.

TABLE II. REVIEW OF EXISTING WORKS ADVANTAGE AND DISADVANTAGE

Reference	Aim	Used technique	DL technique	Accuracy	Positives	Negatives	Scope for improvements
Lu et al. [33]	Cardiovascular disease prediction	DBN	DBN	91.26%	Good stability	Minimum accuracy rate	Applying implemented model in terms of depth learning for cardiovascular prediction
Ali et al. [34]	Heart disease prediction	Optimally Configured and Improved DBN (OCI-DBN	DBN	94.61%	Supports doctors to take efficient decisions	Not consider time complexity	Time complexity for the suggested technique will be computed because it most necessary factor in healthcare
Elkholy et al. [35]	Chronic kidney disease prediction	Modified DBN	DBN	98.5%	Beneficial for clinical decision making	Not support for unbalanced dataset	-
Javeed at al. [36]	Human behavior recognition model	Sustainable Healthcare Pattern Recognition (SPHR)	DBN	93.33% and 92.50%	Autonomous feature extraction reduces the dependency on domain expert	It gives lower accuracy for static activities	To perform the suggested model on complex activities
Pan et al. [37]	Heart disease prediction	Enhanced Deep learning assisted Convolutional Neural Network (EDCNN)	CNN	94.9%	Supports specialists to forecast information about heart patient using cloud platforms wherever in the world	Not applied in a real-world	Performance is further improved using feature selection techniques
Chung et al. [38]	Healthcare recommendations	CNN	CNN	90.1%	A dynamic cluster mechanism was suggested as well as prediction accuracy improved based	This recommendations system not suitable for symbolic	Further work can be extended to support symbolic knowledge expansion framework

					on user environment, which changes over time and has dynamic components rather than static components in terms of environmental factors	knowledge expansion framework	using AI techniques
Gaur et al. [39]	Covid-19 detection	Deep CNN	CNN	92.93%	Appropriate for mobile applications	Less amount of X-ray images was used for implementation	Several deep learning approaches and models will be implemented for further research work
Younis et al. [40]	Brain tumor prediction	Visual Geometry Group (VGG16)	CNN	98.14%	The work uses MRI images to classify brain tumors and to support in making fast, effective and correct decisions	Different types of cancer attacks cannot be identified.	Future work will be considered to differentiate brain tumor affected region from unaffected area precisely
Kim et al. [41]	Prediction of five chronic diseases	Character-RNN (Char-RNN)	RNN	77.6%, 82.6%, 80.6%, 82.5%, 96.5%	Efficiency for several chronic disease prediction	This mechanism was applied only to the Korean peoples	Need to apply the suggested model to different ethnicities and lifestyle habits
Zhu et al. [42]	Prediction of future glucose levels	Dilated Recurrent Neural Network (DRNN)	RNN	-	This approach performs better than existing forecasting algorithms	Inaccurate prediction.	In future, the suggested method will be embedded with IoT app
Feng et al. [43]	Healthcare prediction for football players	Smart football player health prediction approach	RNN	81%	Better reliability	Less prediction rate	-
Ma et al. [44]	Parkinson’s chronic disease prediction	Self-attention and RNN	RNN	93.55%	Better Parkinson’s prediction skills	Not implemented in real-time	-
Carrillo-Moreno et al. [45]	Glucose predictor	LSTM	LSTM	-	To offer best prediction to patient, the suggested classifier validates several prediction times and input dimensions	This system considers only three parameters for glucose prediction	Adding few more parameters in the prediction system and computing the importance of these parameters for glucose prediction
Said et al. [46]	Covid-19 detection	Bi-directional LSTM (Bi-LSTM)	LSTM	-	Better detection performance	Experiment was conducted on data from the Qatar	Establishing lockdown relaxation scenario and analyze the impact of the relaxation
Mohamed et al. [47]	RNA mutation prediction	Seq2seq LSTM	LSTM	98.9% and 96.9%	The obtained outcomes illustrate the possibility of applying the LSTM network to RNA and DNA sequences in solving other sequencing problems	Improved computational complexity	-
Algarni et al. [48]	Human emotion recognition	Stacked Bi-LSTM	LSTM	99.45%, 96.87% and 96.68%	The model’s performance results help to make precise medical decisions	The Bi-LSTM provides complexity in weight initialization process	Applying new algorithms on several datasets to validate efficiency in emotion recognition
Mallick et al. [49]	Cancer detection using brain MRI images	Deep Wavelet Autoencoder (DWA)	AE	96%	Achieved good results	Reliability problems	Integrating other variation of AE with DNN
Mahendran et al. [50]	Signal compression	priority-based convolutional AE	AE	-	Zero construction error	Less performance	Improving performance by focusing on the CNN framework
Mansour et al. [51]	Covid-19 prediction	Unsupervised DL based Variational AE	AE	98.7% and 99.2%	Good classification performance	Not suitable for e-healthcare applications	The suggested model embedded with IoT and cloud-based environment
Khamparia et al. [52]	Chronic kidney disease classification	Stacked AE	AE	100%	Good accuracy	Not tested on large datasets	Testing larger datasets for disease classification.

Ebiaredoh-Mienye et al. [53]	Disease prediction	Enhanced SAE	SAE	98%, 97% and 91%	Efficient feature learning and better performance	It doesn't consider several parameters such as computational speed, classification time and etc.	The implemented model incorporated with decision support system to help doctors
Mienye et al. [54]	Heart disease prediction	Stacked SAE	SAE	97.3% and 96.1%	Significant importance in classification performance	Efficiency issues	Focusing on other stacking variation of AE to observe effects on classification performance
Aslam et al. [55]	Breath analysis	Stacked SAE	SAE	98.7% and 97.3%	More reliable	Not accurate	-
Gayathri et al. [56]	Covid-19 prediction	Feed forward neural network	SAE	95.78%	Achieved good accuracy	Not suitable for multi-classification	Covid-19 prediction using other modalities like ultrasound and CT

D. Multimedia Healthcare Applications using Deep Learning Technologies

An integration of several media or several types of data from multiple devices like texts, images, videos or audios called multimedia or multimodal data. To enhance the performance of the application, complementary information can be extracted from each modality by extracting multimodal data. Modality means encode information in a particular way. Various perspectives of a physiological objects using multimodal data provide additional information that can complementary to the analysis. Table III provides multimedia healthcare applications using DL algorithms.

TABLE III. HEALTHCARE APPLICATIONS USING DL ALGORITHMS

Author	**Applications**	**DL technique**	**Multimedia data**	**Database**
Gaur L et al. [39]	Covid-19 classification	Deep CNN	Chest X-ray	Covid-19 radiography database and actualmed-covid-cheat x-ray dataset
Alhussein M and Muhammad G [80]	Voice pathology prediction	Parallel CNN	Voice signals	Saarbrucken Voice Database
Algarni M et al. [48]	Emotion recognition	Bi-LSTM	EEG signal	DEAP dataset
Mukherjee D et al. [81]	Human activity recognition	EnsemConvNet	Time series of data	WISDM dataset, MobiAct dataset, UniMiB SHAR dataset
Yu Z et al. [82]	Disease Prediction	Deep Factorization Machine	Patients medical history	2020 artificial intelligence challenge preliminary competition

E. Applications in Data Science Technology

Different applications of data science in healthcare prediction is explained in this section. This review considers different applications including speech therapy, disease detection, drug discovery, health monitoring, genomics and decision support system.

1) Speech therapy: Speech therapy supports children and adults affected with communication disorder to improve speech and languages. It supports with sound and voice production, early language skills, fluency and clarity. A speech therapist can use several types of therapy to support individuals with communication disorder related to fluency, speech, language, cognition, voice and swallowing. Mahmoud SS et al. (2020) [57] suggested assessment mechanism. Quadrature-based high-resolution time-frequency images with a CNN are used to detect the relationship between speech intensity and three speech intelligibility features in aphasic patients. The outcomes show a linear relationship with statistically significant correlations between the CNN model's normalized Truth-Class Output Functions (TCOA) and patients' pronunciation, tone scores, and fluency. Also, Bastanfard A et al. (2009) [58] proposed a new method that adopts image-based technique to combine visemes in persian by using coarticulation effect. The central frame was selected among various images for each phoneme defining various positions in different symbols. As a result of reconstruction, the weight value was established as criterion to compare viseme similarity. Experimental outcomes demonstrate the excellent precision and robustness of the suggested model.

2) Psychological prediction: This section explains specific DL algorithm used for disease detection including mental health, neurodevelopment disorder, and covid-19.

a) Mental health: In the real-word, the one of the most important and complex concern is auto diagnosis of mental health conditions. The mental health affects the way people behave, think and feel when they cooperate with world around them. Additionally, mental health issues are becoming a leading disability, contributing greatly to the global burden of disease. Du C et al. (2021) [59] designed a DL based Mental Health Monitoring System (DL-MHMS) for academy students. By using EEG signals, this suggested method used the effective CNN to categorize status of the mental health as normal, negative and positive. Zeberga K et al. (2023) [60] used Bidirectional Encoder Representations in Transformers (BERT) for excellently and efficiently recognizing anxiety and depression based posts by monitoring the context and semantic meaning of the words. Additionally, the knowledge distillation approach was proposed to transfer knowledge from a large pretrained model to a smaller model, which enhances accuracy. In last stage, BERT with Bi-LSTM and word2vec efficiently detects depression and anxiety symptoms.

b) Neurodevelopment disorders: Neurodevelopmental Disorders (NDs) affects brain functions as well as neurological developments, which causes problems in cognitive, social and emotional functioning. Some of the NDs are dyslexia, Autism Spectrum Disorder (ASD), and Attention Deficit Hyperactivity Disorder (ADHD). Sewani H et al. (2020) [61] offered an efficient prognosis of ASD using deep neural network particularly for children. This model integrates unsupervised learning, an AE and supervised DL using CNNs. The suggested approach performs better based on several validation and assessment measures. This model was tested on only 1112 rs-fMRI images. Minoofam SA et al. (2022) [62] suggested an adaptive reinforcement learning framework called RALF automatically generates content for students with dyslexia by Cellular Learning Automata (CLA). First, RALF creates samples of online alphabet as a simple form. The CLA system learns every instructions of character formation asynchronously using a reinforcement learning cycle. Then, generates persian words algorithmically. This stage determines the position of the character, cursiveness of the letters and the cell's response to the environment. At last, RALF uses embedded word-generation approach to generate long-texts and sentences. Spaces between words are obtained using CLA neighboring states. The developed model offers many tests and games to enhance word pronunciation and people's learning performance.

3) Covid-19 detection: More than five lakhs people died in India due to the covid-19. Generally, covid-19 often causes respiratory symptoms such as a cold, pneumonia or flu. Covid-19 can attack individuals' lungs and respiratory system. Panwar H et al. (2020) [63] offered a DL algorithm for rapidly prediction of covid-19 cases depending on CT scan and X-ray images because the X-ray images offers necessary information in the covid-19 recognition. The model can identify covid-19 positive cases in less than two seconds, which is quicker than RT-PCR test. Kogilavani SV et al. (2022) [64] proposed several CNN designs like VGG-19, Densenet121, MobileNet, NASNet, Xception and EfficientNet to identify covid-19. This model didn't detect covid-19 affected areas in the lungs.

4) Drug discovery: The importance of the drug discovery procedure is the advancement of novel drugs with potential interactions along with therapeutic targets. Drug discovery is depending on the conventional method, which focuses on holistic treatment. The medical communities of the world began to use the allopathic method to treatment and recovery in the last century. This change has led to victory in fighting against diseases, but has resulted in high healthcare burden and drug costs. Xiong Z et al. (2019) [65] introduced a novel graph neural network framework named Attentive FP to represent molecular, that used attention model to learn from suitable drug discovery datasets. The suggested approach achieves good performance on diverse datasets and that its learning is interpretable. The suggested Attentive FP automatically learns intramolecular interactions from specific tasks, helps derive chemical insights directly from data beyond human perception. ul Qamar MT et al. (2020) [66] analyzed the viral three-Chymotrypsin-Like cysteine protease enzymes, which is necessary for coronavirus lifecycle and controls its replication. This mechanism has been constructs 3D homology model by analyzing Chymotrypsin-Like cysteine protease sequences and screened it against a medicinal plant library comprising 32,297 potential anti-viral phytochemicals/ traditional Chinese medicinal compounds. The analysis demonstrates that the first nine hits the process of drug development to combat covid.

5) Healthcare monitoring: Data science serves important role in IoT. These devices consist of wearable devices that monitor heartbeat, temperature and medical parameters of the patients. Then, collected data is analyzed using data science. Based on the analytical results, doctors can able to monitor patient's circadian cycle, their BP, and calorie intake. Ali F et al. (2021) [67] recommended BD analytics engine depending on data mining approaches, ontologies and Bi-LSTM. The data mining approaches are employed to preprocess the healthcare data and dimensionality reduction. The suggested ontologies are used to learn semantic knowledge about entities and features, and their relationships in Blood Pressure (BP) and diabetes domain. Finally, Bi-LSTM classifier is suggested to categorize effects from the drug side and abnormal states in individuals. The obtained results of the suggested method correctly handle big amount of data and enhances classification accuracy and prediction of drug side effect. M Abd El-Aziz R et al. (2022) [68] suggested IoT supported health monitoring system, which improves the data processing efficiency with the rapid adoption of cloud computing and expands data access in the cloud. The collected information from the real-time environment was stored in the cloud for data science processing. In this, improved pigeon optimization was suggested to combine the stored data in the cloud that supported for enhancing prediction rate. Following that, feature extraction and selection are performed with the help of optimal feature selection approaches. To categorize human healthcare, Backtracking Search-Based DNN (BS-DNN) was suggested.

6) Genomics: Genomics is the study of the sequencing and analysis of genes. A genome contains DNA and all the genes of an organism. Since the compilation of the Human Genome Project, research has progressed rapidly and embedded itself in the data science and big data fields. Nasir MU et al. (2022) [69] suggested CNN based AlexNet to predict genome multi-class disorder for developing Advance Genome Disorder Prediction Model (AGDPM). This model was capable of genome disorder prediction and it uses large amount of data to processes patient's genome disorder data. The suggested prediction system improves biomedical system based on predict genetic disorders and reduces high mortality rates.

7) Decision support system: The goal of a Decision Support System (DSS) is to enhance healthcare delivery through improving clinical decisions with targeted clinical knowledge, patient data and other health related information.

Malmir B et al. (2017) [70] presented a DSS called Fuzzy Expert System(FES) to support doctors for better decision making in medical diagnosis. This suggested model conducts a cross-sectional study to gather information about diseases by asking clinicians on all signs based on diseases. According to this information, then fuzzy rule-based system with the necessary symptoms necessary signs based on the suspected disease was developed. To prove effectiveness of the suggested method, two case studies conducted on kidney stone and kidney infection. Khiabani SJ et al. (2022) [71] developed DSS in terms of neural network and statistical process control charts for identifying and control of Myocardial Infarction (MI) and continuous observing of patient BP. A group of patients was used to prove the suggested system's efficiency. The outcomes validate that the suggested model can detect MI by the parameter of accuracy and precision.

III. Results and Discussions

A review of data science and deep learning techniques for healthcare prediction with high accuracy is discussed in this section.

Fig. 7 illustrates the various deep learning techniques contributes to covid-19 prediction by the parameter of accuracy. The analysis demonstrate that the AE performs over other deep learning techniques including SAE, and CNN. But it is important to note that each work uses different datasets to prove its effectiveness. Correspondingly, the work based on AE [51] predicts covid-19 using chest x-ray images. It is necessary to diagnose covid-19 using other modalities such as CT, MRI and so on.

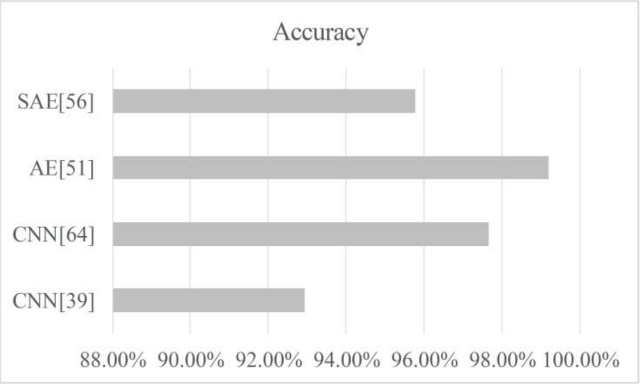

Fig. 7. Comparison of covid-19 detection using reviewed techniques.

Table IV shows the comparison of DL techniques in terms of precision and sensitivity for heart disease prediction. The analysis shows that the EDCCNN technique occurs better precision than other techniques. For the sensitivity analysis, the authors [54] uses optimized feature learning techniques, this supports to achieves a highest sensitivity of 100%.

Even though AI-based DL are efficiently predicting the data, some of the classifiers reduce the accuracy due to their limited data size, high dimensionality, efficient feature selection technique, model generalizability, and clinical implementation. The explanations for these limitations are given as follows:

1) *Limited data size:* One of the challenges facing this study was inadequate data for training the classifier. The less input data size allows a number of the training set, which reduces the accuracy of the presented methods. Hence, to improve the accuracy of the training samples and to train a large number of datasets new methods are used, which performs better than previous classifiers [72].

2) *High dimensionality:* High dimensionality is another problem faced by the previous methods. The input data set consists of number of data with a high number of features. The current methods face several high dimensionality issues for extracting the features. Hence, new feature-extracting methods are used to overcome these issues [73].

3) *Efficient feature selection technique:* Previously several feature selection and disease prediction methods were employed for predicting the disease in its early stage. But they are limited due to high computational complexity. To overcome this limitation, the most effective feature selection methods and pre-processing methods are used for predicting the data's higher accuracy [74].

4) *Model generalizability:* For improving the prediction results, a change in the research is needed based on the model's generalizability. Generalizability is used to analyze the results from highly populated situations with prediction methods. Previously there were several prediction methods for predicting the patient data in a single site. Nowadays, it is required to predict the patient data in multiple sites, and while improving the predicting data in multiple sites the model's generalizability is enhanced [75].

5) *Clinical implementation:* Finally, AI-based ML and DL methods have provided good results for predicting disease in DS in healthcare predictions. But still, this method faces issues in practical implementations with clinics that are not supported. In the current work, these AI methods are required to validate the clinical setting for assisting the doctor in confirming the findings and decisions [76].

TABLE IV. Comparison of Different Performance Metrics based on Heart Disease Prediction

Methods	Precision	Sensitivity
DBN [33]	-	-
OCI-DBN [34]	93.55%	96.03%
EDCNN [37]	99%	97.51%
Stacked SAE [54]	94.8%	100%

Many clinical elements are involved in EHR-based systems. There are millions of data points available for this. It would not be easy to manage and regulate the whole data of millions of people. There are several critical challenges yet to be overcome:

- There was a lot of unorganized or inaccurate data, making it tough to gain a more profound knowledge of it.

- It is difficult to strike the right balance between the preservation of patient-centric data and the excellence and convenience of this information.
- Keeping data private, storing it efficiently, and transferring it requires a lot of workforces to ensure that these requirements are met continuously.
- Lack of language proficiency when handling data.

IV. CONCLUSION

This manuscript proposes a review of data science and healthcare prediction in data science technology in order to forecast healthcare with high accuracy is successfully predicted. In this, the healthcare prediction is classified using deep learning classifiers based on health issues such as lab reports, medical imaging and EHR. In this, the deep learning classifiers are CNNs, RNN, LSTM, RBMs, DBNs, AEs and SAE. In healthcare services, the analysis shows that the existing approaches are not efficient to handle big data. Existing and future smart healthcare systems requires examinations about the design considerations such as maintainability, performance, accuracy, scalability, cost, security, responsiveness, fault tolerance, and reliability. It's hoped that this review paper will help many scholars to improve their knowledge for their future research work. Future research is planned to review machine and deep learning techniques with an approach that optimises healthcare data in different environment like IoT, cloud and so on.

***Abstract*—Autism spectrum disorder (ASD) is a neurodevelopmental condition characterized by deficits in social interaction, verbal and non-verbal communication, and is often associated with cognitive and neurobehavioral challenges. Timely screening and diagnosis of ASD are crucial for early educational planning, treatment, family support, and timely medical intervention. Manual diagnostic methods are time-consuming and labor-intensive, underscoring the need for automated approaches to assist caretakers and parents. While various researchers have employed machine learning and deep learning techniques for ASD diagnosis, existing models often fall short in capturing the complexity of multisite meltdowns and fully leveraging the interdependence among these meltdowns for severity assessment in acquired facial images of children, hindering the development of a comprehensive grading system. This paper introduces a novel approach using a Long Short Term Memory (LSTM) integrated Convolution Neural Network (CNN) designed to identify multisite meltdowns and exploit their interdependence for severity assessment in ASD. The process begins with image pre-processing, involving discrete convolution filters for noise removal and contrast enhancement to improve image quality. The enhanced image then undergoes instance segmentation using the Segment Anything model to identify significant regions in the child's image. The segmented region is subjected to principal component analysis for feature extraction, and these features are utilized by the LSTM-integrated CNN for meltdown detection and severity classification. The model is trained using children's images extracted from videos, and testing is performed on videos captured during children's observations. Performance analysis reveals superior results, with a training accuracy of 88% and validation accuracy of 84%, outperforming conventional methods. This innovative approach not only enhances the efficiency of ASD diagnosis but also provides a more nuanced understanding of multisite meltdowns and their impact on severity, contributing to the development of a robust grading system.**

Keywords*—Autism spectrum disorder; mutilating meltdown; convolution neural network; long short term memory; multisite meltdown; video classification; image classification

I. Introduction

Autism spectrum disorder (ASD) represents a complex neurodevelopmental syndrome characterized by a wide range of challenges in verbal and nonverbal communication skills, as well as behavioral and social interactions [1]. While ASD can manifest at any age, it typically becomes evident around the age of 2 or 3 when children start to withdraw, exhibit distinct behaviors, and present challenges in social engagement. The etiology of this disorder is diverse, and the underlying neurodevelopmental mechanisms are not fully understood [2].

The detection of a high degree of autism severity in a child is particularly concerning, as it often leads to the development of more frequent meltdowns. These meltdowns not only pose a risk of self-injury to the child but can also result in harm to caregivers or parents [3]. Early diagnosis of ASD is crucial, offering significant benefits in terms of intellectual development, adaptive behavior, and the reduction of overall severity. The advent of noninvasive acquisition technology has made disease diagnosis more feasible, but manual diagnosis remains a highly challenging and labor-intensive task. Consequently, there is a pressing need to develop an automated disease diagnosis tool for ASD.

In recent times, the pervasive influence of artificial intelligence (AI) has become increasingly apparent, bringing about transformative changes across a spectrum of fields and enriching various facets of our everyday existence [4,5]. It has redefined how we approach education [6], fine-tuned financial strategies [7], simplified agricultural workflows [8–16], and elevated healthcare diagnostics to new heights [17–23]. As it seamlessly integrates into these diverse sectors, AI continues to demonstrate its capacity for generating unparalleled efficiencies, refining decision-making procedures, and addressing intricate challenges with a precision derived from data-driven insights[24,25].

Researchers have turned to machine learning and deep learning approaches to enhance the accuracy of ASD diagnosis. These models leverage the concept of correlation and co-variation among spatio-temporal data. Specifically, Convolutional Neural Networks (CNNs) have proven highly capable of extracting features based on spatio-temporal descriptors to classify various gestures exhibited by ASD children. However, existing models have limitations, as they fail to compute the appearance of multisite meltdowns and fully exploit the interdependence among these meltdowns for severity computation in the acquired facial images of children, hindering the development of a comprehensive grading system [26].

This paper presents a novel approach, introducing a Long Short-Term Memory (LSTM) integrated Convolutional Neural Network designed to detect multisite meltdowns and exploit their interdependence for severity computation in ASD. The proposed methodology involves initial image pre-processing

*Correspondence: sumbulalam@presidencyuniversity.in (S.A); ygulzar@kfu.edu.sa (Y.G.)

using contrast enhancement and histogram equalization to improve image quality. The enhanced image is then subjected to an instance segmentation technique, termed the "segment anything" model, to identify significant regions in the child's image. These segmented regions undergo principal component analysis for feature extraction, which is then employed in the novel LSTM-integrated CNN [27] for meltdown detection and severity classification, achieving increased accuracy. The model is trained using images of children acquired from videos, and testing is conducted using videos acquired during children's observations.

The subsequent sections of the article are organized as follows: Section II provides a detailed problem statement and a review of the literature on detecting the meltdown state of autism spectrum disorder. Section III outlines the proposed deep learning methodology for detecting and classifying multisite meltdown states and their severity to establish a grading system. Section IV presents an experimental analysis of the proposed methodology on the disease dataset, including performance metrics such as accuracy through a confusion matrix. Finally, Section V concludes the work and offers future suggestions.

II. Related Work

In this part, numerous conventional approaches using machine learning and deep learning architecture to detect the autism spectrum disorder along meltdown state using behavioral and kinematics features has been detailed as follows:

A. *Autism Spectrum Disorder Detection using Restricted Kinematic Features*

In this literature, machine learning model is used to detect the Autism spectrum disorder using the restricted kinematic features from the kinematic data. In this computed on basis of movement during motor task. Entropy, amplitude, velocity, acceleration were considered as kinematic features and considered as symptom of the ASD. Machine learning classifier such as support vector machine were employed to classify or detect the ASD using the feature values which has cognitive flexibility and it has high manifestation [28].

B. *Autism Spectrum Disorder Detection using Autoencoder-based Support Vector Machine - Recursive Feature Elimination Technique*

In this literature, deep learning architecture is used to detect the ASD through functional connectivity features of the multiple regions. Functional connectivity feature is extracted and those features are employed to Recursive feature elimination technique to select the primitive features. Next, Autoencoder model is used to extract the high latent features and complicated features. It is considered as optimal features [29]. Those features were employed to softmax classifier which employs the Support vector machine to detect the ASD.

C. *Autism Spectrum Disorder and Meltdown Detection on Facial Geometric Features using Recurrent Neural Network*

In this literature, recurrent neural network is employed to detect and classify the autism spectrum disorder during the meltdown crisis. Initially model extracts the micro facial expression of children as geometric features and detects the child with autism or without autism. On detection of autism state , children is classified with severity of meltdown Hidden layer of the model process the feature to produce the optimal severity state of the children with meltdown [30].

D. *Autism Spectrum Disorder and Meltdown Detection using Recurrent Attention Network on Morphological Features*

In this literature, recurrent attention network is employed to detect and classify the autism spectrum disorder during the meltdown crisis. Initially model extracts the morphological features and detects the child with autism or without autism. On detection of autism state, children are classified with severity of meltdown. Attention layer of the model process the feature embedding to produce the optimal severity state of the children with meltdown with high efficiency [31].

E. *Autism Spectrum Disorder and Meltdown Detection using Deep Neural Network on Audio-based Features*

In this literature, deep neural network is employed to detect and classify the autism spectrum disorder during the meltdown crisis using audio based signals. Initially model extract the audio based features on transforming the speech data to mel spectrogram and those audio based feature like pitch, RMS and MFFS used to detect the child with autism or without autism. On detection of autism state, children are classified with severity of meltdown. Dense layer of the model process the features as embedding of features to produce the optimal severity state of the children with meltdown with high efficiency [32].

III. Proposed Model

In this section, we introduce a sophisticated system for grading multisite meltdowns and classifying the severity of autism spectrum disorder in children. Our approach integrates a Long Short-Term Memory (LSTM) with a Convolutional Neural Network (CNN) specifically tailored for assessing the intensity of meltdowns across various sites, encompassing expressions of distress such as crying, screaming, and stimming. The step-by-step processing to achieve this overarching objective is detailed below:

A. *Image Preprocessing- Discrete Convolution Filter*

This section outlines the application of noise reduction and contrast enhancement techniques to the acquired training images through the utilization of a discrete convolution filter. The initial phase of noise reduction in training images serves to eliminate blurriness, while the subsequent contrast enhancement enhances the overall image quality. The discrete convolution filter method, employed in this process, effectively heightens the sharpness of object edges within each image [33].

The discrete convolution filter method is instrumental in achieving this enhancement, producing a pronounced increase in edge sharpness. A special case of this method involves the averaging of brightness values, exemplified by the formula:

$$\text{f(i,j)=w*h=}\sum_{m=-a}^{a}\sum_{n=-b}^{b} w(m,n)h(i+m,j+n) \quad (1)$$

This Formula depicts a linear operation wherein the resulting value in the output image pixel f(i,j) is calculated as a linear combination of the brightness in a local neighborhood of the pixel h(i,j) in the input image. The function (w) in this context represents the convolution kernel, encapsulating the linear operations involved in this discrete convolution process.

B. Instance Segmentation - Segment Anything Model

The enhanced image undergoes application of the instance segmentation technique, known as the "Segment Anything" model, aimed at delineating significant regions within the child image. This model excels in segmenting every pixel with similar values, employing boundary probability algorithms (gPb and UCM) to calculate edge and its weight. A threshold is then applied for each pixel and its adjacent pixel to refine the segmentation process [34].

The instance segmentation process, as expressed by the following formula:

$$L(x,y)= \sum_{i=0}^{i<x,} \sum_{j=0}^{y<j} I(i,j) \text{ where } 0<x<N \text{ and } 0<y<M \quad (2)$$

Where $0<x<N$ and $0<y<M$, involves aggregating pixel values within the specified range, providing a comprehensive representation of the preprocessed image. To integrate similar pixels within edges, a connected component approach is employed. The result is a hierarchical organization of regions obtained through a coarse-to-fine process.

C. Feature Extraction - Principle Component Analysis

The application of Principal Component Analysis (PCA) serves as a pivotal step in discerning the normal and meltdown states of children with autism. PCA, leveraging spatio-temporal information within each frame, identifies highly discriminating features. The execution of PCA results in a set of training data characterized by disconnectedness among data points and dense similarity within classes [35].

The analysis extends to examining segmented objects across two consecutive frames of images, calculating and defining features at various focal points such as the left eye, right eye, right mouth corner, left mouth corner, and nose. Each principal component represents the maximum variance among these focal points. To handle the complexity of computing features in high dimensions, PCA effectively minimizes dimensions without significant loss of feature information through matrix formation and distance calculation.

The composed feature vectors encapsulate facial interest components. Given an image of size $N×N$, it is initially transformed into a 1D vector U, housing variance values of substantial magnitude. The variance for a specified feature X in an image is calculated by the formula:

$$\text{variance(y)} = \frac{\sum_{i=1}^{n} \text{b(yi – y) (yi – y)}}{n-1} \quad (3)$$

Furthermore, the covariance of features is calculated for the objects X and Y that change together with the mean, expressed as:

$$\text{Covariance(y,x)} = \frac{\sum_{i=1}^{n} \text{a(yi – y) (xi – x)}}{n-1} \quad (4)$$

The resulting Covariance Matrix, a $N×N$ feature matrix, is represented by:

$$M_{ij}\text{= Covariance(x,y)} \quad (5)$$

D. Eigen Vector Analysis for Facial Feature Classification

The computation involves deriving the Eigen vector, denoted as M_{ij}^{Eigen} , serving as a feature vector that encapsulates principle feature groups. These feature values are accompanied by Eigen values and are pivotal for the subsequent classification of facial features.

For each meltdown and normal state, the associated feature values fall within the range of 0 to 1. Here, 0 signifies the normal state, while 1 designates the meltdown state. Table I presents the Eigen vector, composed of features extracted specifically for the meltdown state.

TABLE I. LIST OF FEATURE EXTRACTED FOR MELTDOWN STATE

Feature	Description
Eyes Closed	Distance between two eye lids
Mouth Open	Distance between two lips
Lips enlargement	Radius of the lips
Object in ears	Hand in the ears
Object in head	Hand in the head or hair

These features provide a detailed description of facial expressions during the meltdown state, including eye and mouth behaviors, lip enlargement, and hand placements indicative of distress. The Eigen vector, with its associated Eigen values, serves as a valuable tool for the effective classification of these facial features, contributing to a comprehensive understanding of autism states.

E. Long Short Term Memory Integrated Convolution Neural Network

The extracted features play a pivotal role in the functionality of the novel Long Short-Term Memory Integrated Convolutional Neural Network (LSTM-CNN) designed for the detection and classification of meltdown states, with a focus on assessing the severity. This innovative approach leverages hyperparameter-optimized layers to enhance the processing of information [36].

1) Long short term memory: The Long Short-Term Memory (LSTM) component within our integrated model is a key element endowed with the unique ability to learn and comprehend long-term dependencies through its intricate network connections. It excels in the storage of pertinent information within a memory cell while effectively discarding extraneous details. Each LSTM unit comprises a memory cell equipped with two gates: input and output, and a forget gate. In the context of our research, the LSTM model serves as a repository for multisite meltdown feature maps, a product of the convolution and max-pooling layers in the Convolutional Neural Network (CNN). These feature maps encapsulate crucial patterns essential for the accurate detection and classification of meltdown states.

In order to fine-tune the performance of our LSTM-CNN model, we employ hyperparameter optimization, as outlined in Table II.

TABLE II. HYPERPARAMETER TUNING

Hyperparameter	Value
Learning rate	10^{-6}
Epoch Value	100
Activation function	ReLu
Loss Function	Cross Entropy

The hyperparameters, meticulously chosen and specified in Table II, play a pivotal role in shaping the learning dynamics of our model. The learning rate, set at 10^-6, determines the step size during optimization, ensuring a balance between accuracy and efficiency. The epoch value of 100 signifies the number of times the entire dataset is processed during training, influencing the model's convergence. The ReLU activation function is employed to introduce non-linearity, enhancing the model's capacity to learn intricate patterns. Finally, the Cross Entropy loss function measures the dissimilarity between predicted and actual values, guiding the model towards optimal performance. This comprehensive hyperparameter tuning aims to maximize the LSTM-CNN model's efficacy in detecting and classifying meltdown states with a nuanced understanding of their severity.

2) Convolution neural network: The Convolutional Neural Network (CNN) serves as a cornerstone in our methodology, tasked with processing the intricately extracted features across multiple layers. Its primary objective is to adeptly detect and classify the multisite meltdown state, discerning the severity level inherent in each case. The CNN's architecture is meticulously designed, incorporating essential elements such as the convolution layer, max-pooling layer, and fully connected layer.

The convolution layer plays a critical role in feature extraction, employing filters to scan and identify distinctive patterns within the input data. This process enables the CNN to capture essential spatial hierarchies and dependencies in the multisite meltdown features. Subsequently, the max-pooling layer strategically downsizes the spatial dimensions of the extracted features, promoting computational efficiency and reducing the risk of overfitting.

The fully connected layer, a crucial component of the CNN architecture, is responsible for processing linear features extracted from the preceding layers. It incorporates an activation function to introduce non-linearity, allowing the model to learn complex relationships within the data. Furthermore, the softmax function within the fully connected layer serves a dual purpose – detection and classification. It assigns probabilities to different meltdown states, facilitating a nuanced understanding of the severity levels associated with each classification.

To guide the training process effectively, a loss function is integrated into the fully connected layer. This function calculates the classification error, providing feedback to the model during the training phase. The objective is to minimize this error, enhancing the CNN's ability to accurately detect and classify multisite meltdown states.

For a visual representation of our proposed model's architecture, refer to Fig. 1. This diagram encapsulates the intricate interplay between the convolution layer, max-pooling layer, and fully connected layer, offering a comprehensive overview of the network's structure and functionality. The synergy of these components within the CNN underscores its efficacy in robustly addressing the detection and classification challenges posed by multisite meltdown scenarios.

Fig. 1. Proposed architecture.

- Convolution Layer: The Convolution Layer is a pivotal element in our architecture, containing multiple filters and kernels that convolve with features extracted from different regions. This convolution operation produces a feature map that represents the underlying patterns in the meltdown state. Mathematically, convolution involves the multiplication of the feature vector, containing information about the meltdown state in a specified region, with multiple filters [37]. The convolution process is expressed as in the Formula:

$$x_n = \sum_{K=0}^{N-1} Y_K F_{n-k} \tag{6}$$

Here, *Y* represents the feature, and *F* is the filter.

The convolution layer generates a feature map through convolution operations, encompassing both low-level and latent features. The convergence of this feature map is facilitated by epochs, incrementally increasing feature generation. Normalization through the Rectified Linear Unit (ReLU) activation function further refines the feature map, obtaining a linear representation. The cosine distance measure is then employed to compute the distance among features.

- Pooling Layer: The Pooling Layer follows the convolutional operations, serving to further reduce the features obtained from the convolution layer. This step is crucial for high-level meltdown feature extraction and is essentially a form of down-sampling, diminishing the dimensions of facial features and retaining only selected weighted meltdown features. The Max Pooling layer plays a vital role in connecting the meltdown features into small patches, estimating the maximum number of features for each subset. This process enhances model generalization [38].

- Long Short Term Memory Layer: The LSTM Layer is employed to store the feature map derived from the convolution and max-pooling layers of the Convolutional Neural Network. It excels in preserving long-term dependencies through its intricate network connections. The stored meltdown features, each assigned a weight value, reside in the memory cell of each LSTM unit. These features, converted into a feature matrix, are input into the LSTM for the fusion of multisite meltdown information [39].

$$C_t = \tanh(X_t * V_t + H_{t-1} * W_t) \tag{7}$$

In the CNN-LSTM hybrid model, normal and meltdown features are extracted from both the convolutional and LSTM layers. The ordering of these features is then utilized, where *Ht* represents cell memory information, and *Wt* represents the weight vector.

- Dense Layer – Fully Connected Layer: The Dense Layer, organized as a fully connected layer, processes the feature map composed of multisite meltdown features across facial regions. This layer extracts discriminative features related to crying, stimming, and screaming. The activation function is applied for feature normalization and flattening, addressing non-linearity and overfitting concerns in the feature maps.

- Softmax Layer: The Softmax Layer, integrated into the fully connected layer, is crucial for detecting the meltdown state. It combines these states, assigning aggregate weights to identify the severity of multisite meltdown states using a Naive Bayes classifier. A loss layer is further incorporated to minimize feature variance across classes. The Softmax function, as represented in Formula (8), calculates the probability distribution:

$$\text{Softmax Function } P_j = \frac{e^{x_j}}{\sum_1^k e^{x_k}} \tag{8}$$

where, e^{xj} is the feature map long dependency vector.

- Classifier and Decision Rule: The feature vector is projected for classification by applying Bayes theorem, utilizing a maximum likelihood function to aggregate similar emotion features of autistic children based on feature values. The final classification result is generated by integrating results according to the decision rule. Feature values related to crying, screaming, and stimming form distinct classes. The Maximum Likelihood function, as given in Eq.9, incorporates the class, feature values, and density function:

$$f_n(y, \theta) = \prod_{k=1}^{n} f_k \tag{9}$$

Here, *Y* is the class of the meltdown, θ is the vector containing feature values, and f_k is the density function. This comprehensive approach ensures a robust and nuanced classification of multisite meltdown states based on their severity levels.

The algorithm offers a holistic approach to Multisite Meltdown Detection and Severity Classification. It integrates preprocessing, segmentation, feature extraction, and a robust combination of Convolution Neural Network and Long Short-Term Memory for accurate and nuanced results. The inclusion of a variety of techniques, such as contrast enhancement, instance segmentation, and feature mapping, contributes to the algorithm's effectiveness in handling complex scenarios related to autism severity classification. The architecture demonstrates a deep understanding of both low-level and high-level features, providing a comprehensive solution for the challenging task at hand.

IV. Experimental Results

In this pivotal section, we delve into a thorough analysis of the experimental outcomes, leveraging cross-fold validation on a simulated dataset within the Python environment [40]. The performance evaluation of our proposed architecture for autism severity classification is meticulously conducted, with optimal parameters defining the model's performance. The implementation utilizes the versatile Scikit-learn package, incorporating various machine learning algorithms, and OpenCV for efficient image processing and preparation.

A. Dataset Description - Meltdown Crisis

The cornerstone of our investigation lies in the Meltdown Crisis dataset, a robust collection designed for identifying multisite meltdown severity in autism children. Comprising 59 videos, this dataset offers a detailed narrative, encompassing facial expressions and physical activities during the meltdown crisis. The dataset is structured into emotion frames and non-emotion frames, categorizing various states such as normal, post-crisis, and meltdown crisis states. For streamlined evaluation, the dataset is strategically partitioned into training, testing, and validation sets [41].

The training phase involves the utilization of images extracted from children in the videos, while testing is conducted on videos observed during children's activities. Fig. 2 presents the confusion matrix for the validation dataset, consisting of 59 videos. This visual representation encapsulates the model's proficiency in classifying instances across different categories.

Fig. 3 provides a comprehensive snapshot of the training and validation accuracy of our model. This graphical representation elucidates the learning trajectory of the model over multiple epochs. The model achieves commendable results, boasting an 88% training accuracy and an 84% validation accuracy, reflecting its robust learning capabilities.

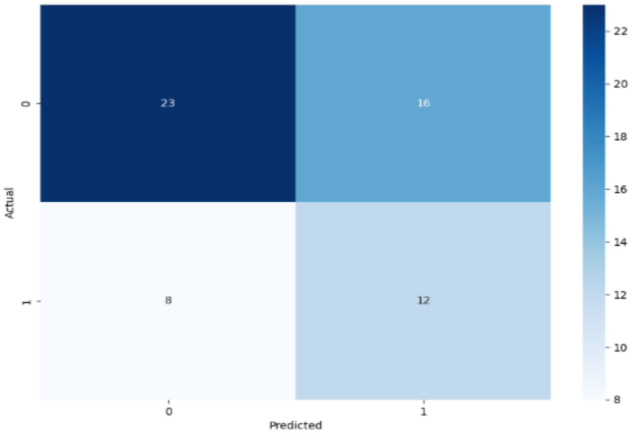

Fig. 2. Confusion matrix.

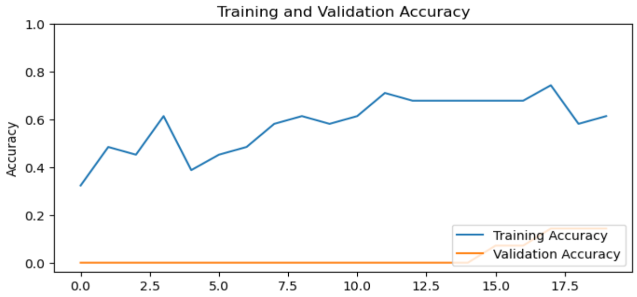

Fig. 3. Training and validation accuracy of the model.

Performance analysis extends to the examination of the training and validation loss, as illustrated in Fig. 4. These curves offer insights into the model's optimization process, demonstrating a balanced and decreasing trend in error reduction over the course of training and validation.

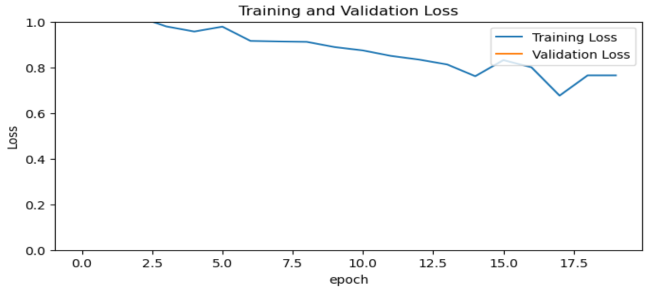

Fig. 4. Training and validation of the model.

TABLE III. Performance Evaluation of the Model

Technique	Accuracy		Loss	
	Training	Validation	Training	Validation
CNN+LSTM	88	84	0.8	0.1

Table III meticulously encapsulates the quantitative results of our model. The training accuracy, validation accuracy, training loss, and validation loss are presented, offering a detailed performance snapshot. The CNN–LSTM models were meticulously trained for 100 epochs, employing a batch size of 128, and utilizing a cross-entropy loss function. These parameters were strategically chosen to ensure a robust and effective training process.

The proposed model exhibits superior performance when benchmarked against conventional approaches. With a training accuracy of 88% and a validation accuracy of 84%, coupled with minimal training and validation loss, our CNN–LSTM model demonstrates efficacy in autism severity classification. These findings underscore the potential of our integrated architecture in providing nuanced and accurate assessments in the context of multisite meltdown grading.

V. Conclusion

In this study, we introduced a novel approach for detecting multisite meltdowns in children with Autism Spectrum Disorder (ASD) using a Long Short-Term Memory (LSTM) [42] integrated Convolutional Neural Network (CNN). Our designed architecture aims to leverage the dependency among multisite meltdowns to enhance the severity computation, ultimately contributing to the development of a robust grading system. The comprehensive pipeline of our model encompasses pre-processing techniques to enhance image quality, the utilization of the Segment Anything model for segmentation, and principle component analysis for feature extraction. These steps are crucial in isolating significant regions within child images and extracting pertinent features.

The extracted features are subsequently fed into the CNN+LSTM classifier, which effectively detects and classifies multisite meltdowns, providing valuable insights into their severity. The model's performance analysis yielded promising results, with a training accuracy of 88% and a validation accuracy of 84%. This underscores the efficacy of our proposed architecture in accurately identifying and grading multisite meltdowns in children with ASD.

While our current model has shown promising results, there are avenues for future research and improvement. Firstly, the inclusion of a larger and more diverse dataset could enhance the model's generalization capabilities. Exploring advanced techniques for feature extraction and segmentation may further refine the model's ability to capture subtle nuances in facial expressions during meltdowns.

Additionally, investigating real-time applications and deployment in clinical settings could provide valuable insights into the model's practical utility. Fine-tuning hyperparameters and exploring alternative neural network architectures may also contribute to optimizing the model's performance.

Analysis of Synthetic Data Utilization with Generative Adversarial Network in Flood Classification using K-Nearest Neighbor Algorithm

Wahyu Afriza, Mardhani Riasetiawan*, Dyah Aruming Tyas
Department of Computer Science and Electronics, Gadjah Mada University, Yogyakarta, Indonesia

Abstract**—Indonesia is a country with a tropical climate that has high rainfall rates and is supported by the uncertainty of weather and climate conditions. With the uncertainty of weather and climate as well as flood events, minimal predictive information on flooding, and the lack of availability of data on the causes of flooding, a comparison of synthetic data generation from the minimal data available from BMKG with synthetic data generation from Kaggle online platform data in the form of temperature and humidity data, rainfall, and wind speed from BMKG and annual rain data from Kaggle was analyzed. This research aims to obtain the results of data comparison analysis of synthetic data generation from different datasets with the benchmark of classification system results using K-Nearest Neighbor (KNN) and accuracy evaluation with Confusion Matrix. The research process uses climate data from the BMKG DI Yogyakarta Climatology Station within 20 months, the Geophysical Station within 12 months, and Kerala data with a range of 1901–2018. Synthetic data generation is done using the Conditional Tabular Generative Adversarial Network (CTGAN) model. CTGAN produces quite good data in terms of distribution and data differences if the original data is large and the synthetic data generated is small. The KNN classification system on the BMKG data experienced overfitting, as indicated by the accuracy value in the evaluation increasing in the range of 85–94% and the validation decreasing in the range of 89%–65%. This is because there is no uniqueness in the data and too little original data made into synthetics, which affects the difficulty of the classification system in identifying data that is quite different in distance and data values generated by CTGAN. In Kerala, the accuracy value on evaluation is in the range of 92–95%, and validation is in the range of 0.7–0.83%, with Classifier k1 being the most optimal system.**

Keywords—Classification; rainfall; synthetic data; KNN; GAN

I. Introduction

Indonesia is a tropical country located in the equatorial region with high rainfall. Today's climate change is affecting the weather and climate to the extent that high water discharge causes flooding. Water discharge can be caused by heavy rains with short or long durations, as in the rains that hit the Asian sub-continent with the deadliest floods that damage the environment, agricultural land, and basic health facilities [1]. A flood is a state of water inundation for a certain time, even though it is in an area that rarely floods with the support of rainfall and a long duration [2]. Floods can affect living things, wind pressure, temperature, watercolor, wind direction, humidity, and more, and have the potential to damage property and buildings [3], as well as adversely affect human health, the environment, cultural heritage, and economic activities [4].

The characteristics of heavy rainfall are strongly influenced by spatiotemporal patterns, space- and time-based models, and the amount of rainfall. Location: with damage intensity within the watershed, damage patterns (flooding from rivers, flooding from inland waters, sediment-related disasters, and other) vary depending on the distribution of rainfall. In order to implement effective flood control measures, it is important to understand the rainfall patterns that occur in the watershed and take countermeasures based on the characteristics of the associated hazards [5].

Some of the factors that affect the occurrence of floods are temperature, humidity, dew point temperature, wind speed, river flow volume, water level, and rainfall volume. The amount of rainfall is a major factor in the hydrological cycle process by monitoring the balance of freshwater and saltwater resources. Process of data acquisition can be done with the use of the Internet of Things based on data from the sensors used. Rainfall prediction or forecasting plays an important role in hydrological modeling and management of water resource issues such as flood warnings and real-time control of urban drainage systems [6].

In this research, a comparative analysis of the use of synthetic data in making a classification system based on the machine learning algorithm K-Nearest Neighbor (KNN) is carried out. Synthetic data generation is carried out due to the lack of availability and types of data features that can be obtained from BMKG Online Data (https://dataonline.BMKG.go.id/) and open data from online platforms for the classification of flood disaster events. The data used is BMKG data with rainfall data parameters, temperature and humidity, wind speed, and flood events as benchmarks for measuring and determining potential flood classes as well as monthly and annual flood data. This research is intended as an analysis of the use of synthetic data on climate data and natural disasters.

II. Research Methodology

A. System Needs Analysis

There are several stages in designing a classification system, including design, data preparation, training, and testing of a classification system based on the K-Nearest Neighbor (KNN) algorithm. The data used is BMKG data as training and validation data and Kerala data. Dataset creation includes downloading data and merging BMKG and BPBD data to become BMKG data with data that has a flood class label. The flood level data entry is in accordance with Table I. Then, the Kerala data underwent a download process without any additional processing.

TABLE I. FLOODING LEVEL IN YOGYAKARTA

No.	Flood Level	Flood High
1	Tidak/No	0 cm
2	Ringan/Low	< 100 cm
3	Tinggi/High	≥ 100 cm

BMKG training data has a time span of twenty months starting from January 2022 to August 2023; BMKG validation data has a time span of twelve months or one year starting from October 2022 to September 2023; and Kerala data in the form of rainfall data and annual flood classes has a time span of 1901–2018.

The BMKG training data will be divided into a 3:1 ratio for training and testing, so that 75% of the data will be used in the training process and 25% of the data will be used in the testing process, which can be used as confusion matrix-based evaluation results. The BMKG data has a total of 320 rainfall data points over a time span of twenty months. In the validation of BMKG data, the data is fully used as validation of the classification system results. Furthermore, Kerala data totals 118 data points, which will be divided into 100 training data points with the same division as BMKG data, namely 75% and 25%, and 18 data points as validation data from the Kerala classification system.

B. Synthetic Data Generation

Synthetic data is artificial data generated from the original data. Synthetic data can overcome the problems of data security, data confidentiality, unbalanced data, and others. The generative adversarial network works based on two neural networks: the discriminator and the generator [7]. GAN has several mathematical formulas for calculations. In GAN, there is a discriminator in Eq. (1), a generator in Eq. (2), and training for the discriminator and generator is shown in Eq. (3) and Eq. (4) [8].

$$L_D = Error(D(x),1) + Error\big(D\big(G(z)\big),0\big) \tag{1}$$

$$L_G = Error\big(D\big(G(z)\big),1\,\big) \tag{2}$$

$$V(G,D) = E_{x\sim P_{data}}\big[\log\big(D(x)\big)\big] + E_{z\sim P_z}[\log(1-D(G(z)))] \tag{3}$$

$$D^*(x) = \frac{p_{data}(x)}{p_{data}(x) + p_g(x)} \tag{4}$$

$$V(G,D^*) = E_{x\sim P_{data}}\big[\log\big(D^*(x)\big)\big] + E_{x\sim P_g}\big[\log\big(1-D^*(x)\big)\big] \tag{5}$$

C. Classification Method Implementation

After obtaining data from the source, the data will undergo a merging process between climate data and flood event data, then data cleaning will be carried out from unnecessary data or data with empty values and 8888 (unmeasured data) by manipulating the data using the median value.

The KNN method will use BMKG data which will be divided into train and test data. After defining the data, we will look for the minimum and maximum distance from the calculation of the train data distance and then the minimum distance from the calculation of the test data distance to the train data which will be assigned to several flood classes. The data will be classified into three flood classes, namely the No, Mild, and High classes as shown in Fig. 1.

D. Evaluation and Validation

The system evaluation process will be carried out by testing whether the system is able to classify rainfall, temperature, humidity, and wind speed data that can potentially flood into three flood classes. The measurement will be carried out by utilizing the Confusion Matrix Theory, which will compare the output of the system with the actual label of the data and will then produce accuracy, precision, Recall, and f1-score numbers according to Eq. (6) to Eq. (11) In the validation process, the same thing is done but with different data, namely data that has never experienced the train and test process.

$$Accuracy = \frac{TP+TN}{TP+TN+FP+FN} \tag{6}$$

$$Precision = \frac{TP}{TP+TN} \tag{7}$$

$$Recall = \frac{TP}{TP+FN} \tag{8}$$

$$FI - Score = \frac{1}{\frac{1}{recall}+\frac{1}{presisi}} \tag{9}$$

III. RESULT AND DISCUSSION

The datasets used in the research are from BMKG data and Kerala data, which are then divided into train, test, and validation data. BMKG data are gather from the filed sensor in the real situation. Kerala data will later be used in making a classification system with a validation process from different data and the training process that has been carried out. BMKG data that has been downloaded from the BMKG and BPBD

DIY online portals has a distribution of rain event data totaling 320 and 159 in BMKG training and validation data, respectively. The cleaning process is done by deleting the non-rain values in the BMKG data. In Kerala data, no cleaning was done because all data will be used.

After the non-rain data was eliminated, data manipulation was performed to fill in the values of the variable components in each column that were zero, null, and unmeasured except RR. The review for data manipulation was conducted only on the Tavg, RH_avg, and ff_avg features. Referring to Fig. 2, the data distribution on each feature except rainfall data (RR) is unevenly skewed with the category "skewed negative," or the mean value is lower than the median value of the data. In this situation, data manipulation using the median value aims to direct the distribution to a normal distribution. This was also done on the validation BMKG data.

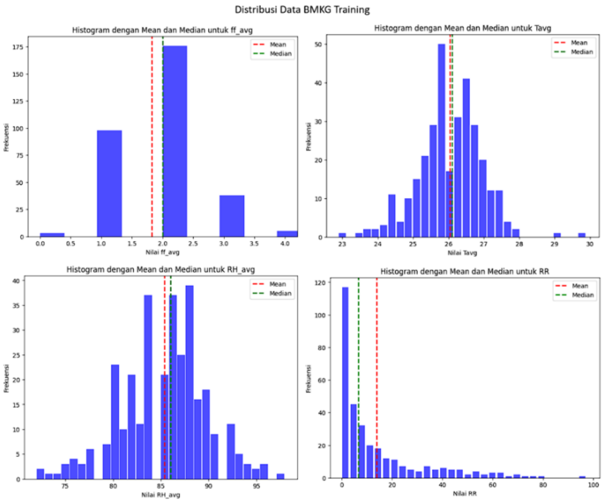

Fig. 2. Distribution of feature data.

After doing data manipulation on data rows that are 0, null, and unmeasured, as shown in Table II, In Kerala data, there are two flood classes, namely YES and NO as shown in Table III.

In the BMKG training data that has been processed, the data is not balanced between classes. If the process of making a classification system using this data is not followed, the result of the classification system will produce a poor system and undertraining, a situation when the classification system can recognize one class well but cannot recognize the other class, which tends to result in the classification system that has been made classifying data for the majority class [9]. This can be overcome by multiplying existing data with generative data or synthetic data.

The data generation process is carried out with CTGAN. This was done to prevent the potential for an undertrained classification system. The generative process was carried out with five experiments with different amounts of data. The flood class in the data will be converted into an integer or number, with 0 as no flood, 1 as a minor flood, and 2 as a high flood. The original flood data, with a total of six minor flood events and one high flood event, doubled without changes to two for the model calculation process, will be trained by GAN and generate synthetic data.

TABLE II. TOTAL BMKG DATA IN EACH CLASS

4		NO	10

Furthermore, synthetic data was created for each data point. In BMKG data, synthetic data for mild flood and high flood classes is made into 30, 60, 90, 120, and 150 data points. In Kerala, synthetic data for yes and no classes was made into 150 of all the data and only 6 data samples. The distribution and differences between synthetic and real data can be seen in Fig. 3 to Fig. 14.

No.	Model	YES	NO
1	*Classifier k*	52	48
2	*Classifier k1*	202	198
3	*Classifier k2*	156	156

Before making a classification system in each experiment based on the data that shown in Table IV and Table V, the K value is determined as a consideration for determining neighbors in calcification using the Euclidean distance, which has a calculation formula as in Eq. (10) and Eq. (11).

$$d(x,y) = \sqrt{\sum_{i=1}^{m}(x_i - y_i)^2} \quad (10)$$

$$d = \sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2} \qquad (11)$$

In the process of determining the value of K, the best value was found using repetition operations throughout the classifier experiment. Based on the accuracy results, a K value of 5 is obtained with the consideration of a good and consistent accuracy value, with an average accuracy value of 91.38% on BMKG data and 92.26% on Kerala data.

The classification system that has been created in each experiment will be evaluated to determine and assess the ability or performance of the system. In the system evaluation, each classifier is evaluated by utilizing the confusion matrix theory based on the formulas in Eq. (6) to Eq. (9). In the evaluation process, test data is used, which amounts to 25% of the total of all classes. The confusion matrix results of each classifier can be seen in Table VI for the BMKG data and Table VII for the Kerala data, as well as the comparison graph in Fig. 15.

TABLE VI. BMKG DATA CLASSIFICATION EVALUAION

No.	Model	Precission	Recall	F-1 score	Accuracy

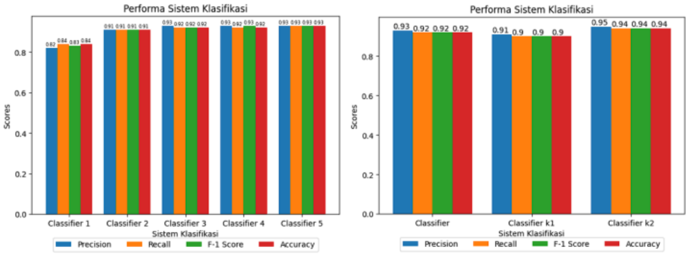

Fig. 15. Comparison of evaluation in each model.

Validation data on BMKG data has a total of 159 data points that have undergone data pre-processing. In the BMKG validation data, there are 156 non-flooding events, 2 minor floods, and 1 high flood. While in Kerala, the train data amounted to 18 data points, with 8 flood data points and 10 non-flood data points. In the validation test, the same process as the evaluation is carried out but with data that has never been trained and tested, utilizing the confusion matrix theory based on the formulas in Eq. (5), (6), (7), and (8) with the predicted data and the original label data. The results of the BMKG training data classification system validation can be seen in Table VIII, and the Kerala data system validation can be seen in Table IX. Then, the result comparison graph is in Fig. 16.

TABLE VIII. BMKG DATA CLASSIFICATION VALIDATION

No.	Model	Precission	Recall	F-1 score	Accuracy
1	*Classifier 1*	0.96	0.89	0.93	0.89
2	*Classifier 2*	0.96	0.86	0.91	0.86
3	*Classifier 3*	0.97	0.77	0.86	0.77
4	*Classifier 4*	0.97	0.74	0.83	0.74
5	*Classifier 5*	0.97	0.65	0.78	0.65

TABLE IX. KERALA DATA CLASSIFICATION VALIDATION

No.	Model	Precission	Recall	F-1 score	Accuracy
1	*Classifier k*	0.75	0.75	0.75	0.77
2	*Classifier k1*	0.78	0.88	0.82	0.83
3	*Classifier k2*	0.71	0.62	0.67	0.72

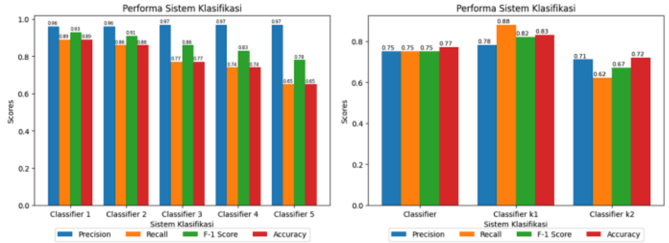

Fig. 16. Comparison of evaluation in each model

Referring to Fig. 17, the comparison of evaluation and validation results on BMKG data shows a significant difference in data, so the classification system from BMKG data has poor results, although Classifier 1 has the least difference. While in Kerala data, the evaluation and validation results are quite consistent in their improvement, with Classifier k1 being the most optimal, which is the creation of synthetic data from all the original Kerala data.

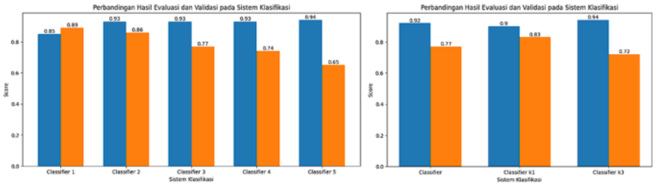

Fig. 17. Comparison of accuracy in evaluation and validation.

IV. CONCLUSION

The research indicates that the BMKG data, which includes temperature, humidity, rainfall, and wind speed features, does not have unique characteristics for each class. As a result, the classification system derived from this data suffers from overfitting, leading to imbalanced results between evaluation and validation. On the other hand, the Kerala data exhibits unique features for each class, which allows for a more accurate classification system. This system achieves an evaluation accuracy of 90-95% and a validation accuracy of 72-83%.

Synthetic data generated from Generative Adversarial Networks (GANs) can create a large amount of data from a small amount of original data. However, the quality of this synthetic data is dependent on the quantity of original and synthetic data used. This can affect the similarity of the synthetic data to the original data, and vice versa. In terms of the classifiers, Classifier 1 (with 30 sample data), Classifier 2 (with 60 data samples), and Classifier k1 show similar accuracy values on evaluation and validation. However, Classifier 3, Classifier 4, Classifier 5, and Classifier k3 exhibit a significant difference in accuracy values on evaluation and validation.

In summary, the BMKG data's lack of unique class characteristics leads to overfitting in the classification system, resulting in imbalanced evaluation and validation results. In contrast, the Kerala data, with its unique class characteristics, produces a more accurate classification system. Synthetic data, generated from GANs, can be highly useful, but the quality of this data depends on the quantity of original and synthetic data used. Finally, the classifiers show varying accuracy values on evaluation and validation, with Classifiers 3, 4, 5, and k3 exhibiting significantly different results compared to Classifiers 1, 2, and k1. The analysis of synthetic data utilization with Generative Adversarial Network (GAN) in flood classification using the K-Nearest Neighbor (KNN) algorithm is an innovative and promising research area. To further advance this work and contribute to the field, the following future work suggestions are proposed Explore and develop more advanced GAN architectures to generate synthetic flood-related data. Investigate different GAN variants, such as Wasserstein GANs or Progressive GANs, to improve the quality and diversity of synthetic data. Conduct a thorough investigation into the hyperparameters of both the GAN and KNN algorithms to optimize their performance. This includes tuning learning rates, batch sizes, and other relevant parameters to achieve better results in terms of classification accuracy and computational efficiency. Extend the analysis by incorporating and comparing the performance of other machine learning models for flood classification. This could include algorithms like Support Vector Machines (SVM), Decision Trees, or Random Forests. A comprehensive comparison will provide insights into the strengths and weaknesses of different approaches. Test the proposed framework on a broader range of datasets to evaluate its generalizability. This includes datasets from different geographical locations, varied environmental conditions, and various types of flooding scenarios. Assess the robustness of the model across different contexts. By addressing these future work areas, the research can make significant contributions to the field of flood classification, synthetic data generation, and the intersection of GANs and KNN algorithms.

A Piano Single Tone Recognition and Classification Method Based on CNN Model

Miaoping Geng, Ruidi He*, Ziyihe Zhou
The Conservatory of Music, Hebei Institute of Communications, Shijiazhuang, Hebei 050010, China

***Abstract*—In order to improve the recognition and classification effect of piano single tone, this paper combines the CNN (Convolutional Neural Networks) model to construct the piano single tone recognition and classification model, and equalizes the uniformly irradiated parabolic tone transmission hardware. In this paper, the analytic method is used to calculate the direction diagram of the tone transmission hardware, and the analytical expression for calculating the gain of the tone transmission hardware is obtained. Moreover, this paper gives the calculation and analytical expression of the hardware gain of the tone transmission in the main lobe, and obtains the calculation method of the relative position of the two tone transmission hardware by using the conversion relationship between the global coordinate and the local coordinate. Finally, the variation law of the received power with the azimuth/elevation angle of the receiving tone transmission hardware and the incident high-power microwave frequency is given. The experimental study shows that the piano single tone recognition and classification method based on CNN model proposed in this paper can play an important role in piano single tone recognition. This article improves the note recognition algorithm for piano music by combining note features with frequency spectrum to obtain note spectrum, which improves the accuracy of audio classification recognition.**

Keywords—CNN model; piano; single tone recognition; classification

I. Introduction

For the interpretation of a beautiful piano piece, if the performer is the driver of the soul of the piece, then a piano with a beautiful tone is the carrier of the soul. Therefore, it is particularly important to understand and study the quality of the piano. The quality of a piano can be judged from six aspects: tone, touch, tuning stability, durability, appearance and tension. However, for players, tone and touch are undoubtedly the most important. It is not an easy task to make a correct judgment on the sound quality of a piano. First of all, it needs to ensure the piano intonation. In the case of intonation, the pronunciation of the bass region should be strong and powerful, the sound should be extended enough, and the pronunciation should not be short or weak. The mid-range requires that the extension of the sound should be as long as possible, the timbre should be beautiful and soft, and the pronunciation should not be dull or blunt. The pronunciation of the high-pitched area should be bright and clear, not too gorgeous or impure, and no reverberation is required. When the timbres of the three sound zones are satisfactory, it should be noted that the transition of the three sound zones should be natural, the timbre should be unified, and the volume ratio should be coordinated. The so-called tactile sensation refers to the responsive ability of the keyboard and the action mechanism to transmit the player's playing force to the strings. The touch of the piano should be comfortable for beginners and comfortable for accomplished players.

Music information signals themselves belong to fuzzy signals and require strict mathematical models to describe them. Traditional information processing methods are difficult to solve the fuzzy situation of music signals. Therefore, some studies use intelligent information analysis and processing methods such as fuzzy systems, neural networks, expert systems, and genetic algorithms to process music information [1].

Fuzzy system has the advantages of not needing precise mathematical model, easy to use human experience knowledge, nonlinear, robust and so on. Since there are many ambiguities in music information, language and thinking, the use of fuzzy sets to describe the characteristics of music, and the use of fuzzy logic and fuzzy reasoning for feature analysis and identification, should be said to be the closest to the cognitive process of people's music. At present, many studies have proved that the fuzzy system is an effective method for the study of music information. In the automatic chord analysis system of literature [2], the process of listening, feeling and understanding music all use the membership function of the fuzzy set, and the basic membership function The function is designed according to music theory and can be modified by a few simple parameters, which facilitates the study of music information from both music theory and human perception.

In order to improve the effect of piano single tone recognition and classification, this paper combines the CNN model to build a piano single tone recognition and classification model to improve the efficiency of intelligent processing of piano tones.

The contribution of this article is as follows: Section I is the introduction. Related work is given in Section II. Calculation and Analysis of front door of coupling quantity of piano tone transmission is given in Section III. Section IV delves in to the empirical model, results, analysis and discussion. Finally, Section V concludes the paper. This article improves the note recognition algorithm for piano music by combining note features with frequency spectrum to obtain note spectrum, which improves the accuracy of audio classification recognition.

II. Related Work

Neural network has the advantages of distributed information storage, parallel processing, self-organization, and self-learning, the existing research results use two types of neural networks [3]: (1) Multilayer perceptron (BP network): Using a layered neural network can make the system not only start from the notes, but also from the overall structure. Highly comprehensive processing of music information. The hierarchical recurrent neural network of [4], the first layer is for each measure, and the second layer is for each note. For a rhythm-regular piece like a waltz, both melody and rhythm characteristics can be taken into account. In addition, the use of Makov chains can also make the system predictive. (2) Hopfield network (feedback network): Research in [5] uses the associative memory function of the Hopfield network to recombine the existing melody data to achieve the purpose of composition. The expert system is suitable for embedding a large amount of music knowledge into the computer system, and at the same time enables the system to flexibly use this knowledge to make judgments, and has the ability to acquire and increase knowledge, and is best at simulating human experts to solve complex problems. Study [6] used 26 rules to complete the automatic playing expert system according to the performance characteristics of performers. Study [7] realized an expert system that automatically discriminates Bach's musical style. In the processing of musical information, intelligent methods play an important role. The choice of these methods should mainly be based on specific needs. For example, the analysis of the characteristics of music harmony, timbre, etc. is often inseparable from a fuzzy system that has a strong ability to describe music information. Automatic playing systems usually choose expert systems that are easy to acquire knowledge. Some auxiliary composing systems use expert systems, while others use expert systems. The neural network is used to simulate human image thinking, so as to compose music according to certain requirements [8].

Study [9] argues: "The typical sound quality of an instrument should be attributed to the relative intensities of all harmonics in a definite or relatively definite region in the musical scale." Although this view is not entirely correct, it points out that the sound quality of an instrument is the importance of harmonic amplitudes to the sound quality of musical instruments. In terms of using computer to synthesize piano sound and improving the sound quality of piano sound through computer processing simulation, literature in [10] pointed out that harmonics are an important factor of sound quality, but this paper discusses how to improve the sound quality from the perspective of harmonic amplitude and phase changing with time, piano sound. Study in [11] believes that the harmonic amplitude is an important factor that constitutes the sound quality of the piano, and then uses the method of simulating multiple strings to reasonably adjust the frequency spectrum of the piano to study how to improve the sound of the piano.

When the hammers hit the strings, the piano sound reaches a peak of vibration soon after a brief onset. From a musical point of view, it is better to have a shorter time in this stage. If the time is too long, the sound will appear soft and lack the feeling of rigidity; but it should not be too short, otherwise the sound will have a stiff feeling. When the peak of the sound amplitude is reached, there will be a rapid decay. This period can be divided into two stages: early decay 2 and late decay 3. Of course, the decay speed of this stage will vary greatly with different keys and different percussion strengths [12]. An excellent pianist can well control the percussion intensity and time during the performance, so that the piano can make a full sound and get a good timbre effect. The strings are restrained by the sound felt and the vibration is rapidly attenuated. For the treble keys of a piano, these processes are less complicated, and the time domain graph of the treble keys looks like a straight line with only a sloping downward trend. The time domain characteristics of all these piano sounds are closely related to the piano hardware itself, such as felt, hammer shape, soundboard, etc. That is to say, the hardware of the piano itself is a very important part of the time domain characteristics of the piano sound. determinants [13].

Regarding the influence of the harmonic amplitude of the piano on the sound quality, the literature [14] first recorded the piano, and then took one of the signals, and performed simple processing on the harmonic amplitude, for example, the harmonic amplitude was formed proportionally, or the harmonic amplitude was decreased according to the law form a set of synth sounds, etc. Then compare these synthetic sounds with the original recording of the piano, and finally find that the sound quality after such simple processing is not as good as the original sound, at most only close to the original recording. , processing the harmonic amplitude of the piano is not a simple process, and it also shows that the composition of the harmonic amplitude does affect the sound quality of the piano sound to a great extent. In addition to studying the influence of harmonic amplitude on sound quality, study in [15] found the law of piano harmonics changing with time, that is, the law that different harmonics have different time delays. For example, the first harmonic and the second harmonic appear at different times, and there is a small delay, which means that the second harmonic will come later than the first harmonic. And as the harmonic order increases, their delay time increases.

Using a computer to analyze piano music signals, the processed music information must first be digitally processed, that is, convert the analog music signals collected by the recording equipment into digital music signals. In this process, two aspects are mainly considered: conversion accuracy and operation efficiency. The A/D conversion accuracy is realized by the number of bits of the A/D conversion device; the operation efficiency is related to the digitization accuracy and sampling rate of the music. However, if the data accuracy and sampling rate are too low, it will cause relatively large waveform distortion in the digitization process of the signal [16].

The collected piano music will be studied from the perspectives of physical acoustics, rhythm, fast Fourier transform, wavelet analysis, etc., to study the specific extraction methods and analysis methods of different musical features, and complete the design of pitch, duration, intensity and other feature extraction methods. and its computer implementation. The extraction of musical features provides a practical basis for the design of subsequent piano evaluation systems [17].

The keystroke sensitivity of the piano keys, that is, the response frequency of the keyboard, is one of the main parameters affecting the touch feeling of the piano keys, and it is also a problem that piano manufacturers are concerned about at present. By analyzing whether the response times of the piano keys can reach the standard, the quality of the percussion performance of the piano keys can be judged. To test this parameter, we must first ensure that the strength of hitting the piano keyboard is the same, the interval is even, and the frequency is adjustable, so that accurate test results can be obtained. In terms of testing algorithms, the keystroke sensitivity of piano keys can be effectively detected through waveform normalization, endpoint detection, and single-note separation [18].

III. Calculation and Analysis of Front Door Coupling Quantity of Piano Tone Transmission Hardware Port

On the basis of studying the characteristics of high-power microwaves, in order to quantitatively obtain the coupling number of high-power microwaves through the front door to the port of the piano tone transmission hardware, it is necessary to study the calculation method of the coupling amount of the front door.

A. Description of Calculation Method of Front Door Coupling

The HPM (High Performance Computing) generated in the high-power microwave transmitter transmits the hardware radiation through piano tone. As shown in Fig. 1, piano tone transmission hardware 1 is used as receiving, and piano tone transmission hardware 2 is used as piano tone transmission hardware for transmitting HPM.

When the distance between the received piano tone transmission hardware and the HPMpiano tone transmission hardware is R, the power density S from the HPM to the receiving piano tone transmission hardware is:

$$S = \frac{P_t G_t\left(\theta_2, \varphi_2\right)}{4\pi R^2}\left[\mathrm{W} / \mathrm{m}^2\right] \tag{1}$$

The content calculated by Formula (1) is the power density of the far-field field, and the condition for satisfying the far-field field is:

$$R \geq 2d^2 / \lambda \tag{2}$$

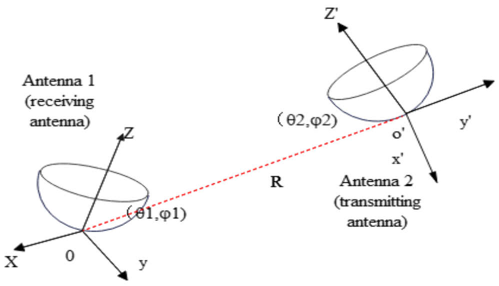

Fig. 1. The relative position of the two piano tone transmission hardware.

According to the Frith transmission formula, the power P_r received as the received piano tone transmission hardware is expressed as:

$$P_r = A_e\left(\theta_1, \varphi_1\right) \cdot S \tag{3}$$

The power received by the piano tone transmission hardware can be obtained from Formulas (1) and (3). In Formulas (1) and (3), the specific gain and effective receiving area of the two piano tone transmissions hardware need to be obtained.

B. Achieve Method of the Gain of the Piano Tone Transmission Hardware

For any form of piano tone transmission hardware, some commercial electromagnetic simulation software (HFSS (High Frequency Structure Simulator), FEKO etc.) can be used to establish the model of piano tone transmission hardware. The direction diagram and gain of piano tone transmission hardware are obtained through simulation.

The parabolic piano tone transmission hardware belongs to a class of piano tone transmission hardware with symmetrical structure, and its direction map and gain can be obtained by analytical method.

As shown in Fig. 2, for the larger rotating paraboloid piano tone transmission hardware with uniform illumination aperture shown in Fig. 2(a), the radiated electromagnetic waves. In essence, it can be equivalent to the electromagnetic wave radiated by the circular aperture (same diameter as the paraboloid) on a metal plate with an infinite size irradiated by a uniform plane wave as shown in Fig. 2(b).

For the equivalent model, the method for obtaining the far-field pattern can be based on the Huygens principle. According to this method, the normalized field strength pattern $E(\theta)$ obtained is shown in Formula (4).

$$E(\theta) = \frac{J_1\left[\pi d_\lambda \sin\theta\right]}{\sin\theta} \cdot \frac{2}{\pi d_\lambda} \tag{4}$$

In the formula, J_1 represents the first-order Bessel function, and θ refers to the angle relative to the focal axis.

d_λ is the wavelength number of the diameter d of the circular mouth, which can be expressed as

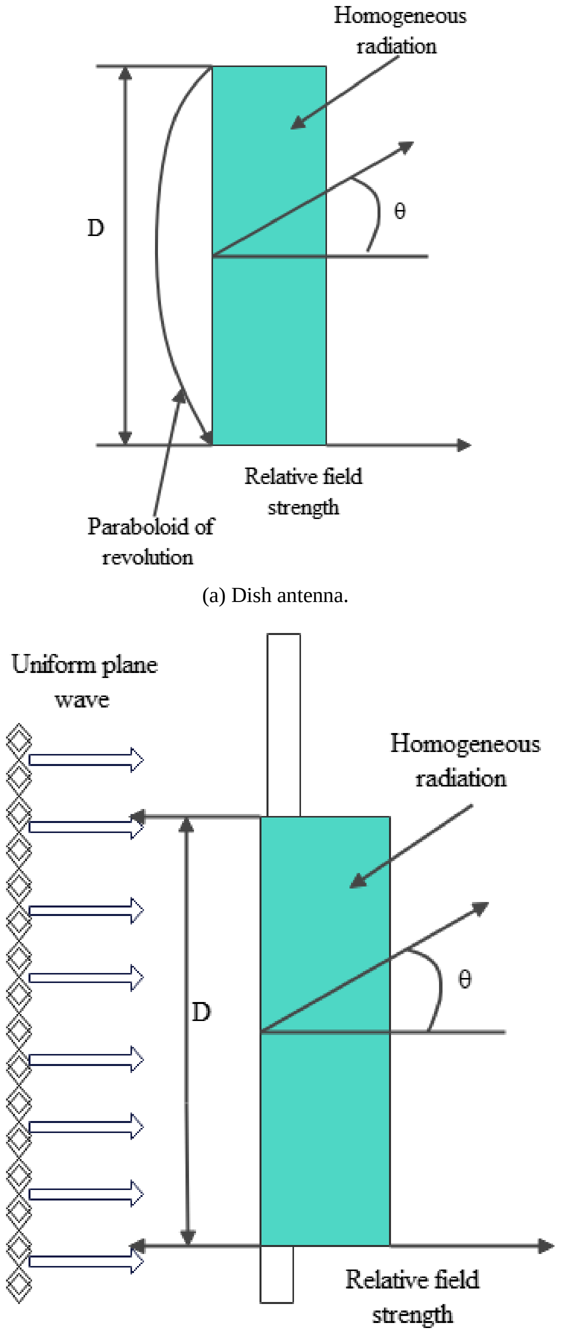
$$d_\lambda = d / \lambda \tag{5}$$

The n -order Bessel function can be expressed as:

$$J_n(z) = \frac{1}{2\pi}\int_{-\pi}^{\pi} \cos(n\theta - z\sin\theta)d\theta \tag{6}$$

The expression of the first-order Bessel function is shown in Formula (7).

$$J_1(z) = \frac{1}{2\pi}\int_{-\pi}^{\pi} \cos(\theta - z\sin\theta)d\theta \tag{7}$$



(a) Dish antenna.

(b) Equivalent model.

Fig. 2. The paraboloid model of revolution and its equivalent model.

Fig. 3 is the normalized field strength pattern when the center frequency of the parabolic piano tone transmission hardware is $f = 10\text{GHz}$ and the aperture is $d = 1\text{m}$.

Formula (8) represents the formula for obtaining the directivity coefficient of the parabolic piano tone transmission hardware:

$$D(\theta,\varphi) = (\tilde{E}(\theta,\varphi))^2 \cdot \frac{4\pi}{\theta_{HP1}\theta_{HP2}} \quad (8)$$

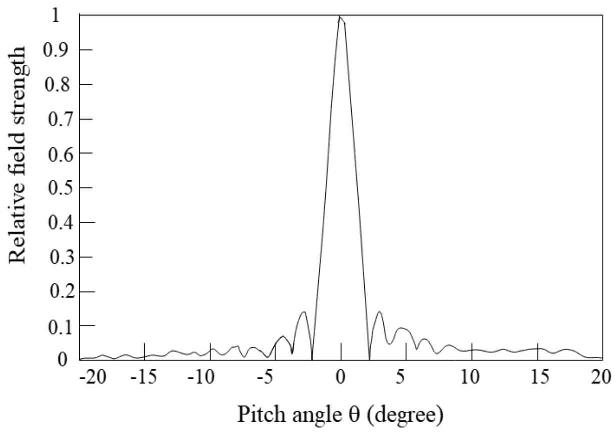


Fig. 3. Normalized direction diagram.

In the formula, $\tilde{E}(\theta,\varphi)$ is the normalized electric field intensity in the direction away from the piano tone transmission hardware, and θ_{HP1} and θ_{HP2} are the half-power beam widths of the main lobes of the piano tone transmission hardware in the two main planes.

The gain of the piano tone transmission hardware in a certain direction θ and φ is defined as:

$$G(\theta,\varphi) = \eta D(\theta,\varphi) \quad (9)$$

In the formula, η is the efficiency factor of piano tone transmission hardware.

When one piano tone transmission hardware (transmit/receive) is located in the main lobe of another piano tone transmission hardware (receive/transmit), the gain of piano tone transmission hardware can be calculated by the following method.

When the receiving piano tone transmission hardware is in the main lobe of the HPMpiano tone transmission hardware, the gain of the transmitting piano tone transmission hardware can be expressed as:

$$G_t = \varepsilon_a \frac{4\pi}{\lambda^2} A_{pt} \quad (10)$$

In the formula, ε_a is the aperture efficiency of the piano tone transmission hardware, and A_{pt} is the actual aperture area of the piano tone transmission hardware.

Similarly, when the HPM transmitting piano tone transmission hardware is located in the main lobe of the receiving piano tone transmission hardware, the gain of the receiving piano tone transmission hardware can be expressed as:

$$G_r = \varepsilon_a \frac{4\pi}{\lambda^2} A_{pr} \quad (11)$$

In the formula, A_{pr} is the actual aperture area of the receiving piano tone transmission hardware.

C. Calculation Method of Effective Receiving Area of Piano Tone Transmission Hardware

The effective receiving area $A_e(\theta,\varphi)$ of the piano tone transmission hardware is related to the gain of the receiving piano tone transmission hardware and the polarization mismatch coefficient, which can be expressed as:

$$A_e(\theta,\varphi)=\rho\cdot G_r(\theta,\varphi)\cdot A_d \tag{12}$$

In the formula, ρ is the polarization mismatch coefficient, the value is between $0\sim 1$, and A_d is the integral effective area of piano tone transmission hardware. When calculating the integral effective area of the piano tone transmission hardware, it is necessary to consider the relationship between the frequency f_t of the HPM transmitting piano tone transmission hardware and the center frequency f_r of the receiving piano tone transmission hardware. When $f_t < f_r$, it is called down-band coupling. When $f_t \approx f_r$, it is called in-band coupling. When $f_t > f_r$, it is called on-band coupling. The up-band coupling and the down-band coupling are collectively referred to as out-of-band coupling.

When calculating the in-band coupling, λ is not only the working wavelength, but also the wavelength corresponding to the center frequency of the receiving piano tone transmission hardware. When discussing the case of out-of-band coupling, the wavelength λ_r corresponding to the center frequency of the receiving piano tone transmission hardware should be used.

In the calculation model of the front door coupling amount, it is necessary to calculate the gain $G_t\left(\theta_2,\varphi_2\right)$、$G_r\left(\theta_1,\varphi_1\right)$ of the transmitting piano tone transmission hardware and the receiving piano tone transmission hardware. Because when calculating the direction map and gain of the piano tone transmission hardware, the angle is the relative coordinate system of the piano tone transmission hardware itself. Therefore, when calculating $\left(\theta_1,\varphi_1\right)$, the coordinates of the transmitting piano tone transmission hardware should be converted into the relative coordinate system of the receiving piano tone transmission hardware. When calculating $\left(\theta_2,\varphi_2\right)$, the coordinates of the receiving piano tone transmission hardware should be converted into the relative coordinate system of the transmitting piano tone transmission hardware.

For any point Q on the piano tone transmission hardware, its coordinate in the local coordinate system of the piano tone transmission hardware is $\left(x',y',z'\right)$, and its coordinate in the overall coordinate system is (x, y, z). Then, the overall coordinates (x, y, z) of the point Q can be regarded as obtained by the local coordinate $\left(x',y',z'\right)$ through two rotation transformations and one translation transformation.

1) When the x angle is rotated counterclockwise around the θ -axis, the corresponding coordinate transformation matrix is:

$$T_1=\begin{bmatrix}\cos\theta & 0 & \sin\theta & 0\\ 0 & 1 & 0 & 0\\ -\sin\theta & 0 & \cos\theta & 0\\ 0 & 0 & 0 & 1\end{bmatrix} \tag{13}$$

2) When the angle φ is rotated counterclockwise around the z-axis, the corresponding coordinate transformation matrix is:

$$T_2=\begin{bmatrix}\cos\varphi & -\sin\varphi & 0 & 0\\ \sin\varphi & \cos\varphi & 0 & 0\\ 0 & 0 & 1 & 0\\ 0 & 0 & 0 & 1\end{bmatrix} \tag{14}$$

3) When $\left(x_0,y_0,z_0\right)$ is translated along the x-axis, y-axis, and z-axis, the corresponding coordinate transformation matrix is:

$$T_3=\begin{bmatrix}1 & 0 & 0 & x_0\\ 0 & 1 & 0 & y_0\\ 0 & 0 & 1 & z_0\\ 0 & 0 & 0 & 1\end{bmatrix} \tag{15}$$

4) In the global coordinates, the corresponding relationship between the point Q (x, y, z) and the point in the local coordinates $Q'\left(x',y',z'\right)$ is:

$$\begin{bmatrix}x\\ y\\ z\\ 1\end{bmatrix}=T\begin{bmatrix}x'\\ y'\\ z'\\ 1\end{bmatrix} \tag{16}$$

The transformation matrix T is:

$$\begin{aligned}T&=T_3\cdot T_2\cdot T_1\\ &=\begin{bmatrix}1 & 0 & 0 & x_0\\ 0 & 1 & 0 & y_0\\ 0 & 0 & 1 & z_0\\ 0 & 0 & 0 & 1\end{bmatrix}\cdot\begin{bmatrix}\cos\varphi & -\sin\varphi & 0 & 0\\ \sin\varphi & \cos\varphi & 0 & 0\\ 0 & 0 & 1 & 0\\ 0 & 0 & 0 & 1\end{bmatrix}\cdot\begin{bmatrix}\cos\theta & 0 & \sin\theta & 0\\ 0 & 1 & 0 & 0\\ -\sin\theta & 0 & \cos\theta & 0\\ 0 & 0 & 0 & 1\end{bmatrix}\\ &=\begin{bmatrix}\cos\theta\cos\varphi & -\sin\varphi & \sin\theta\cos\varphi & x_0\\ \cos\theta\sin\varphi & \cos\varphi & \sin\theta\sin\varphi & y_0\\ -\sin\theta & 0 & \cos\theta & z_0\\ 0 & 0 & 0 & 1\end{bmatrix}\end{aligned} \tag{17}$$

In the actual simulation calculation, the overall coordinates of a certain point on the piano tone transmission hardware are usually known. Therefore, it is necessary to convert the point coordinates in the overall coordinates into the local coordinate system, that is,

$$\begin{bmatrix}x'\\ y'\\ z'\\ 1\end{bmatrix}=T^{-1}\begin{bmatrix}x\\ y\\ z\\ 1\end{bmatrix} \tag{18}$$

Among them, the transformation coordinate T^{-1} is:

$$T^{-1} = \left(T_3T_2T_1\right)^{-1} = T_1^{-1}T_2^{-1}T_3^{-1} = \begin{bmatrix} \cos\theta & 0 & -\sin\theta & 0 \\ 0 & 1 & 0 & 0 \\ \sin\theta & 0 & \cos\theta & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} \cos\varphi & \sin\varphi & 0 & 0 \\ -\sin\varphi & \cos\varphi & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} 1 & 0 & 0 & -x_0 \\ 0 & 1 & 0 & -y_0 \\ 0 & 0 & 1 & -z_0 \\ 0 & 0 & 0 & 1 \end{bmatrix}$$

$$= \begin{bmatrix} \cos\theta\cos\varphi & \cos\theta\sin\varphi & -\sin\theta & -x_0\cos\theta\cos\varphi - y_0\cos\theta\sin\varphi + z_0\sin\theta \\ -\sin\varphi & \cos\varphi & 0 & x_0\sin\varphi - y_0\cos\varphi \\ \sin\theta\cos\varphi & \sin\theta\sin\varphi & \cos\theta & -x_0\sin\theta\cos\varphi - y_0\sin\theta\sin\varphi - z_0\cos\theta \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{19}$$

D. Conversion Relationship between Received Power and Field Strength

Since the calculation model of the coupling quantity of the front door obtains the received power, the required parameter is the field strength value when designing the waveguide plasma limiter. Therefore, it is necessary to obtain the conversion relationship between the power and the field strength.

The conversion relationship between field strength and power is shown in Formula (20).

$$E_{[\mathrm{dB}(\mu V/m)]} = P_{[\mathrm{dBm}]} + AF + 107 \tag{20}$$

In the formula, AF is the piano tone transmission hardware factor.

In Formula (20), the received power can be obtained from the calculation model of the front door coupling, and the unknown parameter is the piano tone transmission hardware factor.

The piano tone transmission hardware factor is defined as the ratio between the electric field E and the piano tone transmission hardware terminal voltage V_L, namely:

$$AF = \frac{E}{V_L} \tag{21}$$

It is converted to decibels and expressed as,

$$E_{[\mathrm{dB}(\mu V/m)]} = V_{[\mathrm{dB}(\mu V)]} + AF_{\left[\mathrm{dB}\left(m^{-1}\right)\right]} \tag{22}$$

The effective receiving area A_e of the piano tone transmission hardware can be described as the ratio of the output power P_{out} of the piano tone transmission hardware to the incident power density P_d of the electromagnetic wave, namely:

$$A_e = \frac{P_{\mathrm{out}}}{P_d} \tag{23}$$

The effective area of the piano tone transmission hardware can also be calculated according to Formula (24).

$$A_e = \frac{G_r\lambda^2}{4\pi} \tag{24}$$

The output power of the piano tone transmission hardware can be expressed as:

$$P_{out} = \frac{V_L^2}{Z} \tag{25}$$

The power density of the incident electromagnetic wave is:

$$P_d = \frac{E^2}{120\pi} \tag{26}$$

From Formula (23) (26), we can get:

$$\frac{V_L^2}{Z} = \frac{E^2}{120\pi} \times \frac{G_r\lambda^2}{4\pi} \tag{27}$$

Therefore, the piano tone transmission hardware factor can be expressed as:

$$AF = \frac{E}{V_L} = \sqrt{\frac{480\pi^2}{Z\lambda^2 G_r}} \tag{28}$$

For the 50 ohm piano tone transmission hardware system, the piano tone transmission hardware factor can be expressed as:

$$AF = \frac{9.37}{\lambda\sqrt{G_r}} \tag{29}$$

It is expressed in decibels as:

$$AF = 19.8 - 20\times\log(\lambda) - 10\times\log\left(\mathrm{G_r}\right) \tag{30}$$

E. Scope of Application of the Calculation Model of Front Door Coupling

The distance from the piano tone transmission hardware is different, so that the field around the piano tone transmission hardware can be divided into three areas: the induction field area, the radiation near field area (Fresnel area) and the radiation far field area (see Fig. 4).

In the induction field area, piano tone transmission hardware does not radiate power. In the radiation near-field area, where it is close to the piano tone transmission hardware, it is difficult to distinguish the main lobe and side lobe of the pattern. As the distance becomes farther, the envelope of the pattern becomes clearer.

The direction map of the piano tone transmission hardware in the far field almost no longer changes with the distance. The measurement results at infinity from the piano tone transmission hardware are compared with the measurement results at a certain distance from the piano tone transmission hardware. If the difference between the two results is acceptable in engineering, the distance is called the Rayleigh distance, and here it is called the inner boundary of the far field.

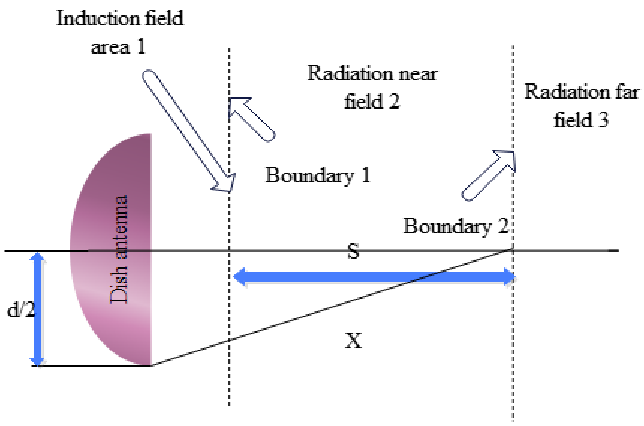

Fig. 4. Division of the piano tone transmission hardware field.

It can be seen from the measurement results that at the position where the Rayleigh distance is located, the distance from the center of the aperture to the observation point is:

$$x - s = \frac{\lambda}{16} \tag{31}$$

From the Pythagorean Theorem, we can get:

$$\left(\frac{d}{2}\right)^2 + s^2 = x^2 \tag{32}$$

Combining Formulas (31) and (32), the expression for the Rayleigh distance S is obtained as:

$$s = \frac{2d^2}{\lambda} - \frac{\lambda^3}{2048} \approx \frac{2d^2}{\lambda} \tag{33}$$

Therefore, the analytical calculation method of the parabolic piano tone transmission hardware pattern obtained in this paper is suitable for the far field.

IV. The Piano Single Tone Recognition and Classification Method based on CNN Model

A. Empirical Model

The system environment adopts Windows 10+Python 3.5, and the model training adopts a more concise and effective TFLearn model library. Due to limitations in conditions, the TensorFlow used in this article is the CPU (Central Processing Unit) version (the training effect may be better using the GPU (graphics processing unit) version), and the training status information comes from the auxiliary function output of TFLearn.

In order to realize the effective identification and classification of piano single tones, this paper combines the CNN algorithm to carry out research, and adopts the note-level method based on convolutional neural network (CNN) for multi-tone steel piano tone frequency recognition. The model flow is shown in Fig. 5.

Information of node (Start time, tone)
End

Fig. 5. Structure design of the algorithm system.

Compare the model proposed in this article with the method proposed in study [4], and explore their performance in piano single tone recognition and classification. Quantitative evaluation was conducted using expert evaluation methods to obtain the results shown in Table I.

B. Results

The multi-tone onset time model detects the onset time points of multiple notes, and the note onset time points can see obvious frequency variation characteristics on the spectrogram, as shown in Fig. 6. The CQT video feature map of the F#4 notes has obvious edge mutation, which is very suitable for CNN.

Using FEKO software, the parabolic piano tone transmission hardware is modeled. The piano tone transmission hardware size is: the aperture is 1m, and the center frequency is 5GHz. The normalized direction diagram of the piano tone transmission hardware is obtained as shown in Fig. 7.

The hardware gain analysis calculation method of piano tone transmission in the main lobe is compared with the results of FEKO software simulation. The FEKO software is applied to model the piano tone transmission hardware of the speaker, and calculate the stereo pattern and gain of the piano tone transmission hardware when the frequency is 10GHz, as shown in Fig. 8.

After the above model is constructed, the effect of the model is verified by the piano single tone recognition and classification method based on the CNN model, and the verification is carried out through multiple sets of piano single tone recognition experiments, and the classification results are counted, and the schematic results shown in Fig. 9 are obtained.

C. Analysis and Discussion

Nowadays, piano music on the internet generally stores digital audio information, which is generated by sampling analog audio data. The higher the sampling frequency, the larger the amount of digital audio data, and the better the fidelity of digital audio. Digital audio, as a manifestation of acoustic signals, can also be analyzed in the frequency domain and decomposed into pitch components of different frequencies. The frequency domain is composed of many sine functions (or cosine functions, or a combination of both), which have different amplitudes and phases, representing the rich information of audio in the frequency domain angle. The digital audio information stored in piano music is directly unfolded as the energy amplitude trend that changes over time, which is called the time-domain characteristics of audio signals and is the most intuitive representation of the signal. Time domain analysis and frequency domain analysis consider signal characteristics from two perspectives. For digital audio, the amount of data in the time domain is very large. The higher the sampling frequency of audio, the larger the amount of data, which often leads to a large computational workload. Compared to time-domain analysis, frequency-domain analysis has a smaller amount of data and can better reflect some substantive features. Therefore, frequency domain analysis has gradually become the mainstream of signal analysis. Frequency domain features are the results of frequency domain analysis, which describe the basic characteristics of audio signals. Using frequency domain features to represent music is not only easy to implement, but also reduces data volume and facilitates data processing.

FEKO has an algorithm that combines the method of moments as well as the more classical high-frequency analysis methods (physical optics) and consistent diffraction theory. It is extremely suitable for application in analyzing the design layout of piano tone transmission hardware, radar cross section (RCS) and other electromagnetic field analysis problems.

For directional piano tone transmission hardware such as parabolic piano tone transmission hardware, the main consideration is the main lobe pattern and gain of the piano tone transmission hardware. Therefore, the calculation results in this paper can be applied to engineering calculations.

From the results of piano single tone classification, the quantitative evaluation results of the method proposed in this article are distributed between [78, 89], while the quantitative evaluation results of the method in study [4] are distributed between [68, 8]. Therefore, it can be seen that the method proposed in this article has certain advantages compared to traditional methods

From the above research, it can be seen that the piano single tone recognition and classification method based on CNN model proposed in this paper can play an important role in piano single tone recognition.

V. Conclusion

Music and speech are both sound signals, and the basic principles of their recognition are similar. That is to say, all of the sound signals are analyzed, and processing processes such as noise processing, feature analysis, and recognition must be applied. The single-tone signal of the piano, as a sound signal, follows the basic laws of acoustics. In the field of speech research, the current technology is relatively stable and mature, so this paper draws on and refers to the technology of speech recognition and applies it to single-speech recognition. At the same time, there are obvious differences between speech and music: individual differences in speech are large. Even if the same person says the same sentence twice, the sound is quite different and cannot be exactly the same. However, for the same musical instrument, such as the piano studied in this paper, the same key is pressed by anyone at any time, the sound difference is very small, and it has a high degree of acoustic similarity. This paper combines the CNN model to build a piano single tone recognition and classification model to improve the efficiency of piano tone intelligent processing. The research shows that the piano single tone recognition and classification method based on the CNN model proposed in this paper can play an important role in piano tone recognition. The follow-up work of this article is as follows: In terms of note feature extraction, it is necessary to further address the interference of harmonic waves caused by fast rhythms. In the design of convolutional neural networks, further in-depth research is needed on the impact of network structure and loss function design on classification performance.

Intelligent Evaluation and Optimization of Postgraduate Education Comprehensive Ability Training under the Mode of “One Case, Three Systems”

Yong Xiang[1], Zeyou Chen[2], Liyu Lu[3], Yao Wei[4]*
School of Civil Engineering, Architecture and Environment, Xihua University, Chengdu, Sichuan, 610039, China[1, 2, 3]
School of Construction Engineering, Sichuan Technology and Business University, Chengdu, Sichuan, 611745, China[4]

***Abstract*—This study aims to explore the intelligent evaluation and optimization methods for the comprehensive ability training of graduate students under the mode of "one case, three systems" to improve the quality and effect of graduate training. Firstly, a weighted clustering algorithm for mixed attributes is designed. Secondly, an evaluation model of postgraduate training quality based on sampling method and ensemble learning is established. Finally, the algorithm's and the model's performance are compared and tested. The test results show that with the increase in the number of experiments, the accuracy of the proposed weighted clustering algorithm can reach more than 90%, which is improved by 10%. The average number of iterations is 276, and the accuracy and F1 value can achieve the highest level with fewer iterations and stable algorithm performance. Compared with the R1 model, F1 and the accuracy of the model proposed in this study are enhanced by 3.29% and 6.75%, respectively. The feature-weighted clustering algorithm and the training quality evaluation model designed here complement each other and jointly construct a more elaborate and comprehensive training system. The feature-weighted clustering algorithm oriented to mixed attributes for the first time combines sampling methods and ensemble learning in the education ability training. Moreover, a multi-dimensional and intelligent postgraduate training evaluation framework is constructed, which provides a new idea for improving the quality of postgraduate training.**

Keywords*—Comprehensive ability training of graduate students; one case; three systems; feature weighted clustering algorithm; sampling method; ensemble learning

I. Introduction

With society's continuous development and change, higher education has faced increasingly complex and diverse challenges in recent years. Improving the quality and comprehensive ability of postgraduate education has become one of the key objectives of the reform and development of higher education [1], [2]. However, the traditional postgraduate training mode has gradually revealed its limitations in meeting the growing social needs and personnel training requirements. Higher education in China is actively exploring and promoting the reform of the education system [3], [4].

In higher education, especially in postgraduate education, intelligent evaluation, and optimization research has gradually attracted widespread attention. Jiang (2021) utilized data analysis and mining technology to comprehensively evaluate the academic achievements, scientific research activities, and practical experience of graduate students to understand the characteristics and potential of students better and provide a basis for personalized training programs [5]. He (2020) discussed the critical issues of cultivating the comprehensive ability of graduate students. For example, how to reasonably integrate elements such as case teaching, curriculum system, mentor system, and practical system and establish effective connections and interactions between these elements to achieve the best effect of comprehensive ability training [6]. Liu (2023) focused on how to use big data analysis (BDA), machine learning (ML), and artificial intelligence (AI) technology to quantitatively evaluate the academic performance, innovation ability, and practical experience of graduate students [7].

The importance of this study cannot be ignored, as it deeply explores intelligent evaluation and optimization methods in the cultivation of postgraduate comprehensive abilities. In the current field of education, although research on intelligent evaluation and personalized learning is increasing, how to effectively integrate these concepts and technologies into postgraduate education models, especially in the application of the "one case, three systems" model, is still an area that has not been fully explored. In addition, the practical application of music education and virtual reality (VR) technology in the education system and how these technologies affect the quality and effectiveness of postgraduate ability development also require more systematic research and evaluation. Hence, this study aims to fill the gap in existing research by introducing intelligent technology and advanced algorithms, enriching understanding and comprehension of intelligent evaluation, personalized learning paths, music education integration, and VR technology application in higher education. Through the implementation of this study, a new postgraduate training evaluation framework based on data-driven and intelligent analysis can be constructed. Moreover, the effectiveness and advantages of intelligent evaluation and optimization methods in practical applications can be more clearly revealed through empirical research. As a result, the quality of postgraduate education has been improved while providing educators with more accurate training decision support. Additionally, through the in-depth analysis and empirical results provided by this study, it is possible to better understand the design principles of personalized learning pathways and how music education and VR technology can be creatively integrated into modern education systems. It can offer new theoretical and practical perspectives for future research in related fields. Compared to previous studies, this study adopts an advanced weighted clustering algorithm for mixed attributes and the evaluation model based on sampling method and ensemble learning, a significant extension of existing educational evaluation methods. The limitation of this study is that the effectiveness of intelligent evaluation and optimization methods may be limited by factors such as data quality, algorithm adaptability, and diversity of teaching environments. Future research must validate the universality and stability of the proposed model in a broader educational context, thus enhancing comparative fairness and the universality of conclusions. Through continuous iteration and optimization, this study aims to improve the intelligent evaluation and optimization framework for cultivating graduate comprehensive abilities, making it an indispensable part of a high-quality postgraduate training system.

In short, with the rapid development of information technology, many colleges and universities began to explore the use of AI, data mining (DM), ML, and other technical means to achieve the evaluation of graduate students' comprehensive ability and the optimization of training programs. Section I summarizes the research background, current situation, and purpose. Section II proposes a weighted clustering algorithm for mixed attributes to solve the attribute evaluation problem. Then, an evaluation model of postgraduate training quality based on sampling method and ensemble learning is established. Section III tests the performance of the algorithm and model proposed here, describes the test data, environment, and results, and compares and discusses the proposed method with the traditional method. Section IV looks forward to the research contribution and future direction, explaining this study's theoretical and practical value and development space. Section V concludes the study.

II. Literature Review

In the research field of "One Case, Three Systems," under the intelligent evaluation and optimization of postgraduate education comprehensive ability training mode, the work of multiple scholars provides key background and support for the current research. Li et al. (2020) introduced the entropy weight method and grey clustering analysis, providing a novel method for evaluating the quality of online teaching [8]. This reflected the scholars' understanding of using multi-dimensional evaluation when facing the problems of online teaching quality. Based on the proposed evaluation model, scholars also proposed a series of strategies to improve the quality of online teaching, thus enriching the practical application of the research. However, this study had limitations, such as the representativeness and feasibility of the datasets used in empirical analysis. Future research can further validate and expand the conclusions of this study through broader data collection and deeper empirical research. Lee et al. (2021) focused on a holistic music education approach for children jointly developed by music therapists and experts, combining technology and music, integrating local culture, and constructing a holistic education framework [9]. The research results indicated that implementing a holistic music education approach can significantly enhance children's abilities with developmental delays, while supportive training has a positive effect. In addition, decision trees explored and developed an intelligent evaluation model with high learning effectiveness. The sensitivity of this model within the sample reached 90.6%, while the comprehensive indicator F was 79.9%, which had a high reference value. In the future, educators can use DM to assist decision-making systems as evaluation tools to evaluate children participating in education in the early and middle stages of the curriculum. It can also predict their continuous implementation and learning effectiveness, help decide whether to continue investing and adjusting the curriculum, and use educational resources more effectively. Yang et al. (2022) investigated the evolution from Assessment of Learning (AoL) to Assessment as Learning (AaL) from four aspects: participants, testing format, process-based multivariate data, and measurement models for multivariate data. They proposed suggestions for interdisciplinary collaboration, integrating education, psychology, and information technology into the theories and methods of educational measurement [10]. In addition, the study emphasized that measurements' effectiveness, ethics, and fairness should also be considered vital issues. Researchers and practitioners in educational measurement must adhere to the pursuit of the substantive significance of measurement and provide unique experience and guidance for the theoretical and practical development of educational evaluation in this tremendous revolution. Wang et al. (2022) constructed a personalized learning model based on distributed computing methods of the Internet of Things (IoT) and clustering algorithms of deep learning (DL). The research results showed that the accuracy of this model on personalized learning platforms based on the IoT and DL algorithms reached 85% [11]. Compared with the latest research models, this model performed better in score prediction and customized recommendations. This model had significant practical value in promoting the development of the IoT and DL in professional learning. This exploration innovatively divided the understanding level of learners at a hierarchical level. It provided personalized learning resources aligned with their cognitive abilities to enhance their knowledge level and achieve personalized learning. These studies focused on improving algorithm performance, offering relevant research for the performance improvement of weighted clustering algorithms in this study. Lee and Hwang (2022) highlighted sustainable education from the perspective of VR technology application, providing innovative insights into the educational research field [12]. By delving into the experience of pre-service teachers in VR content design, they highlighted the importance of this transformative experience in enhancing teachers' technical readiness, digital citizenship, and perceived educational benefits. The study emphasized the importance of introducing emerging technologies into education to promote sustainable education development.

Although the research of the above scholars provided valuable insights into the current fields of intelligent evaluation, personalized learning, music education, and the application of VR technology in education, there are certain limitations to each research. Firstly, many studies were influenced by specific backgrounds, sample sizes, and dataset limitations, which limited their universality and generalization ability. Secondly, the empirical analysis of some studies lacked sufficient breadth and depth, failing to validate the applicability of the proposed model. Besides, some studies still lacked practical application cases in real-world environments, thus limiting their guiding role in practice. However, examining previous research provided this study with a profound understanding of different aspects of the field of education. Still, these findings must be validated in a broader and more diverse context. In addition, there was a relative lack of comprehensive research on cultivating graduate students' extensive abilities under the "One Case, Three Systems" model. Previous research aimed to fill some gaps in previous studies and expand understanding of the practical applications of personalized learning, intelligent evaluation, music education, and VR technology in education. By delving deeper into the limitations of previous research, there was an urgent need for broader, deeper, and more empirical research to enhance the practicality of existing theoretical frameworks and promote their practical application. This study's importance was applying the feature-weighted clustering algorithm and training quality evaluation model to build a more comprehensive framework for postgraduate training evaluation. Compared with the previous research, this study emphasized the total consideration of multi-dimensional characteristics while improving the evaluation model's algorithm performance and accuracy.

III. Method

A. Feature-weighted Clustering Algorithm for Mixed Attributes

The feature-weighted clustering algorithm for mixed attributes proposed in this study is a data clustering technology that deals with numerical and discrete (mixed attributes) data [13,14]. The flow of the clustering algorithm is displayed in Fig. 1:

In Fig. 1, the proposed algorithm's core idea is to give appropriate weights to different attributes in the clustering process to accurately reflect the importance of attributes when calculating the distance or similarity between data points [15]. The specific process is as follows:

Step 1: Improvement of dissimilarity of classification attributes;

Sample distribution information is described by covariance matrix, and the Mahala Nobis distance D_m^2 between sample x_i and cluster center a_j is defined by Eq. (1):

$$D_m^2 = (x_i - a_j)\Sigma^{-1}(x_i - a_j)^T \tag{1}$$

Σ represents covariance matrix, which Eq. (2) can calculate:

$$\Sigma = \frac{1}{n}\sum_{i=1}^{n} x_i {x_i}^T - a_j {a_j}^T \tag{2}$$

On this basis, the proportional coefficient P is introduced to increase the statistical probability of classified samples and unclassified samples in clustering, as illustrated in Eq. (3):

$$P = diag\left(\sqrt{\gamma_1}, \sqrt{\gamma_2}, \cdots, \sqrt{\gamma_m}\right), \gamma = 1 - |C_l| \,/\, |C_{lij}| \tag{3}$$

Fig. 1. Flow chart of feature-weighted clustering algorithm for mixed attributes.

$|C_l|$ refers to the number of classified samples, and $|C_{lij}|$ denotes the frequency of the *j*-th attribute of unclassified sample x_i in C_l . Redefine Mahalanobis distance after orthogonal decomposition of positive definite matrix Σ, as listed in Eq. (4):

$$D_m^2 = \left[PQ\Lambda^{-\frac{1}{2}}Q^T(x_i - a_j)\right]^T \left[PQ\Lambda^{-\frac{1}{2}}Q^T(x_i - a_j)\right] \quad (4)$$

Q is the inverse of the covariance matrix, the off-diagonal element of Λ is 0, and the diagonal element is the eigenvalue of the covariance matrix.

Step 2: Calculation of the weights of the numerical attributes;

The *K* nearest neighbor sample of x_i reads:

$$KN(x_i) = \{x_j | d(x_i, x_j) \le d(x_i, Near(x_i))\} \quad (5)$$

$Near(x_i)$ represents the nearest *K*-th sample point to the Mahala Nobis of x_i. The definition of intra-cluster dispersion d_1 is as follows:

$$d_1 = \sum_{j=1}^{k} \frac{|x_{ij} - KN(x_{ij})|}{max(A_l) - min(A_l)} \quad (6)$$

A_l represents the cluster's feature set of sample points. The definition of cluster dispersion is expressed by Eq. (7):

$$d_2 = \sum_{C} \frac{p(C)}{1 - p(x_i)} \sum_{j=1}^{k} \frac{|x_{ij} - KN(x_{kj})|}{max(A_l) - min(A_l)} \quad (7)$$

$C \neq class(x_i)$. The update of the weights of samples and *X* on the feature set A_l is Eq. (8):

$$w_l^n = w_l^n - \frac{d_1}{mk} + \frac{d_2}{mk} \quad (8)$$

The weights of numerical attributes are mainly determined by d_1 and d_2. The smaller the intra-cluster dispersion is, the greater the inter-cluster dispersion is, and the higher the similarity of samples in changing attributes. On the contrary, the lower the discrimination of attributes for clustering, the greater the weight.

Step 3: Calculation of the weight of the classification attribute [16,17];

$D(A_l) = \{a_l | a_l = x_{il}, 1 \le i \le n, P \le l \le m\}$ is defined as the set consisting of the first attribute of the sample set *X*, and its distribution function is as follows:

$$\begin{cases} p(a) = \frac{|D(A_{l=v})|}{|D(A_l)|} \\ p(r) = \frac{|D(R_{l=t})|}{|D(R)|} \\ p(a,r) = \frac{|D(A_{l=v})|}{|D(R)|} \end{cases} \quad (9)$$

$p(a)$ and $p(r)$ are the marginal probability distribution function of classification attribute *A* and clustering result R; $p(a, r)$ is the joint probability distribution function of *A* and *R*. The mutual information *M* between *A* and *R* can be written as Eq. (10):

$$M(A_l, R) = \sum_{r \in R} \sum_{a \in A_l} p(a, r)\, log\, 2\, \left(\frac{p(a,\ r)}{p(a) * p(r)}\right) \quad (10)$$

The weight of the classification attribute is calculated as Eq. (11):

$$w_l^C = \frac{M(A_l, R)}{\sum_{l=p+1}^{m} M(A_l, R)} \quad (11)$$

Based on these calculations, the revised objective function $E(U, C)$ is obtained, as indicated in Eq. (12):

$$E(U, C) = \sum_{j=1}^{k} \sum_{i=1}^{n} u_{ij}{}^{a}(w_l^n d_1(x_i - a_j) + \gamma w_l^C d_2(x_i - a_j)) \quad (12)$$

Step 4: Update of the cluster center;

The updating equation of the l-th numerical feature c_{jl} of the cluster center c_j is:

$$c_{jl} = \frac{\sum_{i=1}^{n} (u_{ij})^a w_l^n x_{il}}{\sum_{i=1}^{n} (u_{ij})^a} \quad (13)$$

The equation for updating the l-th classification feature c_{il} of the cluster center c_i reads:

$$c_{il} = a_l^s \in D(A_l) \quad (14)$$

s satisfies the condition shown in Eq. (15):

$$\sum_{i=1}^{n} (u_{ij}{}^{a} | x_{ij} = a_l^s) \ge \sum_{i=1}^{n} (u_{ij}{}^{a} | x_{ij} = a_l^t), s \ge 1, t \le |D(A_l)| \quad (15)$$

$|D(A_l)|$ is the number of values of the classification attribute A_l.

Step 5: Initialization of parameters, cluster center matrix, and iteration times;

All variables start from 0, and the maximum number of iterations is set to t.

Step 6: The weighted clustering is completed according to the process shown in Fig. 1.

B. *Evaluation Model of Postgraduate Training Quality based on Sampling Method and Ensemble Learning*

The evaluation model of postgraduate training quality based on sampling method and ensemble learning is an analytical tool for evaluating the process and effect of postgraduate training [18]. The specific structure is presented in Fig. 2.

Fig. 2 signifies that postgraduate training involves data of multiple dimensions, such as academic achievements, scientific research activities, and practical experience. To reduce computational complexity and improve efficiency, the model extracts feature from different training dimensions and gives appropriate weights to different features in the selected samples, accurately reflecting their importance in training quality evaluation.

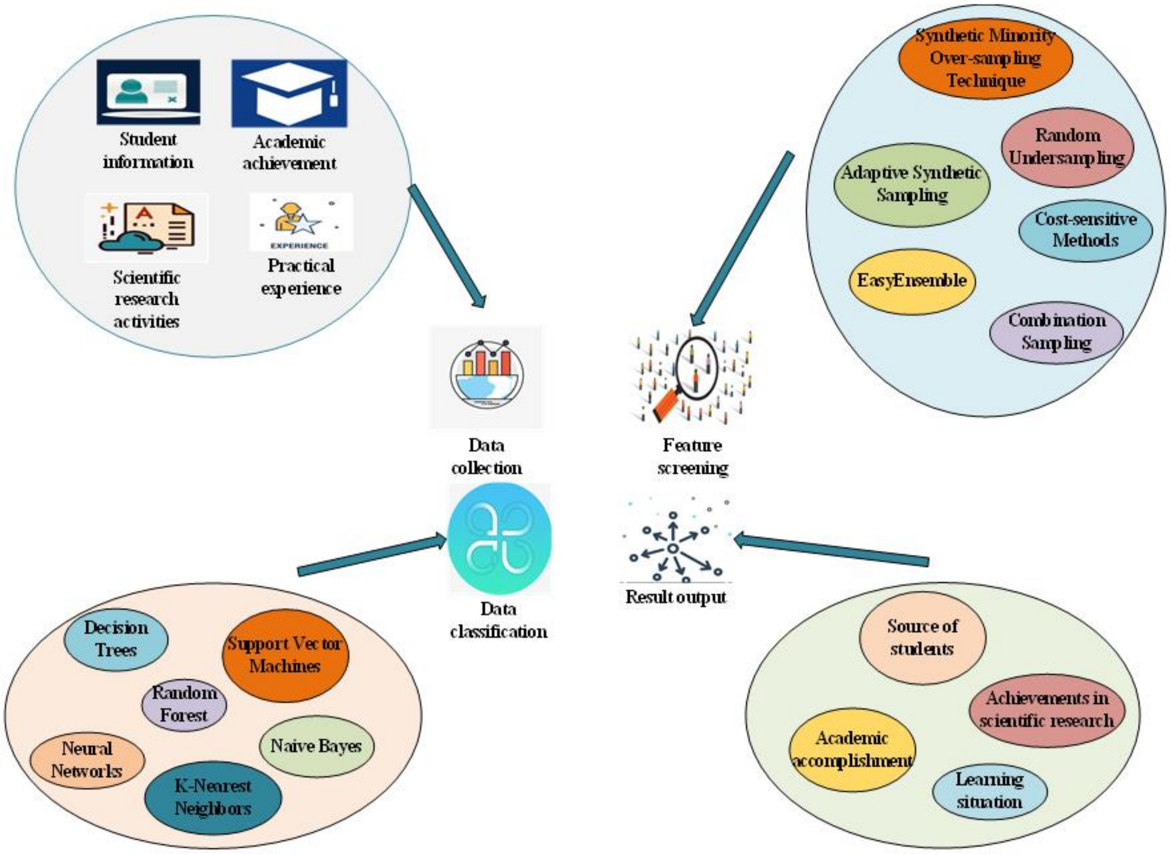

Fig. 2. Model structure of postgraduate training quality evaluation based on sampling method and ensemble learning.

IV. Results and Discussion

A. Data Collection and Experimental Environment

This study employs the Student Performance Data Set data from the University of California, Irvine's UCI ML Repository database as the algorithm performance test's test set and data source. The UCI data set is an open-source dataset proposed by the University of California, Irvine, which is suitable for pattern recognition and ML direction. Many scholars choose to use the data set on UCI to verify the correctness of their proposed algorithms. These data sets are divided into binary classification, multi-classification, and regression fitting problems. The UCI data set provides the main attributes of each data set. It can be used to demonstrate the rationality of various algorithms proposed by oneself through experimental results on its data set. Data address: https://archive.ics.uci.edu/datasets. The Student Performance Data Set aims to predict the performance of students in two secondary schools in Portugal, covering two different subjects: Mathematics (mat) and Portuguese (por). The data collection methods include school reports and questionnaire surveys, encompassing multiple attributes such as student performance, demographics, and social and school-related characteristics [19]. The entire data set contains 649 instances, mainly used for classification and regression tasks. Two independent data sets correspond to two subjects: mat and por. In both data sets, the target attribute G3 refers to the final year grade, while G1 and G2 represent the first and second-semester grades, respectively. It is important to note that there is a strong correlation among G3, G2, and G1. This is because G3 is the final grade (released in Semester 3), while G1 and G2 correspond to Semester 1 and 2 grades. Although it is more challenging to predict G3 without G2 and G1, this prediction is more useful in practical applications. The attributes of this data set include school, gender, age, place of residence, family size, parental cohabitation status, parental education levels, parental occupation, the reason for choosing a school, guardians, school time, study time, number of past classroom failures, additional educational support, family educational support, extra paid courses, and extracurricular activities. Additionally, it also involves whether to attend daycare, whether to plan for higher education, whether there is a romantic relationship, family network access, quality of family relationships, free time after school, frequency of outings with friends, alcohol consumption on workdays and weekends, current health status, and school absences. Data address: https://archive.ics.uci.edu/dataset/320/student+performance.
This study tests the evaluation model of postgraduate training quality based on sampling method and ensemble learning. The ratio of the training set to the data set is 4:1, and the number of training set samples is 622, divided into three levels: high, medium, and low, with the numbers 68, 480, and 74, respectively. The test set's data volume is 156, and the number of high, medium, and low samples is 17, 121, and 18, respectively, which meets the proportional requirements.

The experimental equipment environment of this study is Dell notebook equipment; the CPU model is Intel (R) Core

(TM) i5-7300HQ CPU @ 2.50GHz; the memory is 8G; the graphics card model is GTX1050; the operating system is Windows 11 system, and the software environment is C++ language environment to ensure the stability of the algorithm and model in the process of training and testing.

B. Indicator Setting

1) Feature-weighted clustering algorithm for mixed attributes: This study uses the accuracy F-Measure to evaluate the algorithm's performance. F-Measure is the weighted harmonic average of accuracy and recall. Accuracy indicates the proportion that objects in the same cluster are divided into the same category, and recall reflects the proportion that objects in the same category are assigned to the same cluster. The fuzzy factor is set to 2 in the experiment, the clustering threshold is 0.0001, and the maximum number of iterations T is set to 10000.

When the algorithm is used to verify the comprehensive ability training of postgraduate education, it is verified by the evaluation results of the postgraduate training information data of S University from 2019 to 2022 according to the indicators exhibited in Table I:

Table I describes that 11 secondary refinement indicators are set under the classification of four primary indicators: student source, tutor title, scientific research achievements, and learning situation, and weighted cluster analysis is carried out.

a.

2) Evaluation model of postgraduate training quality based on sampling method and ensemble learning: Aiming at the designed evaluation model, this study evaluates it through three standards: accuracy, recall, and F1 value. F1 value, as a calculation index of the reconciliation of accuracy and recall, can fully reflect the classification ability of the model and is the most representative.

C. Experimental Result

To verify the accuracy of the proposed feature-weighted clustering algorithm, this algorithm is compared with the fuzzy clustering, the goal-Okumoto-kapur with k-prototypes, synthetic minority over-sampling technique, the Adaptive Synthetic Sampling, and the improved genetic fuzzy K-Prototypes algorithms. They are named A1, B2, C3, D4, E5, F6 in turn. Fig. 3 depicts various algorithms' clustering accuracy and clustering effect on data sets.

In Fig. 3(a), as the number of experiments increases, the proposed weighted clustering algorithm can achieve over 90%, which is 10% higher. Fig. 3(b) denotes that the average number of iterations of the algorithm proposed here is 276, and the accuracy and F value can reach the highest level with fewer iterations and stable algorithm performance. Fig. 4 demonstrates the proposed algorithm’s weighted clustering results for postgraduate training quality and various algorithms’ contour change curves with the change of fuzzy factors.

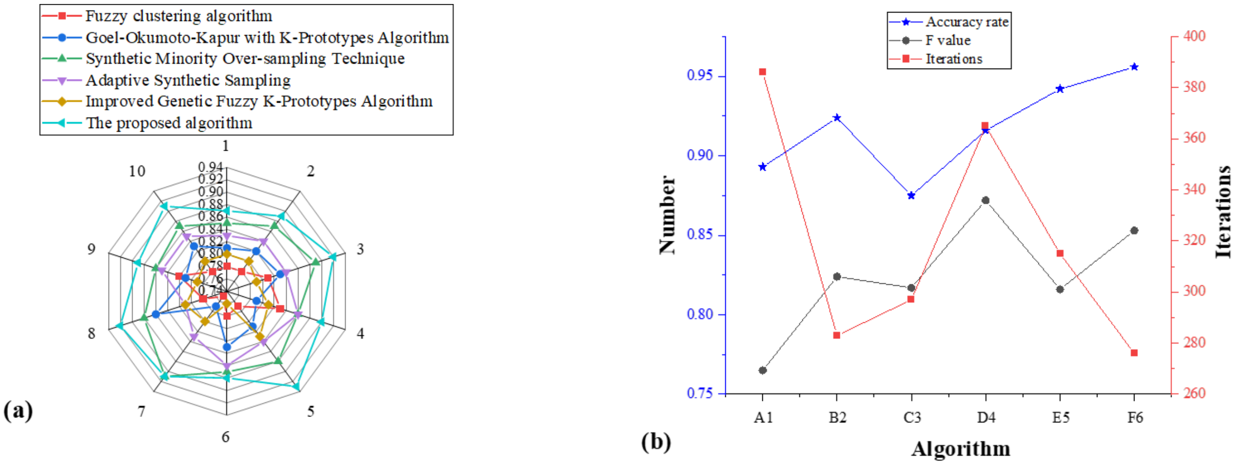

Fig. 3. Clustering accuracy and clustering effect of different algorithms on data sets ((a) Clustering accuracy; (b) Clustering effect).

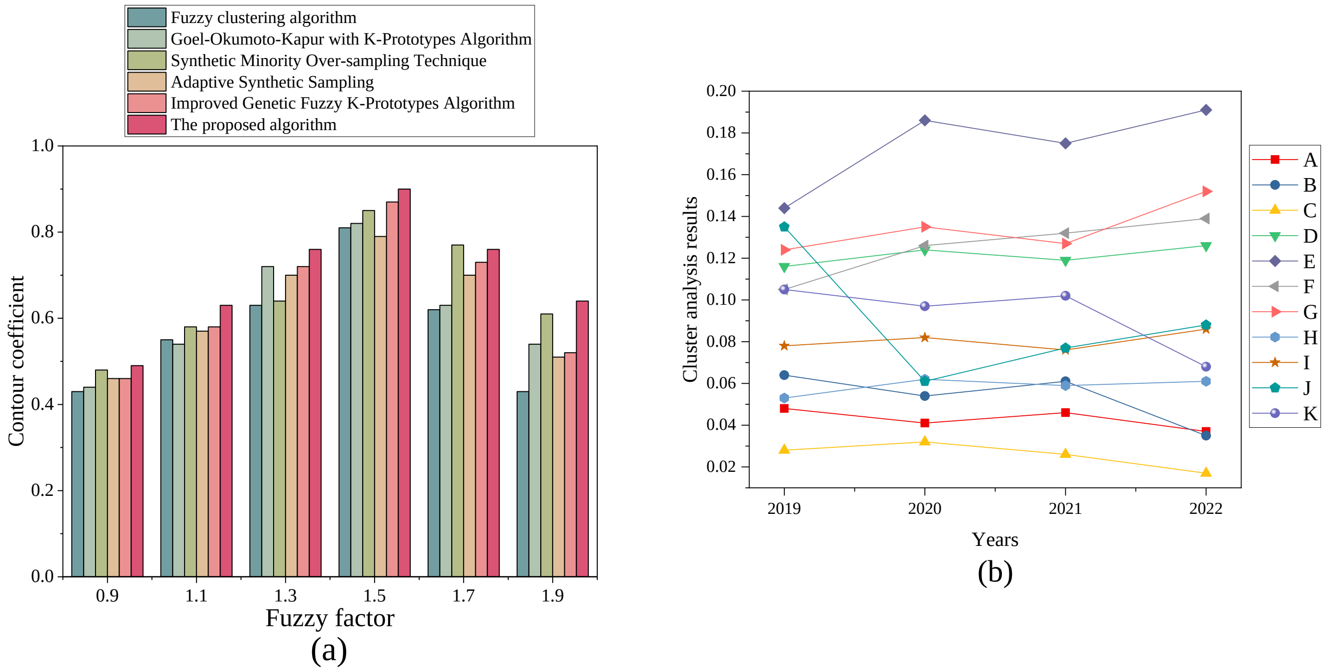

Fig. 4. Evaluation results of postgraduate training quality (a) Changes of contour coefficients of various algorithms; (b) Weighting cluster analysis results for evaluation elements)

In Fig. 4(a), with the fuzzy factor gradually increasing from 0.8 to 2.0, the contour coefficient of the proposed algorithm is higher than other algorithms, and the average value is around 0.2. It illustrates that the weighted clustering algorithm designed in this study can guarantee the data features to the greatest extent and has great advantages for feature extraction. In Fig. 4(b), the weight of evaluation indicators has not changed significantly in recent years. The academic achievements of tutors and the quality of papers published by students have become the most influential factors in the cultivation of postgraduate education ability, accounting for a relatively high proportion, with a comprehensive rate of over 46%. It can be found that the guidance of mentors to students and the students' research results are the core content of current postgraduate education ability cultivation. Fig. 5 presents the comparison of diverse classification and sampling algorithms' evaluation performance:

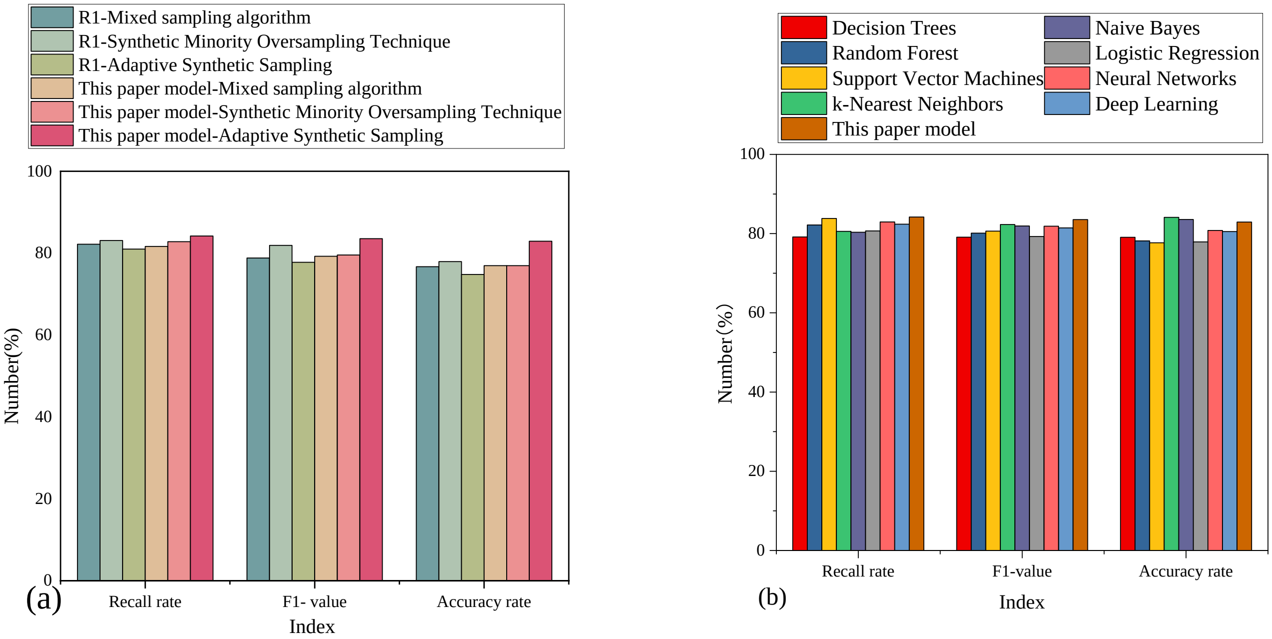

Fig. 5. Comparison of evaluation performance of different sampling and classification algorithms ((a) Comparison of sampling algorithms; (b) Performance comparison of classification algorithms).

In Fig. 5, this study sets the sampling comparison algorithm as a mixed sampling algorithm, synthetic minority oversampling technique algorithm, and Adaptive Synthetic Sampling algorithm. It constructs the R1 model based on a decision tree and random forest as base classifiers. As a meta-classifier, the Gradient Boosting Decision Tree is a quality evaluation model of postgraduate education based on sampling method and ensemble learning. Then, the model's performance is tested. In Fig. 5(a), the F1 value of the model proposed in this study is 83.54%. The accuracy is 82.91%, and its practical application performance is good. Compared with the R1 model, the proposed model’s F1 value and accuracy increase by 3.29% and 6.75%, respectively. In Fig. 5(b), compared with other algorithms, the proposed model has a recall of 84.18%, an F1 value of 83.54%, and an accuracy of 82.91%. This model has higher accuracy and stability and can effectively solve the problems of subjectivity and data imbalance in the evaluation process.

The performance evaluation results of the feature-weighted clustering algorithm on different data sets are outlined in Table II. The EduNLP Student Performance Data Set in Table II analyzes students' literal expressions and evaluates their academic performance and needs through natural language processing technology. Student Performance in Online Learning Data Set is employed to evaluate students' performance in online learning, including learning time, interaction, and other characteristics. Student Academic Performance Data Set (Kaggle) is used to analyze students' academic performance, involving grades, subject preferences and other characteristics. The results reveal that among all data sets, the feature-weighted clustering algorithm performs best on the UCI data set, at 90%, while the performance is relatively low on the Online Learning Data Set, at 81%. On different data sets, the average number of iterations of the algorithm fluctuates in a relatively reasonable range, and the average number of iterations on UCI data set is the lowest, at 276. The algorithm on the UCI data set performs the best in terms of contour coefficients, at 0.2, while the Online Learning Data Set is at 0.16. In all data sets, feature-weighted clustering algorithms use evaluation indicators such as F1 value, accuracy, and recall, providing researchers with a comprehensive performance evaluation. These evaluation results provide a reference for applying feature-weighted clustering algorithms in different backgrounds, and the performance on the UCI data set offers potential best practices for other datasets. The performance on the EduNLP Student Performance Data Set is second, while the performance on Online Learning Data Set is relatively poor, requiring more in-depth research and improvement. The Student Academic Performance dataset performed well, approaching the performance level of the UCI data set.

The performance evaluation results of various intelligent evaluation methods on UCI data sets are suggested in Table III. The results of Table III indicate that the performance of the proposed weighted clustering algorithm for mixed attributes is the best, with a clustering accuracy of 90%, an average number of iterations of 276, and a contour coefficient of 0.2. In contrast, although the STEAM Education+Smart Greenhouse VR [20] algorithm performs relatively stable in clustering accuracy, its overall performance is poor, with a clustering accuracy of 80%, an average number of iterations of 300, and a contour coefficient of 0.15. The Analytic Hierarchy Process+Delphi method [21] achieves good clustering accuracy, reaching 85%, but slightly inferior to the proposed algorithm in other indicators. The neural fuzzy method with multiple inputs and outputs [22] has relatively low clustering accuracy and F1 value, at 78% and 73.25%, respectively. However, its average number of iterations is 350, which may have some stability issues. The binary genetic algorithm [23] and the educational data classification method of swarm intelligence [24] obtain 82% and 87% clustering accuracy, respectively. Furthermore, their performances are relatively balanced, but slightly inferior to the proposed algorithm in other indicators. In general, the proposed algorithm has excellent clustering accuracy, average number of iterations, and F1 value, proving its effectiveness in students' comprehensive ability evaluation.

TABLE II. PERFORMANCE EVALUATION RESULTS OF FEATURE WEIGHTED CLUSTERING ALGORITHMS ON DIFFERENT DATA SETS

Data Set	Cluster accuracy (%) (Mean)	Average number of iterations	Contour coefficient (Mean)	Evaluation indicators	F1 value (%)	Accuracy (%)	Recall rate (%)
Student Performance Data Set (UCI)	90	276	0.2	Feature-weighted clustering	83.54	82.91	84.18

D. Discussion

Zhu (2023) paid attention to using intelligent methods to design personalized learning paths and course recommendation systems to improve graduate students' comprehensive ability training effect according to their interests, abilities, and backgrounds [25]. Thurzo (2023) used BDA, ML, and DM technology so researchers could analyze students' learning behavior, performance, and progress and dig out meaningful information for cultivating graduate students' comprehensive ability to evaluate and optimize their intelligence [26]. Shan (2023) focused on building a complete comprehensive ability evaluation system, including academic ability, innovation ability, practical ability, and other indicators and standards, to conduct intelligent evaluation and optimization more effectively [27]. The algorithm and model proposed in this study can achieve an accuracy of over 90% with an increase in the number of experiments, an improvement of 10%, and an average iteration of 276 times. Therefore, the accuracy and F-value can reach the highest level. With the fuzzy factor increasing from 0.8 to 2.0, the proposed algorithm's contour coefficient is larger than other algorithms, and the average value is about 0.2. The proposed model's F1 value is 83.54%, and the accuracy is 82.91%. Compared with the R1 model, the proposed model's F1 value and accuracy are improved by 3.29% and 6.75%, and the recall and F1 values are 84.18% and 83.91%. Compared with the traditional methods, the feature-weighted clustering algorithm for mixed attributes can better consider the relationship between different attributes and improve the accuracy and interpretation of clustering. The evaluation model of postgraduate training quality based on sampling method and ensemble learning can make personalized evaluation and training suggestions according to the situation of individual students to better meet their needs and development direction.

V. CONCLUSION

The proposed weighted clustering algorithm based on mixed attributes can better handle multi-attribute data and accurately evaluate graduate students' comprehensive ability. The evaluation model of graduate students' training quality based on sampling method and ensemble learning provides new ideas and tools, and personalized training suggestions can better meet the needs of graduate students. Applying the algorithm and model to emergency management helps improve the quality and effect of graduate students' training in this field. However, the proposed methods and models still need adaptive adjustment in other fields, and their versatility is limited. In future research, people can consider introducing multiple data sources, such as text, image, and voice, to carry out multimodal data fusion to evaluate graduate students' comprehensive ability. In addition, applying the proposed methods and models in other professional fields has been explored to verify their applicability and effectiveness in different fields.

***Abstract*—Retinal disorders such as age-related macular degeneration and diabetic macular edema can lead to permanent blindness. Optical coherence tomography (OCT) enables professionals to observe cross-sections of the retina, which aids in diagnosis. Manually analyzing images is time-consuming, difficult, and prone to mistakes. In the dynamic and constantly evolving domain of artificial intelligence (AI) and medical imaging, our research represents a significant development in the field of retinal diagnostics. In this study, we introduced "RetiNet", an advanced hybrid model that is derived from the best features of ResNet50 and DenseNet121. To the model, we utilized an open-source retinal dataset that underwent a meticulous refinement process using a series of preprocessing techniques. The techniques involved Histogram Equalization for the purpose of achieving optimal contrast, Gaussian blur to mitigate noise, morphological operations to facilitate precise feature extraction, and Data Balancing to ensure impartial model training. These operations led to the attainment of a test accuracy of 98.50% by RetiNet, surpassing the performance standard set by existing models. A web application has been developed with the purpose of disease prediction, providing doctors with assistance in their diagnostic procedures. Through the development of RetiNet, our research not only transforms the accuracy of retinal diagnostics but also introduces an innovative combination of deep learning and application-oriented solutions. This innovation brings in a novel era characterized by improving reliability and efficiency in the field of medical diagnostics.**

Keywords—Retinal disease; RetiNet; hybrid model; learning; Web application; gaussian blur; histogram equalization

I. Introduction

This Retinal disorders commonly result from a combination of predispositions and environmental factors, mostly affecting the structures within the eyes, such as the membrane, lens, and nerve systems within eye. These conditions exert a significant impact on individuals' quality of life. Notably, approximately 7% of those aged 65 and above report experiencing a form of visual impairment [1]. The importance of timely and accurate diagnosis cannot be overstated in mitigating the severity of these conditions. The usage of inappropriate diagnostic approaches may exacerbate the issue. Diabetic Eye Disease (DED), comprising conditions such as diabetic retinopathy, glaucoma, and cataracts, is a significant cluster of visual impairment that impacts individuals with diabetes. Extended periods of diabetics can result in a decline in visual acuity and, in severe cases, substantial visual loss. As stated by the World Health Organization (WHO), among the global population of 2.2 billion people affected by visual impairments, it is estimated that approximately one billion cases may have been preventable with proper diagnostics and treatment [2].

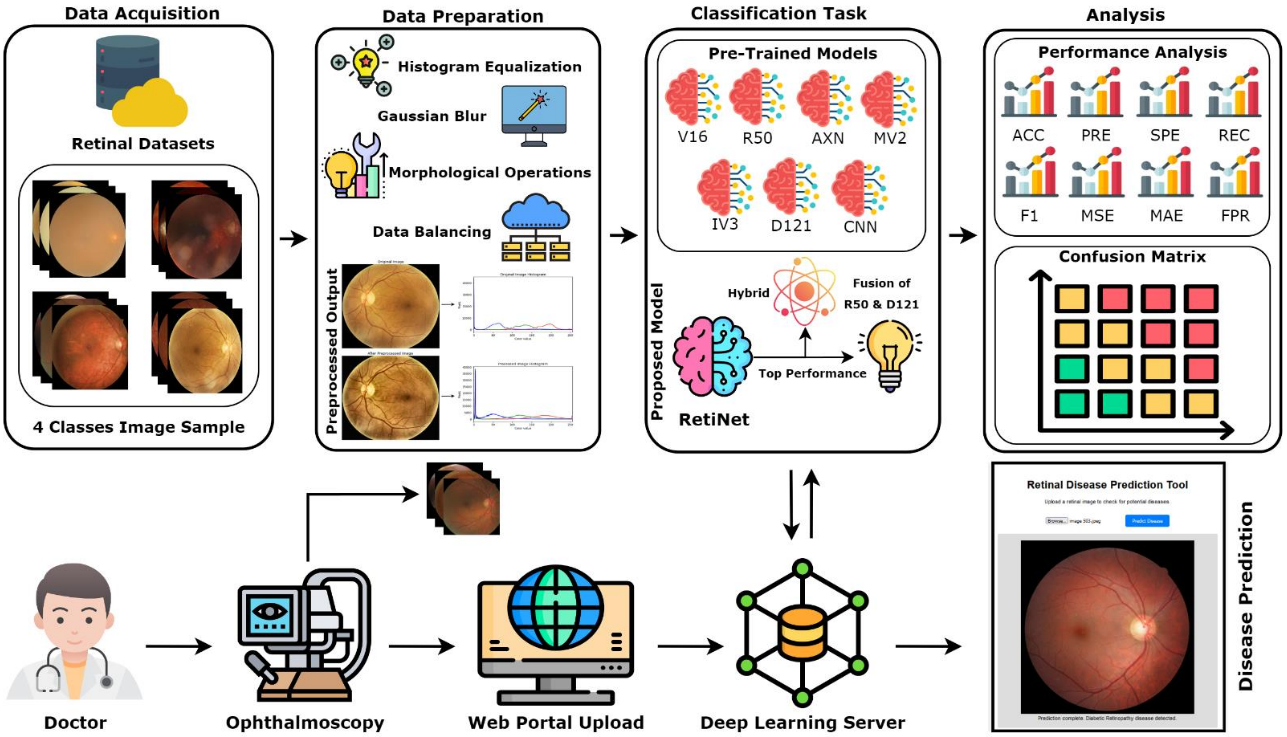
Artificial Intelligence has become an essential resource in assisting healthcare professionals in the early diagnosis of diseases [3, 4]. Currently, numerous AI-driven systems integrate medical test results with domain-specific knowledge to detect and categorize diseases. Furthermore, deep learning (DL) has been employed in various practical contexts, showcasing its promise. Specifically, researchers have utilized DL techniques to identify retinal disorders by analyzing retinal fundus images. Although DL approaches in the field of machine learning (ML) succeed at distinguishing between healthy and diseased retinal images, the challenge of classifying varied retinal disorders into multiple classes remains complex and unresolved.

Numerous studies have attempted to predict or characterize retinal health by analyzing eye images. For instance, the authors in [5] proposed an enhanced technique that employs a novel CenterNet model in conjunction with a DenseNet-100 feature extractor. The study aimed to identify and characterize lesions associated with diabetic retinopathy and macular edema. The approach demonstrated exceptional accuracies of 97.93% and 98.10% when assessed on the APTOS-2019 and IDRiD benchmark datasets. In a comparable way, the study conducted by [6] tested the performance of three distinct classification algorithms across various classes. These algorithms included the Convolutional Neural Network (CNN), Visual Geometry Group 16 (VGG16), and InceptionV3. The analysis and comparison of each approach were performed using the confusion matrix.

The prevalence of retinal disease in ophthalmology has been a significant concern due to its diverse manifestations and rising frequency. Traditional diagnostic approaches, although valuable, may prove ineffective due to inherited human fallibility, namely inaccurate assessment of the intricate details of retinal vision. In order to address challenges, we devised "RetiNet". RetiNet has been developed to surpass the existing limitations in the field of retinal image diagnosis by harnessing the potential of DL to address the associated challenges. The primary focus of RetiNet is the enhancement of diagnostic accuracy. Our study presents a comprehensive approach that presents cutting-edge AI techniques aiming to improve the standards of retinal disease detection. Fig. 1 represents the overall workflow of the proposed system. The primary findings of the study are as follows:

- This study introduced "RetiNet", a novel hybrid model generated from the fusion of ResNet50 and DenseNet121.
- A comprehensive set of preprocessing techniques were utilized, including Histogram Equalization, Gaussian Blur, Morphological Operations, and Data Balancing. The methods guaranteed optimal image quality and consistency, hence facilitating efficient model training and accurate diagnosis.
- The performance of RetiNet surpasses that of other popular models. The outcome emphasizes the efficiency of our hybrid methodology, demonstrating its potential for real-world implementation and reliability.
- This study incorporates a web application in a novel way, providing an efficient instrument for the diagnosis of retinal diseases.

The paper's structure is outlined in the following manner: Section II thoroughly examines previous research. Section III, which focuses on technique, addresses several issues such as data acquisition, data preparation, use of pre-trained models, proposed models, and their corresponding hyperparameters. Section IV provides an in-depth analysis of the results obtained from the research. Section V is on the development and implications of a functional web application. Section VI involves a discourse and comparative examination with prior research. Section VII eventually concludes the article by presenting essential findings and valuable perspectives.



Upload a retinal image to check for potential diseases.

Prediction complete. Diabetic Retinopathy disease detected.

Fig. 1. The overall architecture of the proposed hybrid model RetiNet.

II. Literature Review

Throughout several decades, the scientific community has diligently advocated for the advancement of automated diagnostic systems, with the ultimate goal of revolutionizing the field of medical diagnostics. Traditional expert systems, albeit groundbreaking, operated based on meticulously defined rules, occasionally encountering difficulties when confronted with complex classification challenges. Nevertheless, introducing machine and deep learning has brought forth a renewed vigor in this sector. Through the use of data training, these algorithms have made a substantial contribution to the improvement of research endeavors. Significantly, within the scope of medical research, machine learning distinguishes itself due to its remarkable versatility, demonstrating proficiency in detecting and classifying a multitude of disorders across various domains.

In a recent study by Arslan et al. [7], various CNN architectures were employed to evaluate a 2748 Retinal Fundus images dataset. This dataset comprised 1374 images from healthy individuals and 1374 images from diverse diseased groups. The CNN models underwent thorough evaluation using the 10-fold cross-validation methodology. Remarkably, the EfficientNet architecture demonstrated superior performance with an impressive accuracy and recall rate of 94.88% in measurements. Similarly, Malik et al. [8] developed a rapid diagnosis approach for eye diseases by utilizing a diverse range of machine learning models using Neural Networks. This array consisted of algorithms such as the Decision Tree, Random

Forest, and Naïve Bayes. The ICD-10 codes were used for specific disease diagnoses. Among the classifiers, the Random Forest model had superior performance, achieving an accuracy rate of 86.63%. The Neural Network model closely trailed after, achieving an accuracy rate of 85.98%. In a separate investigation centered on Optical Coherence Tomography, Metin and Karasulu [9] employed two CNN models, ResNet50 and MobileNetV2, as the foundation for their research. When the aforementioned models were employed to analyze data pertaining to several retinal diseases, ResNet50 exhibited an accuracy of 94% whilst MobileNetV2 dropped to 81%.

Sarki et al. [10] introduced an automated technique for the detection of Diabetic Eye Diseases (DEDs) by the analysis of retinal fundus images. The classifier chosen for their study was the CNN model, which was further optimized by fine-tuning using the RMSprop optimizer. The dataset, comprised of images from multiple sources, was specifically curated to facilitate multi-class classification. Remarkably, their classifier achieved an accuracy rate of 81.33% in retinal disease classification. Hussain et al. [11] conducted another study utilizing a dataset consisting of 251 spectral-domain optical coherence tomography (SD-OCT) images. Among the sample, a total of 192 cases were indicative of retinal diseases, while the remaining 59 cases were of healthy eyes. The researchers utilized the Random Forest classification technique to differentiate between data indicative of illness and normal conditions. To ensure the model's robustness, a 15-fold cross-validation process was utilized, yielding a remarkable classification accuracy of 96.89%.

Additionally, Almansour et al. [12] introduced a CNN architecture that drew inspiration from the VGG16 model, with a specific focus on glaucoma detection. The researchers acquired data from a total of seven distinct databases. The localization of the Region of Interest (ROI) was given particular emphasis, resulting in the allocation of a total of 2084 samples for classification subsequent to ROI analysis. To enhance the performance of the VGG16 model, two more layers were incorporated, ending with the Softmax activating function. Upon evaluating the combined data from all the datasets, the model demonstrated a noteworthy accuracy rate of 78%. In an independent study, Seker et al. [13] developed a CNN model using Keras framework for the purpose of glaucoma classification. The fundus images were first subjected to preprocessing using the Irfanview graphic schemes prior to being inputted into the classification pipeline. The suggested framework was robust, consisting of 49 layers and employing the Adam optimizer with binary cross-entropy loss function. This demonstrates a classification accuracy of 85%.

The limitations in the current retinal disease identification using conventional imaging techniques have been evident through various research. Numerous contemporary models encounter challenges pertaining to the accuracy rate of predictions and the complexity involved in augmenting retinal image datasets. In order to address these challenges and enhance the quality of retinal diagnostics, we introduced “RetiNet”. The primary objective with RetiNet is to utilize its hybrid architecture to achieve exceptional accuracy in the diagnosis and classification of retinal diseases. This attempt highlights our commitment to enhancing diagnostic skills and redefining the parameters of retinal imaging diagnostics.

III. Methodology

A. Data Acquisition

In the context of retinal disease diagnosis investigation, we employed an extensive dataset of retinal images collected from the renowned open-source platform Kaggle [14]. The dataset is crucial to our study as it contains many images corresponding to various eye conditions. This comprehensive collection allows for a balanced and intricate approach to our analysis. The dataset consists of 1074 images depicting Healthy Eyes, 1038 images of Cataract, 1098 images implying Diabetic Retinopathy, and 1007 images displaying Glaucoma. Such heterogeneity not only contributes to the robust classification of various eye diseases but also provides a dimension of authenticity to our investigation. For an understanding of the range of diversity present in the dataset, Fig. 2 may serve as a useful reference, as it displays sample images from each category. The utilization of this dataset has played a pivotal role in our research, facilitating the establishment of evaluations and findings based on empirical evidence from the real world.

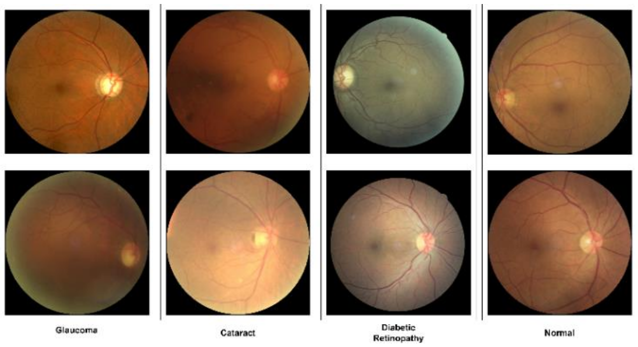


Fig. 2. Sample images of the four classes from the selected retinal datasets.

B. Data-preparation

1) Histogram equalization: The study utilized a specialized histogram equalization technique to manage variations in contrasts across color images effectively. The first step involved the conversion of each image from the RGB color system to the YCbCr color space. The application of histogram equalization was restricted solely to the Y channel, representing luminance, to mitigate any potential color distortion. The equalization procedure commenced by calculating the histogram for the Y channel, which signifies the distribution of pixel intensities. The resulting Cumulative Distribution function (CDF) was utilized to remap each pixel intensity, r in the Y channel according to the following formula:

$$s = \frac{(CDF(r) - CDF_{min})}{(1 - CDF_{min})}\ (L-1) \tag{1}$$

Here, L is the grayscale level, and CDFmin is the smallest non-zero value in the CDF.

This process facilitates the even dispersion of luminance intensities, consequently enhancing regions with low contrast. After equalization, the modified Y channel was reintegrated into the YCbCr image, which was subsequently transformed back to RGB. This approach resulted in a standardized contrast through the entire dataset, generating a consistent foundation for subsequent analysis. Algorithm 1 outlines the operational steps involved in the implementation of histogram equalization.

Algorithm 1: Histogram Equalization for Retinal Images

```
Procedure ColorHistEqu (Image $I$, GrayscaleLevels $L$)
    $I_{YCcCr} \leftarrow$ Convert $I$ to YCbCr color space
    Extract $Y$ channel as $I_Y$
    Initialize histogram array $H$ [0….$L$-1] to zeros
    Initialize CDF array $CDF$ [0….$L$-1] to zeros
    for each pixel $p$ in $I_Y$ do
        $H\ [intensity\ of\ P] \leftarrow H\ [intensity\ of\ P] + 1$
    end for
    $CDF\ [0] \leftarrow H\ [0]$
    for $i$ = 1 to $L$-1 do
        $CDF\ [i] \leftarrow CDF\ [i-1] + H[i]$
    end for
    $cdf_{min} \leftarrow$ minimum non-zero value of $CDF$
    for $i$ = 0 to $L-1$ do
        $normalized_{cdf}\ [i] \leftarrow \frac{(CDF[i]-cdf_{min})}{(1-cdf_{min})}\ (L-1)$
    end for
    for each pixel $p$ in $I_Y$ do
        $P_{newintensity} \leftarrow normalized_{cdf}[intensity\ of\ P]$
    end for
    Replace Y channel in $I_{YCbCr}$ with $I_Y$
    Convert $I_{YCbCr}$ back to RGB color spcae
    Save $I_{YCbCr}$ as 'Output.jpg'
    return $I_{YCbCr}$
end procedure
```

2) Gaussian blur: The Gaussian blur is a widely used convolutional technique where Gaussian Kernel G is convolved with an image I. In the domain of image processing, a technique akin to a weighted average of pixel values is employed, wherein the weights progressively diminish as the distance from the center pixel increases. The Gaussian function in two dimensions is mathematically defined in Eq. (2).

$$G(x,y) = \frac{1}{2\pi\sigma^2}\, e^{-\frac{x^2+y^2}{2\sigma^2}} \tag{2}$$

Here, the variables x and y represent spatial coordinates, whereas σ is the standard deviation that governs the extent of the Gaussian kernel's distribution. The kernel radius is commonly selected as μ =3 σ to account for more than 99% of the Gaussian distribution. To implement the Gaussian Blur on an image, a convolution operation is executed between the image and the Gaussian kernel.

$$(I * G)(u,v) = \sum_{x=-\mu}^{\mu}\sum_{y=-\mu}^{\mu} I(u-x, v-y)\cdot G(x,y) \tag{3}$$

The variable (u, v) represent the pixel coordinates in image I, whereas the variables (x, y) iterate over the dimensions of the Gaussian kernel. The outcome, denoted as $(I * G)(u, v)$, represents a blurred image.

The convolution process is employed to amplify the influence of the central pixels relative to the distant ones, resulting in a visible smoothing effect. As σ increases, the level of blurring becomes more pronounced, resulting in a greater impact on the surrounding pixels. Algorithm 2 is an illustration of the Gaussian blur technique.

Algorithm 2: Gaussian Blur for Image Smoothing

```
Procedure GaussianBlur(Image $I$, StandardDeviation $\sigma$)
    Compute Gaussian kernel radius $\mu \leftarrow 3\times\sigma$
    Initialize Gaussian Kernel G with size $(2\mu+1)\times(2\mu+1)$
    for $x = -\mu to \mu, y = -\mu to \mu$ do
        $G[x+\mu][y+\mu] \leftarrow \frac{1}{2\pi\sigma^2}\, e^{-\frac{x^2+y^2}{2\sigma^2}}$
    end for
    Normalize kernel $G$ such that its sum is 1
    for each pixel $(u, v)$ in $I$ do
        $I_{blurred}[u][v] \leftarrow \sum_{x=-\mu}^{\mu}\sum_{y=-\mu}^{\mu} I(u-x, v-y) \times$
        $G[x+y][y+\mu]$
    end for
    return $I_{blurred}$
end procedure
```

3) Morphological operations: The assessment of eye diseases using retinal images requires meticulous attention to image quality and clarity. Morphological methods, which are fundamentally non-linear in nature, have been integral to our efforts in enhancing these images based on their form. For instance, the dilation technique is used to amplify white regions of the foreground of images. The process of enlarging retinal images improves recognizable characteristics, particularly, blood vessels, to make them easier to identify when applied on images. The concept can be articulated as,

$$f \oplus s\ (x,y) = max_{(a,b)\in s}\{f(x-a, y-b)\} \tag{4}$$

In contrast, erosion functions as an inverse of dilation as it reduces the white regions in the images. This contraction is highly advantageous for the purpose of severing associated objects or eliminating minor noise components, as observed in the context.

$$f \ominus s\ (x,y) = min_{(a,b)\in s}\{f(x+a, y+b)\} \tag{5}$$

The improvement of images can be achieved by implementing the opening operation, which involves a sequential process of erosion followed by dilation. This technique effectively eliminates minor protrusions or objects, which is a necessary tool for reducing noise and artifacts. This operation can be represented as,

$$f \circ s = (f \ominus s) \oplus s \tag{6}$$

The final component of the morphological approaches is the closure procedure. Starting with dilating, followed by degrading an image, it adeptly closes tiny holes or breaches in the foreground, required to restore the discontinuities in blood vessels. The aforementioned procedure can be depicted as,

$$f \bullet s = (f \oplus s) \ominus s \tag{7}$$

Following the series of preprocessing techniques, such as histogram Equalization, Gaussian Blur, and Morphological Operations, the retinal images underwent processing to achieve optimal clarity and enhancement of features. The images generated are prepared for training and subsequently fed into our neural network model, as illustrated in Fig. 3. The histogram of both images (original and preprocessed) shows the changes after applying all the preprocessing techniques (Histogram Equalization, Gaussian blur, and morphological operations).

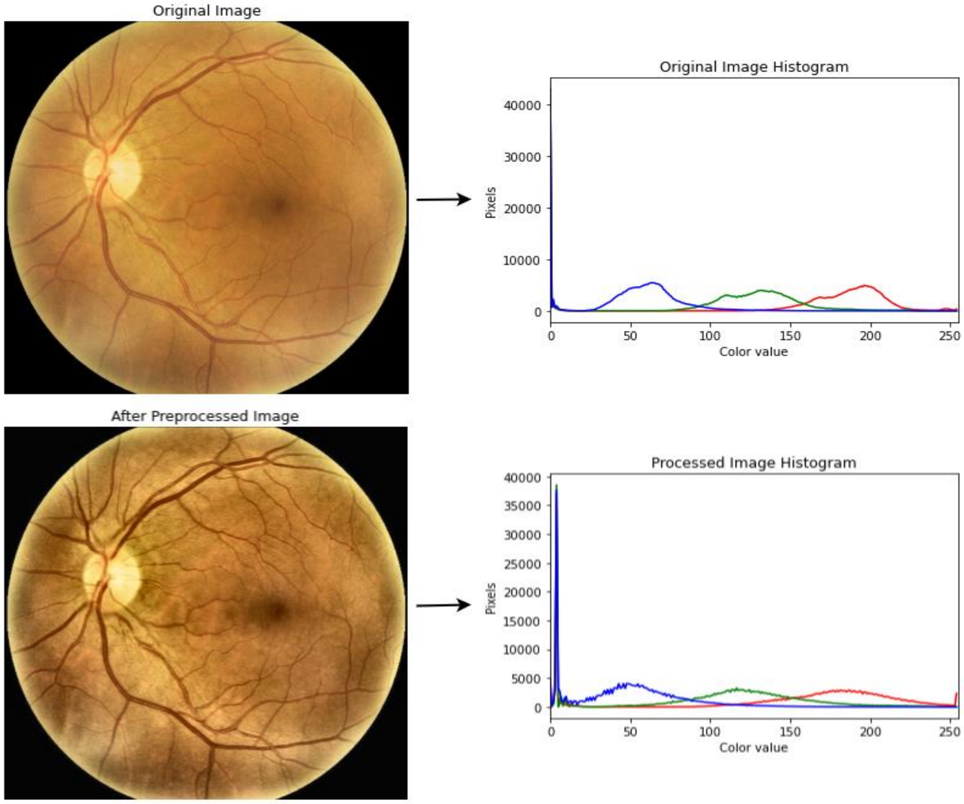

Fig. 3. After all preprocessed steps histogram showing the changes of image enhancement ratio.

4) Data balancing: In the domain of machine learning and data analysis, the presence of an unbalanced dataset has the potential to introduce bias into the model predictions, particularly when one class is disproportionately represented in comparison to the others. The disparity between the classes was detected in our study by analyzing retinal images. The data under-sampling method was employed to resolve this issue. Strategic undersampling involves reducing the number of instances in the overrepresented or majority classes in order to align with the size of the minority class rather than artificially increasing the number of instances in the underrepresented class. This approach equalized 1000 images for each class covering Normal, Diabetic Retinopathy, Cataract, and Glaucoma. While implementing this strategy decreased the overall amount of data for the majority classes, it played a vital role in achieving a balanced distribution of data. A balanced dataset reduces the potential for biased predictions while simultaneously improving the model's capacity for generalization. Algorithm 3 illustrates the general under-sampling technique.

Algorithm 3: Data Undersampling for Class Balance

```
Procedure Undersample (Dataset $D$)
    Determine the size of the smallest class, $minSize$
    for each class $c$ in $D$ do
        $data_c \leftarrow$ Data instances of class $c$
        if size of $data_c > minSize$ then
            Randomly select $minSize$ instances from $data_c$
            to form $newdata_c$
        else
            $newdata_c$
        end if
    end for
    Merge all $newdata_c$ to form the balanced dataset $D'$
    return $D'$
end procedure
```

After establishing a balanced dataset, we further split our data into training, test, and validation subsets to assist the modeling stage. The division adopted a ratio of 70:20:10. The training set consists of 70% of the images from each class, serving as the fundamental data for model learning. The test set comprised 20% of the data and was used to evaluate the performance of the training model on previously unseen data.

The remaining 10% of the data was allocated as the validation set, which serves as an essential component for repeated modification and fine-tuning of the model during the training process. Table I presents a comprehensive analysis detailing the distribution of images across each set and class. The table presented visually demonstrates the rigorous distribution method adopted to achieve effective model training and validation.

TABLE I. FINAL DATA DISTRIBUTION FOR EACH CLASS AND THE ALLOCATION OF DATA INTO TRAINING, TESTING, AND VALIDATION SETS

Class	Original	Balance
Normal	1074	1000

C. Model Evaluation and Classification

The primary objective of our proposed approach is to automatically identify eye disorder while delivering an improved level of classification accuracy. To address the challenges of classifying retinal conditions from retinal datasets, we have developed a novel and robust hybrid CNN model RetiNet. This model is characterized by its distinctiveness, reliability and resilience. In the pursuit of identifying the most effective transfer learning approach for the classification task at hand, we tested seven recognized pre-trained models: VGG16 [15], ResNet50 [16], AlexNet [17], MobileNetV2 [18], InceptionV3 [19], DenseNet121 [20] and a CNN [21]. Table II provides an overview of the important characteristics and fundamental elements of the chosen deep CNN models. The subsequent sections provide a comprehensive evaluation of the architecture and performance of RetiNet, as well as the primary focus of the study.

TABLE II. FEATURES AND ATTRIBUTES OF EVALUATED DEEP LEARNING MODELS

Model	Input Shape	Custom Input Shape	Parameters	Size (MB)
VGG16	224×224	224×224	138,35,7544	528
ResNet50	224×224	224×224	25,636,712	98
AlexNet	227×227	224×224	62,378,344	233
MobileNetV2	224×224	224×224	35,38,984	14
InceptionV3	229×229	224×224	23,851,784	92
DenseNet121	224×224	224×224	80,62,504	33
CNN	224×224	224×224	78,81,365	39
RetiNet	224×224	224×224	35,100,000	136

1) Proposed Models (RetiNet): In the context of eye disease classification from retinal images, a sensitive field of study, the deliberate and evidence-driven decision to combine the capabilities of ResNet50 and DenseNet121. ResNet50 is renowned for its innovative skip or “residual connections” which efficiently counteracts the vanishing gradient issues that often arise in deep neural networks. This ensures that, regardless of the depth of the network, gradients flow smoothly, hence facilitating rapid learning. This ResNet has consistently exhibited its efficacy in many image classification challenges, successfully detecting both broad structures, such as the overarching form of blood vessels, as well as the intricate details, such as subtle deviations that may indicate potential disorders. In contrast, DenseNet121 exhibits an exceptionally thick architecture, where each layer establishes intimate interconnections with all other layers, facilitating a seamless transmission of information.

Since minor details in retinal images might function as early indicators of disorders such as diabetic retinopathy or glaucoma, the dense linkage encourages feature reuse. Additionally, it functions as a built-in regularization mechanism, safeguarding against overfitting, a critical consideration when dealing with constrained datasets. While architectures such as VGG and Inception possess their own merits, our hybrid model is particularly well-suited for the complex demands of retinal image classification due to the combination of the depth and skip connections of ResNet50, along with the extensive feature extraction capabilities of DenseNet-121. The proposed RetiNet model is outlined as follows:

When presented with an input image I, both the ResNet50 and DenseNet121 architectures execute a series of convolutional operations to extract feature maps.

$$F_{resnet}(I) = ResNet50\ (I) \tag{10}$$

$$F_{densenet}(I) = DenseNet121\ (I) \tag{11}$$

where, F_{resnet} and $F_{densenet}$ are the feature maps from ResNet50 and DenseNet121, respectively.

Furthermore, we apply global average pooling (GAP) to these feature maps to get a fixed-size feature vector. For a given feature map F, the GAP operation can be expressed as,

$$GAP\ (F) = \frac{1}{W \times \mathrm{H}} \sum_{i=1}^{W} \sum_{j=1}^{H} F(i,j) \tag{12}$$

where, W and H are the width and height of the feature maps, respectively.

However, the feature vectors obtained from the GAP operation on both networks are concatenated.

$$C = Concatenate\ (GAP(F_{resnet}), GAP(F_{densenet})) \tag{13}$$

The concatenated feature vector C is passed through a dense layer with a ReLU activation function,

$$D = \sigma(W_d \times \mathrm{C} + b_d) \tag{14}$$

where, σ is the ReLU activation function, W_d represents the weight of the dense layer and $b_d$is the bias.

Finally, the feature vector from the dense layer is passed through another dense layer with softmax activation to classify the image into the four classes of eye disease.

$$O = Softmax(W_o \times \mathrm{D} + b_o) \tag{15}$$

where, W_o represents the weights of the output layer and b_o is the bias.

The output O will be a vector with four values, each representing the probability of the image belonging to the corresponding class (Normal, Diabetic Retinopathy, Cataract, and Glaucoma). Algorithm 4 demonstrates the procedural steps of the proposed RetiNet model. Furthermore, Fig. 4 illustrates the architecture of the hybrid model.

Algorithm 4: RetiNet: Hybrid Model for Eye Disease Classification

```
Procedure RetiNet (Image I)
    $I_{norm} \leftarrow$ Normalize $I$
    $F_R \leftarrow$ ResNet50_Extract ($I_{norm}$)
    $F_D \leftarrow$ DenseNet121_Extract ($I_{norm}$)
    $G_R \leftarrow$ GAP ($F_R$)
    $G_D \leftarrow$ GAP ($F_D$)
    $C \leftarrow Concat\ (G_R, G_D)$
    $D \leftarrow Dense\_ReLU\ (C)$
    $O \leftarrow Softmax\ (D)$
    return $O$
end procedure
```

D. Hyperparameters Optimization

Hyperparameters are significant variables that might have an influence on the training dynamics and overall performance of the model [22], [23]. The variables include the number of epochs, batch size, image dimensions, optimizer options, activation functions, learning rate, decay rate, dropout rate, and regularization parameters. During the experiment, we repeatedly modified several parameters, including batch size, learning rate, and regularization variables, resulting in improvements in the model's accuracy and efficiency. RetiNet was subjected to benchmarking against several prominent architectures, namely VGG16, ResNet50, AlexNet, MobileNetV2, InceptionV3, DenseNet121, and a customized CNN. The training process for each model consisted of 300 epochs, during which various optimizers were employed to facilitate a comprehensive evaluation. To fine-tune our model and to determine the optimal hyperparameter configuration, we apply the keras-tune tool, followed by an extensive grid search technique. Table III presents the final set of hyperparameters post-tuning.

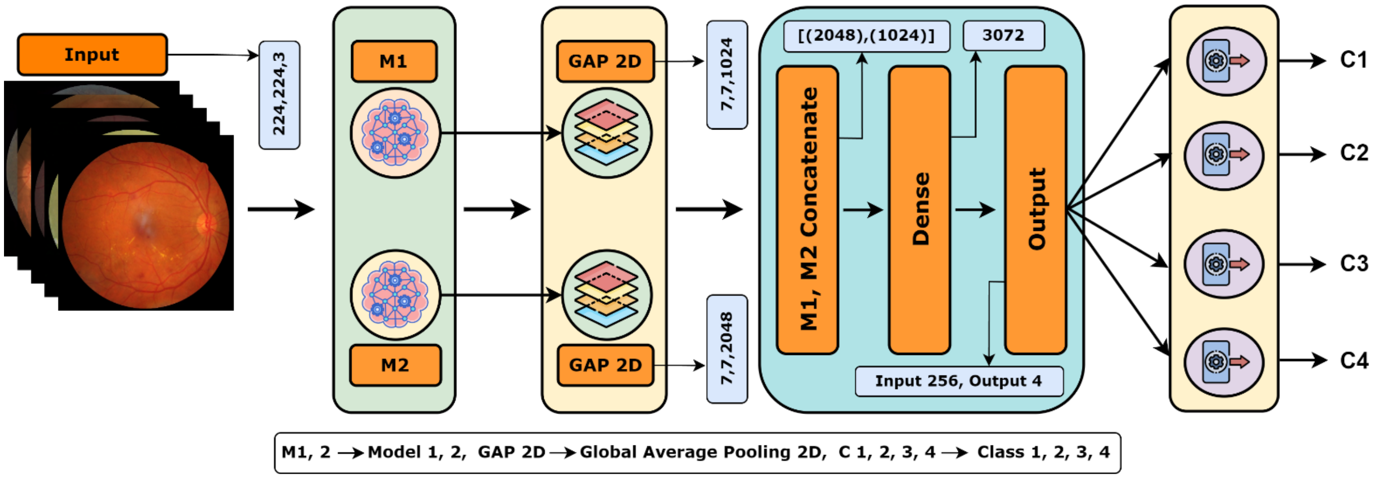

Fig. 4. The architecture of the proposed model RetiNet.

TABLE III. OPTIMIZED HYPERPARAMETERS FOR MODEL TRAINING

Model	No. of Epochs	Batch Size	Image Size	Optimizers	Activation Function	Learning Rate	Decay Rate	Dropout Rate	Regularizer
VGG16	300	64	224×224	Adam	Softmax	0.000001	1e-3	0.5	5e-4
ResNet50	300	64	224×224	SGD	ReLU	0.0001	1e-4	-	1e-4
AlexNet	300	64	224×224	Adagrad	ReLU	0.00001	1e-2	0.2	5e-4
MobileNetV2	300	64	224×224	SGD	Softmax	0.1	1e-4	0.5	1e-5
InceptionV3	300	64	224×224	Adam	Sigmoid	0.001	1e-3	-	1e-4
DenseNet121	300	64	224×224	Adam	ReLU	0.0000001	1e-2	-	1e-4
CNN	300	64	224×224	Adam	ReLU	0.001	1e-2	0.5	1e-4
RetiNet	300	128	224×224	RMSProp	Sigmoid	0.001	1e-6	0.9	1e-4

IV. ANALYSIS OF EXPERIMENTAL OUTCOMES

A. Environmental Setup and Tools

We implemented all the deep learning models using Keras (version 2.10.0) and TensorFlow (version 2.0) frameworks using Python 3.7. For data visualization, we deployed the Seaborn and Matplotlib packages. The evaluation was carried out on a device powered by an AMD Ryzen 7 CPU clocked at 3.90 GHz, 32 GB RAM, and an AMD Radeon RX 580 series GPU, functioning on a Windows 10 operating system.

B. Assessment Metrics

To comprehensively evaluate the performance of our model in the classification of retinal images, we adopted a set of statistical metrics that involves Accuracy, Specificity, Recall, Precision, False Positive Rate (FPR), F1-score, Mean Squared Error (MSE), and Mean Absolute Error (MAE).

Accuracy: Represents the proportion of correct predictions made by the model over the total predictions.

$$Accuracy = \frac{TP+TN}{TP+FP+TN+FN} \tag{16}$$

Here, TP = True Positives, TN= True Negatives, FP= False Positives and FN = False Negatives.

Precision: Indicates the fraction of relevant instances among the instances that the model predicted as positive. It provides insight onto the correctness of positive predictions.

$$Precision = \frac{TP}{TP+FP} \tag{17}$$

Recall: Signifies the proportion of real positive occurrences that the model managed to predict accurately, demonstrating its ability to detect positive cases.

$$Recall = \frac{TP}{TP+FN} \tag{18}$$

Specificity: Measures the actual negative rate, indicating the model's effectiveness in accurately recognizing the negative class amongst all the classes.

$$Specificty\ = \frac{TN}{TN+FP} \tag{19}$$

FPR: Proportion of negative instances that are incorrectly classified as positive.

$$FPR = \frac{FP}{FP+TN} \tag{20}$$

F1-Score: Provides a balance between Precision and Recall by combining them into a single measure. This metric also shows how well a model can be used to identify both positive and negative data.

$$F1 - score = 2 \times \frac{Precision \times Recall}{Precision+Recall} \tag{21}$$

MSE: Determines the average squared variance between the predicted outcomes and the actual values, delivering a sense of prediction error size.

$$MSE = \frac{1}{n}\sum_{i=1}^{n}(y_i - y^{\wedge}{}_i)^2 \tag{22}$$

Here y_i is the actual value, $y^{\wedge}{}_i$ is the predicted value, and n is the number of observations.

MAE: Provides the mean of the absolute variance between predictions and actual observations, exhibiting the model's accuracy.

$$MAE = \frac{1}{n}\sum_{i=1}^{n}|y_i - y^{\wedge}{}_i| \tag{23}$$

C. Study Outcomes

In this study, eight algorithms were utilized to classify retinal image data. These algorithms comprised seven transfer learning models and the novel RetiNet model. These models aim to assist in identifying eye conditions by accurately detecting abnormalities in retinal images. In order to conduct an extensive evaluation, each model underwent training for 300 epochs, with the results being recorded at each iteration. The performance measures of each model can be calculated by utilizing Eq. (16) to Eq. (23). This thorough methodology provides a profound understanding of the functioning of each model when exposed to retinal data.

This study systematically evaluated the performance of eight distinct models on their ability to classify retinal images with high consistency. Fig. 5 illustrates the performance of all the models. Among the employed transfer learning models, VGG16 exhibited commendable performance, achieving an accuracy of 91.58% and a precision of 92.1%. These results serve as evidence of its proficiency in accurately classifying positive instances. The model, ResNet50, achieved an accuracy of 86.36% and a specificity of 86.7%, indicating its ability to classify negative samples effectively. The AlexNet model, with its accuracy and recall rates of 92.76% and 92.9%, respectively, demonstrated its adeptness in identifying actual positive rates.

The MobileNetV2 and InceptioV3 models exhibited distinct performance characteristics, achieving accuracies of 93.31% and 93.5%, respectively. Both models displayed impressive F1 scores, representing the harmonic mean of accuracy and recall, indicating a well-balanced performance across both metrics. InceptionV3 demonstrated a balanced detection capability, as evidenced by the achievement of an F1-score of 93.35%. When comparing the performance of DenseNet121 and CNN, it is observed that both models achieved satisfactory results, with accuracies of 90.86% and 88.34%, respectively. These findings suggest that there may be potential for further enhancement in the model's performance. The accuracy rate of the improved model, RetiNet is 98.50%. Another notable statistical measure that evaluates the average squared variations between predicts and actual observations, known as the Mean Squared Error (MSE), was found to be exceptionally low for RetiNet at 0.015. This indicates that the predictions made by RetiNet are highly accurate and closely aligned with the actual results.

Nevertheless, the focal point of the assessment was the cutting-edge RetiNet model. The system exhibits a remarkable level of accuracy of 98.50% and F1-score of 98.65%. Additionally, it demonstrates a precision of 98.7% and an impressively low FPR of 1.7%. This accomplishment showcases the proficiency of RetiNet in accurately identifying and distinguishing retinal abnormalities with high precision.

The combination of all these measurements offers an exhaustive overview of the capabilities of each model. The detailed analysis depicted in Fig. 5 not only highlights the potential of models such as RetiNet but also paves the path for future advancements in the field of retinal image diagnostics.

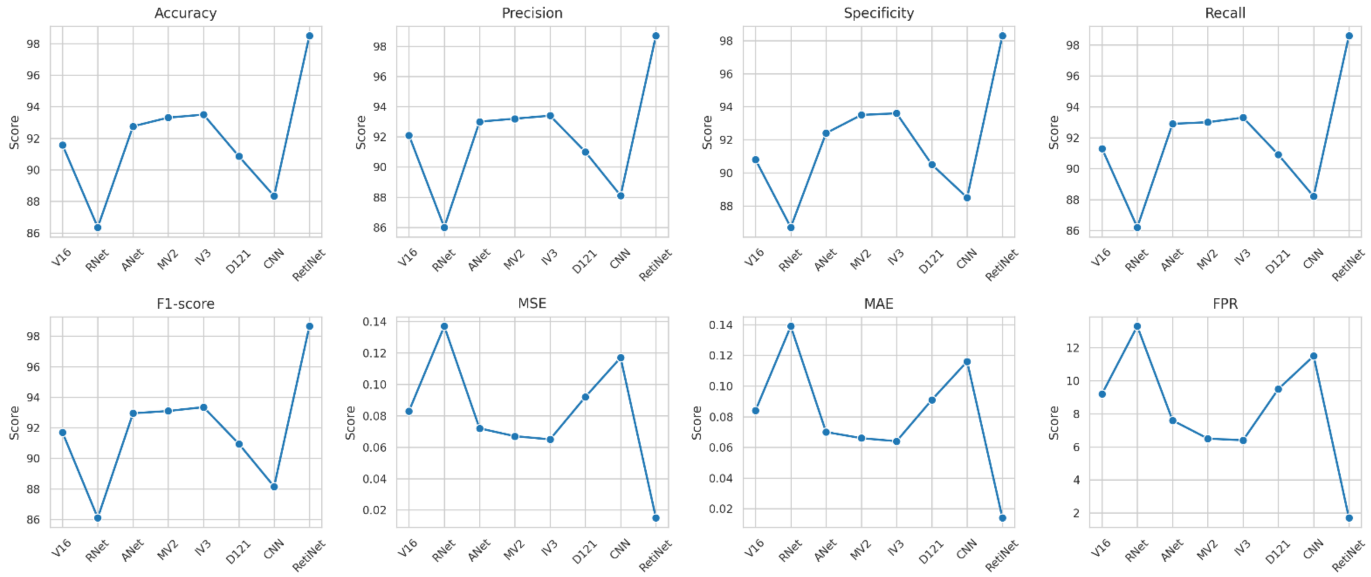

Fig. 5. Comparative performance matrics of retinal image classification models. Here ‘V16’ indicates ‘VGG16’, ‘RNet’ indicates ‘ResNet50’, ‘Anet’ indicates ‘AlexNet’, ‘MV2’ indicates ‘MobileNetV2’, ‘IV3’ indicates ‘InceptionV3’, ‘D121’ indicates ‘DenseNet121’.

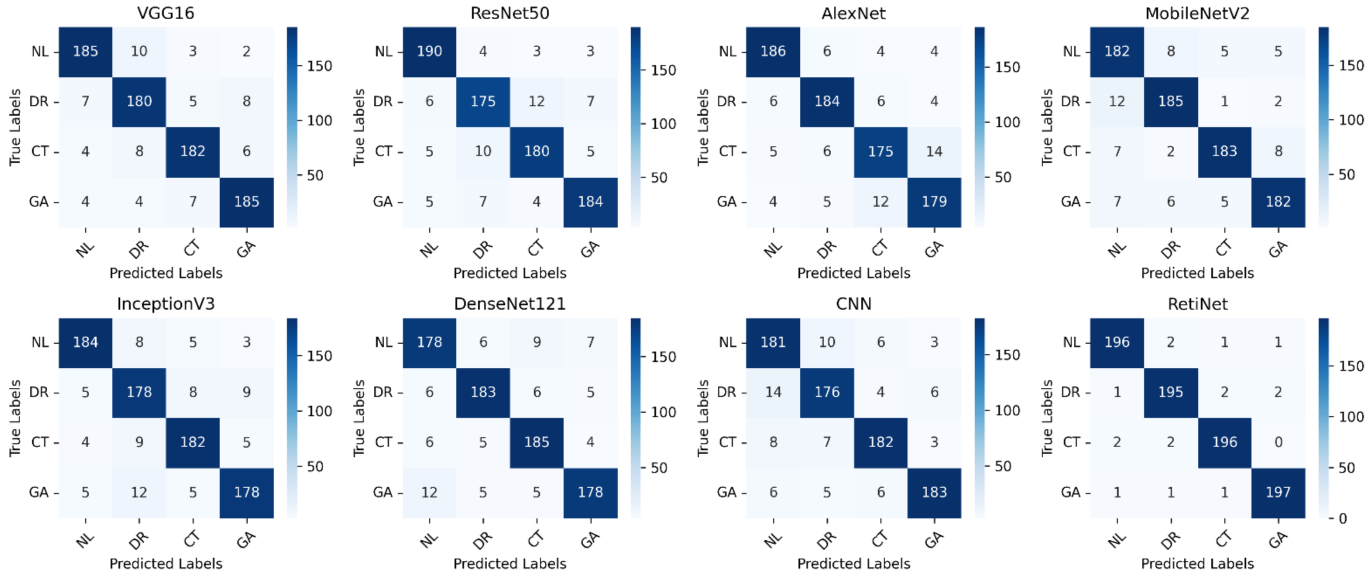

Fig. 6. Confusion matrix of all classification models. Here ‘NL’ indicates ‘Normal’ class, ‘DR’ indicates ‘Diabetic Retinopathy’ class, ‘CT’ indicates ‘Cataract’ class, GA indicates ‘Glaucoma’ class.

During the testing phase, the model's performance is evaluated using confusion matrices and observing significant patterns of classification and misclassification illustrated in Fig. 6. Out of the 200 Normal data, the VGG16 model accurately classified 185 data while misclassifying 15 data. More specifically, 10 of the data was misclassified as Diabetic Retinopathy. In the Diabetic Retinopathy class, 180 images were correctly identified, whereas five images were incorrectly categorized as Cataract. On the other hand, 182 images depicting Cataract were accurately identified, whereas eight images were erroneously interpreted as Diabetic Retinopathy. Lastly, 185 images were accurately classified in the Glaucoma class, yet seven were mislabeled as Cataracts.

The ResNet50 model accurately classified 190 images as normal and misclassified 10 images, of which four were incorrectly labeled as Diabetic Retinopathy. In the class focused on Diabetic Retinopathy, 175 images were accurately recognized, whereas 12 were mislabeled as Cataract. Among the images in the Cataract class, 180 were found to be correct, while five were classified as Glaucoma. Finally, for the Glaucoma class, 184 accurate classifications were made, and four images were misclassified as Cataract.

AlexNet properly classified 186 images as Normal, while six images as misdiagnosed as Diabetic Retinopathy. In the case of Diabetic Retinopathy, 184 images were correctly classified, except six were misclassified as Cataract. From the

Cataract class, a total of 175 images were correctly identified, and 14 were wrongly identified as Glaucoma. A total of 179 images from the Glaucoma class were classified, and 12 were misclassified as Cataract. The model MobileNetV2 demonstrated proficiency in correctly classifying 182 images as Normal but misclassified eight as Diabetic Retinopathy. The condition known as Diabetic Retinopathy found 185 accurate classifications, but 12 images were mistakenly classified as Normal. The model correctly classified 183 Cataract images but labeled 8 as Glaucoma. Similarly, 182 Glaucoma images could be correctly predicted but seven images were misinterpreted as Normal.

In the case of the model InceptionV3, 184 Normal images were correctly classified and eight were classified as Diabetic Retinopathy. The model identified 178 images of Diabetic Retinopathy but incorrectly identified eight images as Cataract. Within the Cataract class, 182 images were diagnosed, but 5 were misdiagnosed as Glaucoma. From the Glaucoma class, 178 instances were identified, while 12 instances were misidentified as Diabetic Retinopathy. The DenseNet121 properly identified 178 Normal images while incorrectly identifying six as Diabetic Retinopathy. The model accurately classified 183 Diabetic Retinopathy images yet six images wrongly fell into the Cataract category. Within the Cataract class, a total of 185 images were correctly recognized, while four images were erroneously classified as Glaucoma. In the Glaucoma class, there were 178 accurate predictions and 12 instances where the classification was incorrectly assigned as Normal.

In the CNN model, 200 Normal images were tested, of which 181 were correctly classified, while 10 were inaccurately classified as Diabetic Retinopathy. The model properly recognized 176 Diabetic Retinopathy images while incorrectly reporting 14 as the Normal group. For cataract, 182 were accurately recognized, with three misinterpreted for Glaucoma. In the Glaucoma category, 183 were correctly classified, with five misclassified as Diabetic Retinopathy.

Finally, the RetiNet model, the standout performer, successfully identified an outstanding 196 out of 200 Normal images, with only two misclassifications into the Diabetic Retinopathy group. It also properly detected 195 Diabetic Retinopathy images, with misinterpretation of two images into the Cataract class. In the cataract group, 196 interpretations were correctly made, with only two misclassifications into the Glaucoma class. The Glaucoma class witnessed 197 valid classifications with just a single misclassification into the Cataract class. The performance of all the eight models employed in the study is presented in Table IV.

TABLE IV. PERFORMANCE SCORES OF ALL EMPLOYED MODELS FOR RETINAL DISEASE DIAGNOSIS

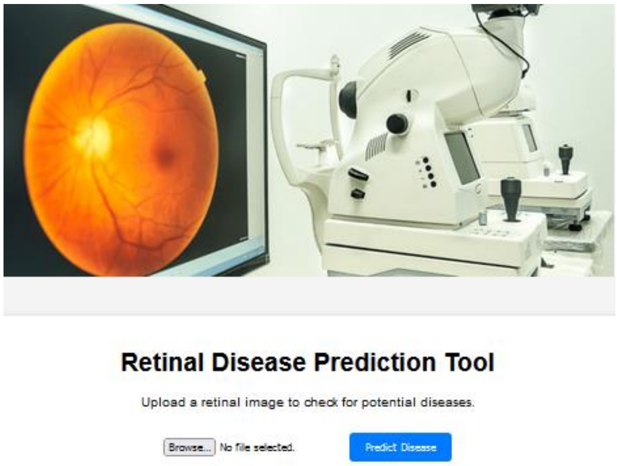
Model	VGG16	ResNet50	AlexNet	MobileNetV2	InceptionV3	DenseNet121	CNN	RetiNet
Accuracy	91.58%	86.36%	92.76%	93.31%	93.50%	90.86%	88.34%	98.50%
Precision	92.10%	86.00%	93.00%	93.20%	93.40%	91.00%	88.10%	98.70%
Specificity	90.80%	86.70%	92.40%	93.50%	93.60%	90.50%	88.50%	98.30%
Recall	91.30%	86.20%	92.90%	93.00%	93.30%	90.90%	88.20%	98.60%
F1-score	91.70%	86.10%	92.95%	93.10%	93.35%	90.95%	88.15%	98.65%
MSE	0.083	0.137	0.072	0.067	0.065	0.092	0.117	0.015
MAE	0.084	0.139	0.070	0.066	0.064	0.091	0.116	0.014
FPR	9.2%	13.3%	7.6%	6.5%	6.4%	9.5%	11.5%	1.7%

V. WEB INTERFACE

A precisely designed digital interface has been built exclusively for medical professionals, with a focus on facilitating their use of medical imaging for diagnosing different retinal diseases. The implementation of this modern interface plays a crucial role in facilitating healthcare professionals, particularly doctors, and experts, in effectively and accurately identifying the medical issues impacting their patients. Fig. 7 displays the general interface of the web application.

Doctors initiate the procedure by entering medical images of the patient's retina into the system. The images are instantly uploaded to the server and merged into the proposed RetiNet diagnostic model. Concurrently, the diagnostic form that goes with it is filled out with essential patient data and sent to the server again.

During this phase, the server conducts an essential verification process evaluating the quality of the retinal images that have been submitted to ensure they satisfy the requisite criteria for precise analysis. After conducting this verification process the server utilizes proposed RetiNet technology to examine the images and generate an advanced AI supported estimation of the stage of the disease. This process entails employing of an advanced algorithmic interpretation of the retinal images to determine the condition's progression and severity.



Retinal Disease Prediction Tool

Upload a retinal image to check for potential diseases.

Retinal Disease Prediction Tool

Upload a retinal image to check for potential diseases.

Prediction complete. Diabetic Retinopathy disease detected.

Fig. 8. Disease diagnosis interface.

After the analysis is accomplished, the server aggregates the findings, which include the AI-generated estimate of disease's stage. The doctor is then instantly informed of these findings. Fig. 8 shows the prediction of AI technology help doctors diagnose patients more accurately with more expertise.

VI. Comparison of Existing Studies

This study presents the "RetiNet" model, an advanced CNN model specifically developed for accurately classifying retinal images. One of the primary objectives is to solve the significant challenge of accurately diagnosing retinal disease within the imaging datasets. Prior to training, the dataset was subjected to thorough preprocessing techniques. These techniques involve Histogram Equalization for optimum image contrast, Gaussian Blur for noise reduction, and Morphological Operations for enhanced feature extraction and Data Balancing to offset class imbalances. During the testing phase, RetiNet demonstrates a remarkable accuracy of 98.50%, surpassing other existing models and effectively enabling disease detection. Moreover, A web-based tool has been created to assist medical professionals in detecting and diagnosing retinal disorders. This initiative set the benchmark for retinal image-based diagnosis and provides medical practitioners with a robust diagnostic tool. Table V provides a detailed analysis of the performance of RetiNet in comparison to other prominent models.

TABLE V. Proposed Model Comparison of Existing Studies

Authors	Methods	Accuracy
Arslan et al. [7]	EfficientNet	94.88%
Malik et al. [8]	Random Forest	86.63%
Metin and Karasulu [9]	ResNet50	94.00%
Sarki et al. [10]	CNN	81.33%
Hussain et al. [11]	Random Forest	96.89%
Almansour et al. [12]	Fine-tuned VGG16	78.00%
Seker et al. [13]	Keras-based CNN	85.00%
Barai et al.	Proposed Model (RetiNet)	98.50%

VII. Conclusion

This study discusses the significant advantages of employing retinal images for accurately identifying retinal diseases through utilizing our cutting-edge "RetiNet" model. The study subjects each image to a comprehensive preprocessing procedure that includes Histogram Equalization, Gaussian Blur, Morphological Operations, and Data Balancing. We have obtained the highest degree of classification for images that are well-suited for the purpose of extracting features efficiently. A web application has been designed and developed to assist medical professionals in identifying retinal diseases. Although RetiNet's ability did detect some misclassification, its overriding performance spotlighted the transformational potential of CNN models in retinal imaging. Further studies will prioritize the improvement of these methods in order to increase preciseness, with the ultimate goal of transforming the diagnosis of retinal diseases worldwide and significantly influencing ophthalmic healthcare.

Lecturer, Department of Computer Science & Information Technology, Jazan University Jazan, KSA[4]

Abstract*—A crucial component of industrial operations is the detection of production system failures, which aims to spot any problems before they get worse. By applying cutting-edge methods like deep learning and genetic algorithms, failure detection accuracy may be improved, allowing for preemptive actions to reduce downtime and maximize system availability. These methods improve reactivity to possible errors and solve dynamic issues, which enhances the overall efficiency and reliability of production systems. This study offers a novel method for improving the availability and failure detection of production systems using deep learning techniques and genetic algorithms in a data-driven strategy. The goal of the project is to provide a complete framework for efficient failure detection that incorporates deep learning models, particularly Convolutional Neural Network (CNN) Autoencoder. Furthermore, system configurations are optimized through the use of genetic algorithms, improving overall availability. The suggested model is able to identify complex patterns and connections in the data by being trained on a variety of datasets that contain information about equipment failure. The incorporation of genetic algorithm guarantees flexibility and resilience in system setups, hence augmenting total availability. The study presents a proactive and flexible approach to the dynamic issues encountered in industrial environments, providing a notable breakthrough in failure detection and availability improvement. The proposed model is implemented in Python software. It achieves an astounding 99.32% accuracy rate, which is 3.58% higher than that of current techniques like CNN-LSTM (Long Short-Term Memory), Bi-LSTM (Bi-directional Long Short-Term Memory), and CNN-RNN (Recurrent Neural Network). The data-driven approach's high accuracy highlights its efficacy in forecasting and avoiding problems, which minimizes downtime and maximizes production efficiency.

I. Introduction

Improving the performance of production systems on an ongoing basis is a primary goal in the manufacturing and industrial domains [1]. It is a result of the necessity to maximize productivity, reduce downtime, and guarantee the reliable provision of high-quality goods and services. Production systems must adapt to the competitive environment by moving beyond conventional paradigms and embracing novel approaches in order to remain robust in the face of shifting consumer expectations and technology breakthroughs [2]. This study explores the crucial area of production system improvement in an effort to push the envelope by presenting cutting-edge tactics that go beyond accepted constraints [3]. It begins with the planning and design of the product, moves through the complex manufacturing procedures, and concludes with the distribution and pleasure of the consumer [4].

The intrinsic difficulties that production systems encounter, such as the requirement to strike a balance between competing demands like cost-effectiveness, quality control, and on-time delivery, necessitate improvement [5]. Reactive methods of system optimization, which deal with problems as they arise, frequently lead to inefficient use of resources and more downtime [6]. The emphasis is shifting towards proactive and predictive techniques that foresee problems before they become serious ones as industries seek for leaner, more flexible production processes. In order to improve production system performance, this research will critically assess current approaches and offer novel solutions that make use of state-of-the-art technology [7]. It attempts to close the knowledge gap between theoretical developments and real-world application by offering sectors looking to stay competitive in a time of quickening technology change and shifting consumer expectations practical insights [8].

The early detection and mitigation of possible system failures in production systems represent key problems in the context of industrial operations and critical infrastructure [9]. Conventional failure detection techniques can result in expensive downtime and inefficiencies since they are reactive in nature and frequently rely on rule-based systems or simple algorithms. Recognizing this, the current research offers a deep learning-based data-driven approach for failure detection, which represents a revolutionary paradigm change [10]. Using deep learning to uncover complex patterns from large datasets, this methodology deviates from traditional methods and improves the system’s capacity to anticipate and proactively handle failure situations. [11].

Deep learning has the potential to improve failure detection accuracy and provide the necessary scalability for the complicated production situations of today [12]. Improving availability is a complex task that goes beyond maintaining system uptime. It entails striking a tactical balance between the effectiveness of maintenance, system dependability, and flexibility in response to shifting operating circumstances [13]. In order to identify optimal solutions within the large parameter space of a production system, genetic algorithms, as an optimization tool, replicate the process of evolution and provide a possible path towards overcoming these obstacles.

Conventional methods of accomplishing these goals frequently depend on reactive tactics, which deal with problems only after they occur, resulting in downtime and inefficient use of resources [14]. Genetic algorithms are incorporated into the framework as a complement to the deep learning paradigm in order to optimize system availability. Natural selection and evolution serve as the inspiration for genetic algorithms, which offer a potent way to discover and develop the best possible configurations for the production system. These algorithms constantly alter parameters, searching for configurations that minimize failure risk and maximize total system availability through recurrent processes of crossover, mutation, and selection. This study’s combination of genetic algorithms and deep learning offers a clever and comprehensive method for managing production systems. Through the integration of deep learning’s predictive powers with genetic algorithms’ optimization skills, the suggested framework seeks to create a proactive system that can both detect possible malfunctions and modify the system configuration to improve overall availability. The study is at the vanguard of efforts to transform the monitoring, maintenance, and optimization of production systems due to the synergy between innovative data-driven technologies.

Thekey contributions of the article is,

- The CNN Autoencoder based on deep learning is incorporated for failure detection. By automatically extracting pertinent features from the input data, the CNN Autoencoder improves the model's ability to identify complex patterns that may indicate probable problems, offering a reliable and data-driven method of failure detection.
- The Genetic Algorithm is employed to improve availability by optimizing system configurations in response to changing operating circumstances. This genetic algorithm-based method guarantees flexibility and resilience, tackling the intricacies of industrial production processes and leading to increased availability overall.
- The integration of CNN Autoencoder and Genetic Algorithm, results in a comprehensive approach for availability improvement and failure detection. By using cutting-edge data-driven methodologies to systematically handle both failure detection and system optimization elements, this all-encompassing strategy improves the overall resilience and efficiency of production systems.

There are five primary sections of the paper: In Section II, relevant works in the subject of production system failure detection are reviewed and current techniques are summarized. The issue statement is defined in Section III, along with the shortcomings and difficulties of the existing methods. The suggested technique, which combines genetic algorithms and deep learning to provide an advanced data-driven solution, is described in Section IV. The model's output is shown in Section V, along with a discussion of the model's performance and accuracy in relation to other techniques. The report is finally concluded in Section VI, which summarizes the main conclusions and offers directions for further research into the field of production system failure detection.

II. Related Works

In light of climate change and sustainability issues, this study discusses the pressing need for smart energy production and highlights the shortcomings of conventional first-principle model-based strategies in an environment of growing system scale and uncertainty [15]. The article provides a thorough analysis and emphasizes the ways in which Data-Driven Control (DDC) and Machine Learning (ML) approaches are used to the tracking, regulating, optimizing, and fault-detection of power production facilities. It provides a thorough analysis of the ways in which these cutting-edge techniques help to resolve ambiguities and improve the efficiency of both traditional thermal power generation and renewable energy sources. In regards to visibility, maneuverability, adaptability, economic viability, and safety, the article lists the benefits of ML and DDC. It is crucial to remember that the study does not go into great detail about the particular difficulties or restrictions related to the application of ML and DDC procedures to power production structures, leaving space for additional investigations to investigate the possible downsides and improve these strategies for real-world use. The inherent drawback of data-driven modeling becomes apparent when confronted with the constraints of both online and offline data, including issues such as data incompleteness stemming from loss, uncertainty, and bias.

In the framework of ring spinning technological advances, the study presents a unique method to preventative care with an emphasis on forecasting and health monitoring [16]. It suggests utilizing predictive analytics to create a data-driven preventive service system built on a regularized Deep Neural network (DNN). To keep an eye on crucial parts, the method makes use of a system of sensors that is built into the frames of spinning machines, each of which has many spindles. A GA is developed for multi-sensor assessments and prediction, demonstrating its efficiency in leveraging bigger amounts of data with comparatively small training data sets. With the use of a neural sensor network, the framework provides condition-based evaluation for every component in order to anticipate anomalies, disruptions, and failures in real time. The study does not, however, go into great detail on the shortcomings or difficulties of the suggested model, providing opportunity for more study to investigate such limits and improve the execution for more widespread industrial uses.

In order to forecast failure behavior in the industrial environment, the study investigates the use of sophisticated data analytics, more especially a data-driven Failure Mode and Effective Analysis (FMEA) approach [17]. Utilizing operational and historical data from investment in industrial items' usage stage, the technique applies DL models to improve maintenance scheduling visibility and decision assistance. A real-world scenario in the aviation industry is used to verify the structure, and the results show an astounding 95% accuracy in defect prediction. By incorporating these findings into a data-driven FMEA framework, the dependency on employee knowledge and skill is lessened, and variability in risk and failure probability predictions is eliminated. Nevertheless, the study does not go into great detail about any drawbacks or difficulties with the suggested technique, providing opportunity for more research into real-world implementation problems and wider application across other industrial settings.

This study explores the intricacies of semiconductor production, which is a multistep process that uses a variety of equipment's and sub processes to create miniaturized electronic circuits [18]. With the goal of improving the process of producing semiconductors, the study uses data mining, SPC, and data-driven decision-making frameworks to analyze production process information in great detail. The goal is to use the newest technologies powered by data to increase productivity and reliability. The study highlights the potential for major process enhancements and offers a thorough analysis of current procedures; however, it does not go into great length on the drawbacks or difficulties that come with using methods that use data in the production of semiconductors. Some issues are not completely addressed, such as possible biases, execution difficulties, and the adaptation of these approaches to varied production contexts. To evaluate the applicability and constraints of these methods based on data in a wider range of semiconductor production environments, more investigation is necessary.

This study tackles the critical problem of estimating RUL for equipment predictions, highlighting the importance of precise forecasts in reducing maintenance expenses and improving system dependability[19]. This study presents a new data-driven methodology called Convolutional Neural Network- Long-Short Term Memory- Particle Swarm Optimization (CNN–LSTM–PSO) hybrid DNN, which integrates conventional neural networks, LSTM networks, and CNN. In order to increase the accuracy of Remaining Useful Life (RUL) forecasting, this hybrid model seeks to identify spatial relations from time series with multiple variables data and retain nonlinear properties. To improve the efficiency of the network, the research uses PSO to optimize the network's hyper parameters. The suggested CNN–LSTM–PSO model is noteworthy for its ability to provide multi-step-ahead recommendations. Utilizing a NASA-provided lithium-ion battery dataset, the validation test shows that the CNN–LSTM–PSO model outperforms other cutting-edge ML and Deep Learning (DL) techniques when evaluating a variety of efficiency metrics. To allow for more research into the suggested model's relevance across various datasets and commercial situations, the report nevertheless fails to go into great detail about its drawbacks or possible drawbacks. Further investigation might examine the model's applicability to other machinery kinds and operating environments.

This paper explores the topic of smart production, with a particular emphasis on utilizing Artificial Intelligence (AI), ML, and sophisticated data analysis to optimize semiconductors production processes [20]. It emphasizes how Industrial Internet of Things (IIOT) sensors are being used in production more and more, which means effective data management is required. To solve issues in semiconductor production, the study suggests a dynamic method that combines algorithms for neural networks with evolutionary programming. In particular, the study presents a novel feature selection technique employing neural networks and evolutionary algorithms to improve the production process efficiency. Although the research offers a detailed analysis and innovative approaches, it does not fully address any potential drawbacks or difficulties related to the suggested dynamic algorithms and smart feature selection. Additional investigation is necessary due to practical issues, the algorithms' adaptation to a variety of industrial contexts, and possible limitations. Subsequent investigations have to evaluate the resilience and constraints of these suggested remedies in diverse semiconductor production environments and take into account practical implementation difficulties.

In order to anticipate the initial yields in semiconductor production, the research presents a combined structure that focuses on finding the best companion combinations for the Final Testing (FT) procedure [21]. In order to create an efficient prediction of yield model, the process entails converting categorical information into multivariate vectors using the entity anchoring technique and assessing several ML methods. A Genetic Algorithm (GA) incorporated in the yield prediction framework is used to find the optimal accessory combinations, optimizing for the greatest initial yield estimation, after the best-fit ML model has been identified. By combining the strengths of ML and GA, a smart prediction method is created that stabilizes the Overall Equipment Effectiveness (OEE) for the FT process and reduces the negative effects of improper accessory pairings on yield rates. But the report does not go into great detail about any drawbacks or difficulties with the proposed design, thus there is need for more research to examine concerns of adaptability, versatility, and practical application in various semiconductor production settings. To evaluate the combined framework's resilience and generality in various production contexts, more research is necessary.

In addition to highlighting reliability's critical role in modern production facilities, the article also addresses reliability's influence on systems lives, expenses for upkeep, and repair charges [22]. Although a number of reliability modelling approaches have been investigated, including Fault Trees, Petri Nets, and Markov Chains, the process of developing dependability models is still demanding of labor and dependent on expertise. The report suggests using data from contemporary manufacturing facilities for automation or assist in the creation of dependability models as a solution to this problem. With an emphasis on information-driven reliability evaluation for cyber-physical machines, the suggested methodology seeks to capitalize on the abundance of data produced in sophisticated production lines. A case study is included to test and improve the suggested data-driven strategy from a practical standpoint. Nevertheless, the study does not go into great detail about the possible drawbacks or difficulties with the suggested structure, providing opportunity for further investigation into real-world application problems, potential exaggerations in the data, and the applicability of the method in various manufacturing contexts. To evaluate the security and sustainability of the data-driven resilience evaluation in actual manufacturing environments, more research is necessary.

In order to increase system accessibility and lower life cycle costs, the study tackles the crucial job of forecasting the RUL of systems [23]. Using numerous sensor time series indications, a Deep Long-Short Term Memory (DLSTM) network-based technique is introduced in this suggested solution. Through the usage of its DL framework, the DLSTM model is intended to fuse the aforementioned signals in order to provide precise predictions for RUL by revealing latent long-term relationships. The DLSTM's attributes and network layout are effectively tuned for accurate and reliable predictions in this article using an adaptive moment assessment approach and a grid-based searching strategy. Utilizing two turbofan engine datasets, the DLSTM model's efficacy is verified, showing favorable outcomes when contrasted to other neural network algorithms and the latest methods documented in the available literature. Though there is room for additional studies to examine real-world difficulties in implementation, possible prejudices in the data, and the framework's flexibility to various system forms and operational circumstances, the article does not go into great detail about potential drawbacks or difficulties connected with the recommended DLSTM model. To evaluate the DLSTM model's adaptability and generalization in actual manufacturing environments, more research is necessary.

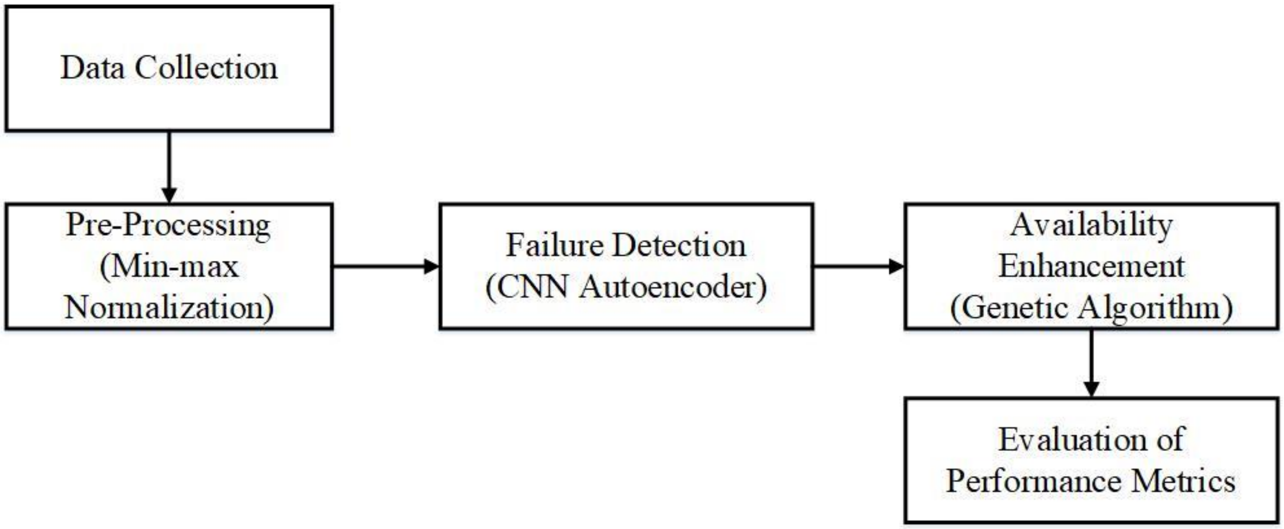
The essential subject of forecasting RUL in diverse engineering and manufacturing scenarios is the focus of the literature review. The use of sophisticated deep learning and machine learning methods, such LSTM networks, is a recurring topic in the development of precise and effective RUL forecasts. These models make use of many sensor time series signals, which makes it possible to identify complex patterns and hidden connections in the data. The importance of RUL prediction in raising system availability, cutting life cycle costs, and improving maintenance plans is emphasized in the studies. To ensure optimal performance, model parameters are often tuned using grid search techniques and adaptive algorithms. Experimental validation on various datasets, such as turbofan engines, consistently shows these models to perform as robustly and competitively against other neural network designs and state-of-the-art methodologies. All of these studies have one thing in common, though: they refrain from going into great detail about the difficulties, biases, and real-world implementation problems that come with using these sophisticated predictive models in industrial settings. This leaves space for future research to address these important issues.

III. Problem Statement

The current problem in industrial environments is the inefficiencies and disruptions brought about by unanticipated breakdowns in production systems, which result in more downtime, less efficient use of resources, and weakened system availability overall. These problems are not fully addressed by traditional reactive techniques to failure detection and system optimization. In order to address this issue, this research offers a novel solution: a deep learning-based, data-driven method for failure detection and availability augmentation that makes use of genetic algorithms. The challenge at hand is creating a comprehensive approach that uses genetic algorithms to dynamically optimize system configurations for increased availability and deep learning techniques to proactively identify failure antecedents in production systems. The goal is to revolutionize the way that production system management is now done by offering a proactive, adaptable framework that not only foresees problems before they happen but also continuously improves the system to maximize availability and overall performance [24]. Because of its ability to improve pattern recognition in industrial data—especially in identifying minor symptoms of equipment failure—the suggested CNN Autoencoder-GA approach has been chosen. The utilization of Convolutional Neural Network (CNN) Autoencoder enables efficient recognition of intricate patterns, and the incorporation of Genetic Algorithms (GA) guarantees the adaptability and durability of system configurations in ever-changing industrial settings. By training on a variety of datasets, the data-driven approach improves the model's resilience and adaptability. On the other hand, the shortcomings of current approaches, like insufficient pattern recognition, static configurations, and insufficient forecasting abilities, make them less appropriate for handling the dynamic issues associated with effective failure detection and availability enhancement in operational systems.

IV. Proposed Cnn Autoencoder – Genetic Algorithm Framework

In this paper, a unique data-driven technique for improving production system availability and failure detection is presented. The suggested system uses state-of-the-art techniques, such as deep learning and evolutionary algorithms, and integrates CNN Autoencoder for accurate failure detection. System configurations are optimized via genetic algorithms, increasing overall availability. The model, which has been trained on a variety of datasets, recognizes intricate patterns, and evolutionary methods guarantee system configuration flexibility. The model, which is implemented in Python, emphasizes how effective the data-driven approach is at issue prediction and prevention, downtime minimization, and production efficiency maximization. It is depicted in Fig. 1.



Data Collection

Failure Detection (CNN Autoencoder)
Availability Enhancement (Genetic Algorithm)
Evaluation of Performance Metrics

Fig. 1. Proposed methodology.

A. Data Collection

Kaggle, a well-known website for data science and machine learning contests, provided datasets for the equipment failure prediction. The meticulously selected datasets, which are publicly accessible on Kaggle, are an invaluable tool for practitioners and academics who are trying to create predictive models that may detect any malfunctions in machinery. The datasets available in Kaggle's repository cover a wide range of sectors and machinery kinds, making it possible to investigate various failure patterns and advance the creation of reliable prediction algorithms. These datasets are a great source of data for developing and accessing machine learning models, and they often contain elements like timestamps, operating parameters, and sensor readings. Researchers may test their models against pre-existing datasets by utilizing Kaggle's equipment failure prediction dataset platform. This approach promotes cooperation and creativity in the domain of predictive maintenance and reliability engineering [25].

B. Preprocessing using Min-Max Normalization

Preprocessing is essential when attempting to improve production system performance using a deep learning-based, data-driven strategy for genetic algorithm-based failure diagnosis and availability augmentation. In particular, applying Min-Max Normalization sticks out as an essential step in bringing the input data into compliance. This method makes sure that every variable contributes equally to the learning process by scaling the feature values within a given range, usually between 0 and 1. Normalizing the input data makes the deep learning model less susceptible to changes in the magnitude of various characteristics and more resilient, which supports steady and efficient training. By reducing the effect of different scales among input characteristics, Min-Max Normalization enhances the overall dependability of the model. This is important when it comes to failure detection and availability enhancement in intricate production systems. Moreover, the use of Min-Max Normalization is consistent with the overall objective of maximizing the accuracy and speed of convergence of the deep learning model. A more effective learning process is made possible by the standardized data distribution, which also helps to avoid particular traits from predominating during the training phase and thereby distorting the model's predictions. When it comes to availability enhancement and failure detection, wherein subtle patterns may signal approaching problems, and when accuracy is critical, the preprocessing step of Min-Max Normalization guarantees that the deep learning model is capable of identifying pertinent patterns and trends, which in turn enhances the model's ability to improve production system performance as shown in Eq. (1).

$$X_{Normalized} = \frac{X - X_{min}}{X_{max} - X_{min}} \quad (1)$$

C. Deep Learning-based CNN Autoencoder for Failure Detection

In the field of industrial system failure detection, this study presents a new method based on Deep Learning using CNN Autoencoder architecture. The main goal is to create a complicated model that can learn nuanced patterns from large, complex information in order to proactively anticipate probable problems. A change from conventional techniques is marked by the use of CNN Autoencoders, which use neural networks' capacity to automatically extract pertinent characteristics from input data. The CNN design is very useful for jobs that need spatial connections, which makes it suitable for examining images, sensor data, and other multidimensional data sources that are frequently found in industrial settings.

An encoding phase that compresses input data into a latent representation and a decoding phase that reconstructs the input from this compressed representation are the fundamental workings of the CNN Autoencoder. The model gains the ability to reflect typical operating patterns throughout training, which makes it sensitive to variations that might signal impending problems. Deep learning guarantees a data-driven and adaptable approach to failure detection, able to identify intricate patterns that may defy conventional rule-based or heuristic techniques. Using this cutting-edge method, the research hopes to enhance the creation of reliable and effective failure detection systems that may improve the performance and dependability of industrial production systems.

The encoder, which is composed with a number of layers of convolution, one or more fully connected layers, and a pooling procedure make up the CNN autoencoder. The decoder is proportionately made up of convolutional and upsampling layers after either two or three fully linked layers. In contrast to the fully connected autoencoder, the CNN autoencoder functions on a series of R includes vectors rather than just one. To keep things simple, let's look at an encoder and a decoder like the ones in Fig. 2 that have one convolutional layer and one fully linked layer. The convolutional component of the encoder works with an input matrix Y ∈ R B×R, wherein R is the sequence's frames count. The layer yields a B × R × C tensor H, the components of which are computed as shown in Eq. (2).

$$\text{K(a,b,c)} = \text{g} \; (\textstyle\sum_{m=0}^{h_{a-1}} \sum_{r=0}^{h_{b-1}} Y(a+m, b+n) h_c(m,n) \qquad (2)$$

where, Y(a, b) is the component at row a and column b of matrix Y, C is the total amount of kernels, g(•) is the non-linear activating operation, and $h_c$is a two-dimensional kernel of size $h_a \times h_b$. Keep in mind that because of zero-padding, K's initial measurements are the identical as Y's. Furthermore, although the operation carried out in the aforementioned equation is really a cross-correlation, the ML group generally refers to it as "convolution to operate.

Convolutional layers are frequently succeeded by a pooling process that lowers the input's complexity. The max-pooling procedure, that determines the highest value across a q × q windows, was utilized in (3):

$$\widetilde{K}\text{(a,b,c)} = \max \; \{\text{K(a',b',c')} : \text{a'} \in [\text{ a . s, a . s+q-1}], \text{b'} \in \; [\text{b . s, b . s+q-1}] \qquad (3)$$

where the step is located. It utilized q = 2 and s = 2 in the present study. A fully linked layer makes up the encoder's last layer.

The decoder is proportionately made up of a fully connected layer as the first layer, a layer that performs convolution, and an upsampling layer that replicates the input matrix's rows and columns using the identical factor 2, in this case that was utilized throughout pooling. In order to achieve two identical dimensions for the final output matrix as X, the system's final layer consists of one kernel and a convolutional layer with a linear activating function.

Applying additional convolutional and fully connected layers to the encoder and subsequently to the decoder would enhance the network's overall depth. In the trials, the real architecture was ascertained employing a validation set.

D. Employing Genetic Algorithm for Availability Enhancement

Towards strengthening the availability of production systems, the study deliberately employs Genetic Algorithms (GAs) as a sophisticated optimization method. Fundamentally, the main issue being addressed is the necessity of a methodical and flexible strategy to improve system availability by means of dynamic configuration optimization. Inspired by the ideas of evolution and natural selection, genetic algorithms are a powerful tool for negotiating the large solution space present in production systems' complexity. Potential system configurations are encoded into a population of people inside this optimization framework, each of which represents a distinct solution to the optimization issue. These solutions' fitness is carefully assessed using predetermined goals that are especially designed to improve system availability. This comprehensive strategy guarantees that the evolutionary algorithm converges to configurations that optimize the production system's overall availability while simultaneously reducing the likelihood of failures.

People in the population go through selection, crossover, and mutation processes as part of an iterative process known as the optimization journey. Individuals are chosen for development based on their fitness, and genetic material is transferred through crossover to produce progeny. Stochastic variations brought about by mutation encourage variety among the population. Motivated by availability-related goals, the fitness evaluation serves as a compass, pointing the algorithm in the direction of configurations that are reliable in reducing the likelihood of failure. The Genetic Algorithm becomes a powerful tool for converging across multiple generations to achieve configurations that dynamically adapt to the changing operational landscape, which eventually results in a production system optimized for increased resilience and availability.

Every individual in the population or possible solution is represented by a chromosome, frequently in binary form. Y_i, where*i* is the person's index, can be thought of as an individual solution in Eq. (4).

$$Y_i = (y_{i1}, y_{i2}, y_{i3}, \ldots, y_{in}) \qquad (4)$$

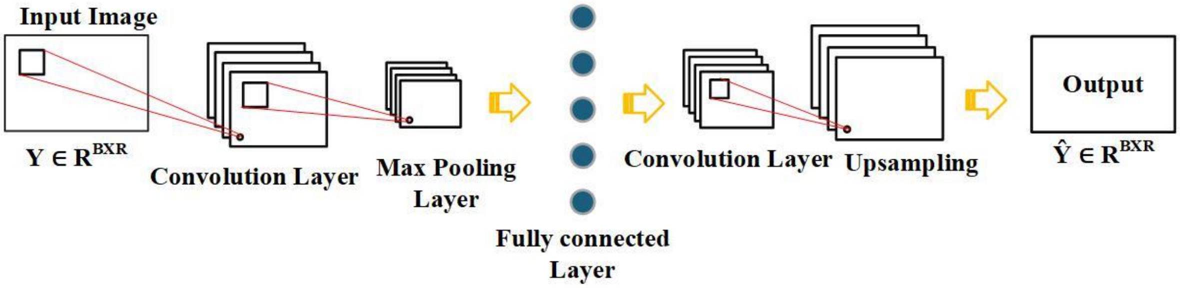

Fig. 2. Architecture of CNN Autoencoder.

The fitness of the individual is assessed by the objective function $f(Y_i)$based on the problem-specific goals. The measure of an individual's performance in relation to the optimization criteria is represented by this function.

The likelihood of choosing a person for development is directly correlated with their level of fitness. Proportional selection is a popular technique of selection in which candidates who are more fit have a larger probability of being chosen as shown in Eq. (5).

$$\text{Q}\ (Selection_i) = \frac{f(Y_i)}{\sum_{j=1}^{N} f(Y_j)} \qquad (5)$$

Crossover generates offspring by fusing the genetic material of two parent solutions. Genetic material is exchanged between parents to form the offspring, and the crossover point is randomly selected as in Eq. (6).

$$Offspring_h = (y_{h1}, y_{h2} \dots, y_{hi}, \dots, y_{hn}) \qquad (6)$$

A mutation modifies a person randomly; usually, this is done by flipping binary representation bits as shown in Eq. (7). The possibility of a mutation happening is determined by the mutation probability, or $Q_{mutation}$.

$$Mutation_h = (y_{h1}, y_{h2} \dots, \tilde{y}_{hi}, \dots, y_{hn}) \qquad (7)$$

where, $\tilde{y}_{hi}$ is the mutated bit.

The genetic procedures result in the creation of a new population. To guarantee that the best answers are kept, the members of the new population replace the members of the old population. Until a termination requirement is satisfied, the algorithm iterates continuously. A maximum number of generations, reaching a particular fitness level, or convergence are examples of common requirements. Through these iterations, genetic algorithms gradually evolve the population in the direction of ideal solutions. The particulars and parameters, including crossover and mutation rates, vary depending on the nature of the optimization task at hand and should be adjusted accordingly. The algorithm for CNN Autoencoder-GA is given below:

Algorithm 1: CNN Autoencoder-GA

Import the required data
Describe the CNN Autoencoder architecture
Develop the CNN Autoencoder
Specify the goal function that the genetic algorithm will optimize
Analyze the system's performance using the specified configuration
Provide a fitness score based on availability and additional pertinent data
Set the Genetic Algorithm up initially
Utilize the Genetic Algorithm to maximize system settings
For increased availability, apply the optimized configuration to the production system

V. Results and Discussion

Through the use of a data-driven approach, this study presents a unique way for improving production system availability and failure detection. The suggested architecture uses CNN Autoencoder for accurate failure detection and makes use of state-of-the-art techniques like deep learning and evolutionary algorithms. Overall availability is increased by using genetic algorithms to optimize system settings. The model recognizes intricate patterns after being trained on a variety of datasets, and evolutionary techniques guarantee system configuration flexibility. The model, which is implemented in Python, highlights the effectiveness of the data-driven approach in identifying and averting issues, reducing downtime, and optimizing production efficiency.

A. Model Accuracy

The degree of agreement between the deep learning model's predictions and the actual results in terms of failure detection and availability enhancement in a production system is known as model accuracy. It measures the model's efficiency in accurately detecting malfunctions and maximizing system availability. The accuracy statistic measures the percentage of cases that are properly categorized out of all the instances that the model evaluates. A high model accuracy suggests a stable and dependable performance, demonstrating the effectiveness of the data-driven, deep learning approach in conjunction with genetic algorithms in accurately predicting failure events and improving production system availability overall.

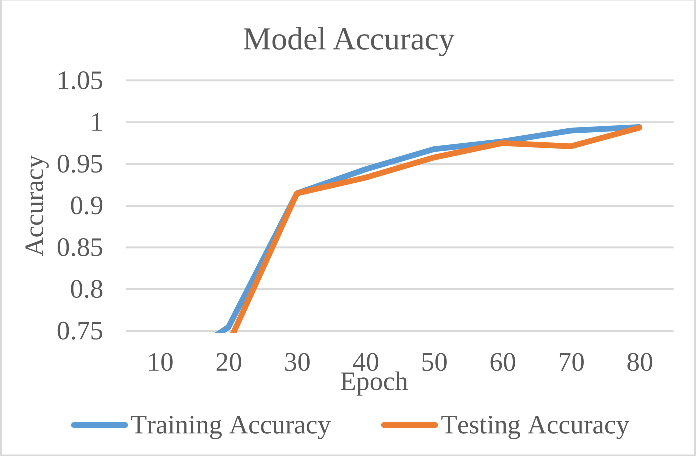

Fig. 3. Model accuracy.

The visual model accuracy graph illustrated in Fig. 3 how well the deep learning-based, data-driven strategy performed in improving production system performance. Any upward trend on the accuracy graph demonstrates an increase in the model's capacity to accurately forecast failure occurrences and raise system availability. In the context of failure detection and availability enhancement, fluctuations or plateaus may indicate regions that require extra data collection or more optimization to reach greater levels of accuracy.

B. Model Loss

When it comes to failure detection and availability enhancement in a production system, model loss is the quantitative measure of how different the actual observed values are from the projected outcomes produced by the deep learning model. This measure captures the discrepancy between the model's predictions and the actual data, indicating the degree of departure or mistake in the model's predictions. One of the main goals of training procedures is to reduce the model loss, which indicates how well the model is able to capture and reflect the underlying patterns in the data. In the context of this study, minimizing model loss is essential to guaranteeing the efficacy of the data-driven, deep learning technique and the use of genetic algorithms for production system performance optimization via improving availability and failure detection.

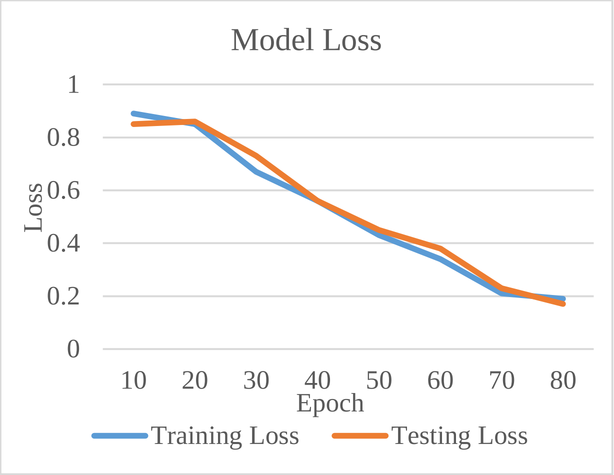

Fig. 4. Model loss.

The deep learning model's predicted mistakes are shown to have evolved in the model loss graph in Fig. 4 within the framework of improving production system performance. The model's enhanced capacity to reduce differences between expected and actual results, especially in failure detection and availability augmentation, is indicated by a declining trend in the loss graph. Finding trends or plateaus in the loss graph could inspire additional research into improving the model's architecture or training parameters to provide predictions that are more accurate.

C. ROC Curve

A graphical depiction known as the Receiver Operating Characteristic (ROC) evaluates the deep learning model's performance in terms of the trade-off between true positive rates and false positive rates.

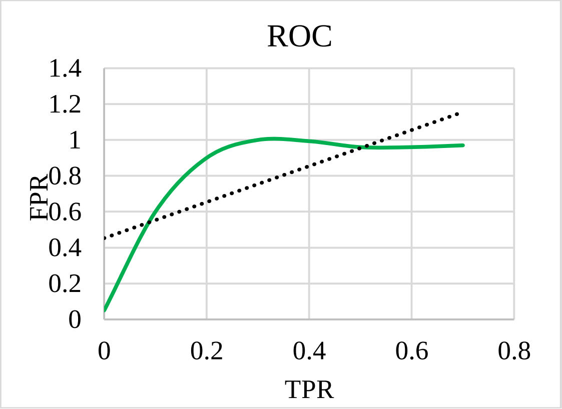

Fig. 5. ROC.

As it is depicted in Fig. 5, a thorough understanding of the model's capacity to distinguish between positive and negative occurrences linked to failure detection and availability enhancement in a production system is offered by the ROC curve, which plots the sensitivity (true positive rate) against 1-specificity (false positive rate) at various threshold settings. An increased area under the ROC curve signifies enhanced model performance in terms of accurate prediction-making while accounting for the proper ratio of true positives to false positives.

D. Performance Metrics

1) Accuracy: Accuracy is used to evaluate the system model's overall performance. Its fundamental premise is that all interactions are foreseeable. The accuracy is provided by Eq. (8).

$$Accuracy = \frac{T_{Pos} + T_{Neg}}{T_{Pos} + T_{Neg} + F_{Pos} + F_{Neg}} \tag{8}$$

2) Precision: Precision describes how comparable two or more calculations are to each other in addition to being correct. The link between accuracy and precision shows how quickly opinions may change. It is discussed in Eq. (9).

$$P = \frac{T_{Pos}}{T_{Pos} + F_{Pos}} \tag{9}$$

3) Recall: The percentage of all pertinent discoveries that were correctly sorted utilizing the procedures is known as recall. By dividing the genuine positive by the erroneously negative values, one may get the proper positive for these integers. The passage is located in Eq. (10).

$$R = \frac{T_{Pos}}{T_{Pos} + F_{Neg}} \tag{10}$$

4) F1-Score: The F1-Score computation combines recall and accuracy. To find the F1-Score, use (11), this divides the recall by the accuracy.

$$F1 - score = \frac{2 \times precision \times recall}{precision + recall} \tag{11}$$

TABLE. I MODEL PERFORMANCE

Model Performance	Percentage (%)
Accuracy	95.54
Precision	93.78
Recall	98.67
F1-Score	99.32

The model given has great efficacy in anomaly identification, as indicated by the performance indicators, which are summarized in Table I. With an accuracy of 95.54%, the model's predictions are shown to be generally accurate. With a precision of 93.78%, the model is able to correctly detect true positives among the occurrences that it classifies as anomalies. At 98.67%, the recall rate is quite high, indicating that the model is capable of accurately identifying a significant proportion of real abnormalities. Moreover, the F1-Score a balanced statistic that takes recall and accuracy into account stands out at 99.32%, highlighting the model's resilience in reaching a pleasing combination of recall and precision. Together, these measures highlight the model's excellent performance in industrial systems' real-time anomaly detection, highlighting its capacity for precise identification and reduction of false positives and false negatives.

TABLE. II COMPARISON OF PERFORMANCE METRICS

Methods	Accuracy (%)	Precision (%)	Recall (%)	F1-Score (%)
CNN-LSTM [26]	95.54	94.67	94.55	92.44
Bi-LSTM [27]	93.78	97.12	92.63	95.87
CNN-RNN [28]	98.67	97.35	94.69	94.26
Proposed CNN Autoencoder-GA	99.32	99.12	98.99	98.34

Table II shows the success of various techniques in the enhancing production system performance research is demonstrated by the classification performance metrics that are supplied. With an astounding accuracy of 99.32%, the Proposed CNN Autoencoder-GA notably surpasses existing models, demonstrating its capacity to accurately identify occurrences relevant to availability enhancement and failure detection.

Furthermore, a significant percentage of real positive cases are captured by the model, as seen by the high recall (98.99%) and precision (99.12%) values. The robustness of the suggested model is further shown by the F1-Score of 98.34%, which takes into account the harmonic mean of accuracy and recall. By comparison, the CNN-RNN approach has a high accuracy of 98.67%, highlighting its ability to make accurate predictions. These thorough metrics offer insightful information on the advantages of each model, with the Proposed CNN Autoencoder-GA demonstrating significant promise as a method for obtaining better results in the intended production system applications. It is depicted in Fig. 6.

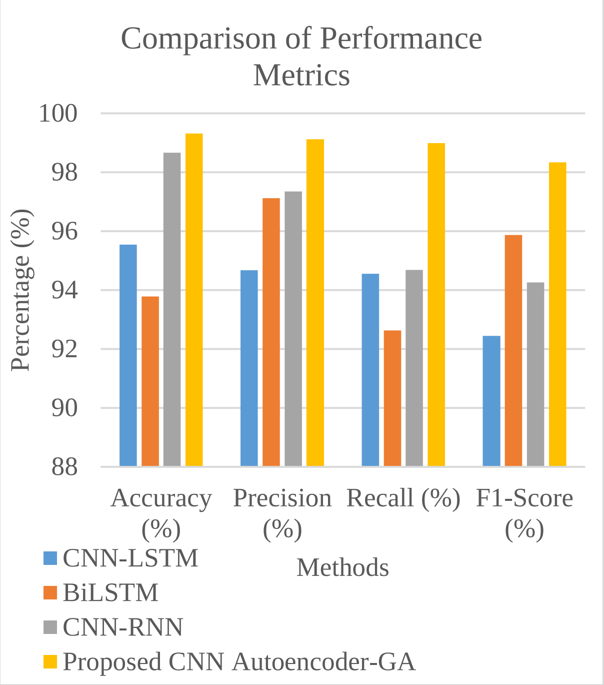

Fig. 6. Comparison of performance metrics.

E. Discussion

Through the integration of state-of-the-art methods for failure detection and availability enhancement in production systems, the suggested approach leads the way in the advancement of industrial operations. Through the use of CNN Autoencoder and deep learning, the model is able to identify complex patterns in a variety of datasets that contain data on equipment failures. A proactive approach to failure identification is made possible by this strong feature extraction capacity, which enables preventive measures to alleviate possible problems before they worsen. Furthermore, system configurations are optimized through the use of genetic algorithms, improving overall availability. With its ability to adapt to changing operating circumstances, this adaptive optimization mechanism provides a robust and effective production system management solution.

The suggested method stands out because to its exceptional accuracy of 99.32%, outperforming state-of-the-art methods such as CNN-LSTM[26], BiLSTM [27], and CNN-RNN [28]by 3.58%. This exceptional accuracy is ascribed to the complementary work of genetic algorithms and deep learning, which together offer a comprehensive approach to availability enhancement and failure detection. The suggested model, in contrast to traditional techniques, captures intricate linkages in the data, allowing for a more sophisticated comprehension of possible errors. By guaranteeing flexibility and resilience in system configurations, the application of genetic algorithms further sets the technique apart and addresses the inherent difficulties of industrial production processes. All things considered, the suggested methodology represents a major breakthrough in failure detection and availability enhancement, not only surpassing previous approaches but also providing a proactive and adaptable solution to dynamic difficulties in industrial situations.

Methodological relevance and industry prevalence served as the foundation for the benchmarking approaches chosen for this investigation. The selection of CNN-LSTM, Bi-LSTM, and CNN-RNN as typical benchmarks for well-established approaches stemmed from their extensive use in industrial settings for time-series data processing. LSTM variations such as CNN-LSTM and Bi-LSTM, which concentrate on managing temporal dependencies, tackle the sequential character of industrial data and guarantee a thorough assessment of the temporal relationship capabilities of the suggested model. Furthermore, the incorporation of CNN-based techniques takes into account the intricacy of equipment failure data, enabling a thorough evaluation of the suggested model's capacity to identify complex spatial patterns. This comprehensive comparison, which includes both CNN-based and LSTM-based approaches, offers a modern, industry-relevant framework that guarantees a careful assessment of the suggested deep learning and genetic algorithm strategy in the context of enhancing production system performance.

VI. Conclusion and Future Scope

This research has shown encouraging outcomes for improving availability and detecting failures, with a focus on using genetic algorithms. With its impressive 99.32% accuracy as well as its excellent precision, recall, and F1-Score values, the suggested CNN Autoencoder-GA model stands out as a reliable option for handling the difficulties associated with complicated production systems. The model's stability and effectiveness are further enhanced by the preprocessing stage's use of Min-Max Normalization, which guarantees that the model can absorb and analyze a variety of standardized input data. The study emphasizes how important cutting-edge methods like CNN and Autoencoder are for identifying complex patterns in real-world data, and how working in tandem with genetic algorithms improves the model's capacity to optimize for better availability and failure detection. In the future, this study will focus on extending the suggested approach's utility to other industrial contexts and investigating how well it can be tailored to real-time production scenarios. Furthermore, additional research on the interpretability of the model's decision-making procedures would improve industry acceptance and confidence in the suggested technique. The model's performance may be further enhanced by including more complex evolutionary algorithms or investigating hybrid models that incorporate other optimization methods. Furthermore, in order to support large-scale production systems, the scalability of the deep learning-based technique should be investigated. The landscape of intelligent systems for fault detection and availability enhancement in industrial settings will be significantly shaped by the ongoing improvement and adaption of these approaches as technological developments persist. All things considered, this work establishes the groundwork for a proactive and effective strategy for managing production systems by utilizing genetic algorithms in conjunction with deep learning.

The study's efficacy may be impacted by real-world unpredictability, and its generalizability to various industrial settings and datasets is restricted. The computational resources required for optimizing system setups and training the deep learning model may give rise to practical limits. The emphasis on accuracy measures obscures a thorough evaluation of the robustness of the model in different scenarios or with respect to outside influences. Furthermore, the Python software implementation might make it more difficult to integrate seamlessly with production systems that use other technology stacks.

***Abstract*—Many inventive techniques have been created in the field of machine vision to solve the challenging challenge of detecting and tracking one or more objects in the face of challenging conditions, such as obstacles, object motion, changes in light, shaking, and rotations. This research article provides a novel method that combines Convolutional Neural Networks (CNNs), Compressive Sensing, Kalman Filtering, and Particle Swarm Optimization (PSO) to address the challenges of multi-object tracking under dynamic conditions. Initially, a CNN-based object classification and identification system is demonstrated, which efficiently locates objects in video frames. Subsequently, in order to produce precise representations of object appearances, utilizing compressive sensing techniques. The Kalman Filter ensures adaptability to irregular observations, eliminates erroneous data, and reduces uncertainty. PSO enhances tracking efficiency by optimizing forecast precision. When combined, these techniques provide robust tracking even in the presence of complex movement patterns, occlusions, and visual disparities. The efficiency of this strategy is demonstrated by an empirical investigation that produces a remarkable tracking accuracy of 98%, which is 3.15% greater than other methods across a range of challenging settings. This technique has been compared to various existing approaches, including the Clustering Method, YOLOV4 DNN Model, and YOLOV3 Model, and its deployment is made easier with Python software. This hybrid technique, which addresses the limitations of separate approaches and offers a holistic approach to multi-object monitoring, has potential applications in surveillance, robotics, and autonomous systems.**

Keywords—Multi-Object tracking; object detection; convolutional neural networks; kalman filtering; particle swarm optimization

I. INTRODUCTION

Computer vision is a dynamic investigation area, which widens its perceptual field across a range of purposes like traffic and navigation systems, motion detection, speech and voice recognition and other applications. In which Object detection by means of a single aspect of the target will not provide a favorable resolution, as the object manifestation may altered depending on light effects, object position shifts, and blurring effects, occlusion and so on. As a result, multi-scale object detection was planned, which delivers further healthy resolution than single-degree object detection [1]. Quite a lot of discriminative appearance Random projections have been expected to venture high dimensions properties like features to a low dimensional space. This compressive sensing is self-sufficient in terms of data, as well as non-adaptive naïve Bayes classifier is used to differentiate among optimistic and undesirable data [2]. Extracts the features through compressive sensing and sparse representation to construct the model more fast and robust, and applied the LS-SVM classifier act as the optimization algorithm to separate positive templates from negative samples, finally hypergraph methodology use to improve the tracking accurately [3].

Majority of the object detection techniques are restricted to only a limited object group, the classification of datasets and of images will be a monotonous task. A training procedure called YOLO9000 was projected, This is a real-time object detector capable of detecting numerous items, including over 9000 samples [4]. In order to detects multiple objects, a Kalman filtering is secondhand, whose object structures will be arbitrary and Gaussian in fauna. Gaussian in personality. Once the location of the item transforms regularly and the movement is piercing, the Kalman filter is secondhand. Kalman filtering has two stages: 1. Prediction, in which the object location is predicted; and 2. Correction, in which the estimated value is approved in relation to the predetermined state assessment. The Particle Swarm Optimization (PSO) method is an extremely efficient object tracking technique that follows objects in moving video in a manner akin to bird flocking. The ideal object frame may be found based on the item's current location, its prior best position, and its best position in the overall frame.

Sparse representation object model is the majority and most commonly used in object recognition, two types of imaging sets were observed to apply. One is for object patterns, which have pixel values from previous frames. Another is inconsequential templates, which include noisy pixels. The pixels that make up object patterns are sparse manner described in a low-dimensional sub space, resulting in a path of non-zero entrances in the sparse medium, which represents the location of the pixel in a precise image frame [5]. However, the object model with thin depiction grieves from heavy obstruction and cannot account for things that come and disappear over time.

Object tracking in video clips is a problem for the available object tracking techniques. For applications ranging from surveillance to robotics and autonomous systems, the capacity to reliably detect and monitor objects in the midst of barriers, changing illumination conditions, object motion, shaking, and rotations is essential. Occlusions, scale shifts, and visual alterations are some of these difficulties. To accomplish this, need to overcome the above-mentioned issues, the paper has proposed CNN based FCT (Fast Compressive Tracking) method in which the sparse random matrix generated multiple object features is fed to the CNN model. The input is fed as two successive image frames, as the predominant features are extracted through the processing of stack of CNN layers and fed to the output layer. In order to improve object representation accuracy, compressive sensing techniques are included. The purpose of the Kalman Filter is to reduce uncertainty, remove erroneous data, and provide adaptation to irregular observations. At the output of the CNN model, Kalman filtering and Particle Swarm Optimization (PSO) is applied in order to locate the locations of the target image features. Particle Swarm Optimization is included to maximize forecasting accuracy and increase tracking efficiency. When these methods are combined, a strong solution that can handle problems like intricate movement patterns, occlusions, and visual imbalances is produced. A Support Vector Machine (SVM) classifier is trained in order to classify the target features of the images from the rest of the images. The proposed algorithm was able to track and detect objects under severe occlusion as well as was able to track images which are inconsistent in nature. CNN used extensively in the area of visual object tracking, with a strong ability to learn distinctive image features depictions, feature map selection methods to select discriminative features and discard noisy or unrelated ones. A multi-domain learning framework, called as MDNet, full network trained offline, and the connected layers counting Online fine-tuning of a single domain-specific layer [26]. CNN focused on visual recognition tasks, contains domain adaptation, fine-grained based recognition, and largescale scene recognition. The potentiality of a visual recognition system to attain elevated classification accuracy on exercise with sparse labeled data has shown to be a long term objective in computer vision research [6].

More reliable and effective multi-object identification techniques are desperately needed in dynamic and complicated situations, which is what inspired the proposed work. Situations where things are obscured, arrive suddenly, or vanish are difficult for traditional object detection techniques to handle. The CNN-FCT Methodology is selected as a ground-breaking solution in response to these constraints because of its exceptional characteristics and capabilities. To solve the issues with previous approaches, the CNN-FCT Methodology combines Convolutional Neural Networks (CNN), Particle Swarm Optimization (PSO), and Kalman Filtering. The model can recognize intricate patterns and representations in a variety of circumstances thanks to the efficient feature extraction provided by CNN. This is especially important to overcome occlusion-related difficulties, when standard approaches might not be able to recognize objects with enough accuracy. Dynamic optimization and tracking techniques are introduced via the combination of PSO and Kalman Filtering. PSO improves the model's ability to adjust to abrupt changes in the scene by improving the predicted positions of objects at each iteration. This is enhanced by Kalman Filtering, which offers a predictive filtering process that makes tracking more accurate particularly when objects appear and disappear. The shortcomings of conventional object detection techniques have been exposed by recent developments in computer vision and machine learning, particularly in situations that are extremely dynamic and unexpected. These issues are acknowledged in the suggested study, which creatively integrates CNN Compressive Sensing, PSO, and Kalman Filtering into the CNN-FCT Methodology. By doing this, the research hopes to greatly improve the performance of multi-object detection systems, strengthening their ability to withstand the intricacies of the real world and advancing computer vision applications across a range of industries.

The key contribution of the paper is given as follows:

- The proposed approach differentiates out since it integrates several innovative techniques. The system integrates CNNs, Compressive Sensing, Kalman Filter integration, and PSO to enhance object tracking effectiveness.

- An effective and precise item categorization and identification system is facilitated by the methodology's early integration of Convolutional Neural Networks (CNNs). This section makes sure that objects are located precisely inside of video frames, providing a solid basis for tracking operations.

- The accuracy of object representations is further improved by the application of compressive sensing methods. This addition improves object representation accuracy by effectively extracting relevant information from the video frames.

- By removing false data and lowering uncertainty in the tracking process, the inclusion of Kalman Filtering gives flexibility to erratic observations. By allowing the technique to adjust to erratic variations in object movement, this contribution enhances the methodology's durability and offers a more precise and dependable tracking mechanism.

- Particle Swarm Optimization is included to improve forecasting accuracy and tracking efficiency. This optimization process helps to maintain object tracking accuracy even in scenarios with occlusions, appearance modifications, and complicated motion patterns.

The remaining sections of the paper are ordered as follows: Section II deliberates about various multi-object tracking algorithms, Section III portrays about problem statement, Section IV discloses about the kernel filtering and sparse representation model, Section V gives a detailed explanation about the proposed CNN-FCT model, and Section VI depicts the investigational consequences and accomplishes the paper.

II. Related Works

As evidenced by this literature review, there are several visual object tracking methods available, we are going to assess few algorithms and methodologies, which have been extensively used for exploring reason.

A. *Fast Visual Tracking*

Li and Wang has proposed Dense Spatio-temporal Context Learning for fast graphic tracking [7]. This method creates a Bayesian framework, for associating the spatio-temporal aspects among the goal object and the foreground and circumstantial images pertaining to the image frames. For rapid learning and detection, this work applied four- Fast Fourier Transformation (FFT) and the results showed that this framework performed well against state-of-the-art techniques with admiration to effectiveness, correctness and robustness.

Bern et, al. [8] has proposed a incremental model algorithm, in which the target obejct is tracked increamently to a low-dimensional subspace presentation and also adapts to the dynamic changes pertaining to the target object. The increamenting algorithm is based on the principal component analysis and forgetting factor, that helps in enhancing the overall performance of the proposed tracking algorithm.

Najeeb and Ghani has made comparative study on the techniques of object tracking in various applications pertaining to computer vision domain namely, traffic surveillance, robot navigation and so on [9]. This paper studied about various object tracking methods, which tracks single or multiple objects in motion form a video sequence. The major object tracking techniques discussed in this survey are kernel tracking, point tracking and Silhouette tracking algorithms.

Dr. D. S. David [10] has proposed innovative and efficient object detection and tracking algorithm that utilizes optical flow in combination with motion vector assessment for object discovery and trailing in a series of frames. The optical flow exposes the details of the moving object and motion vector assessment provides the position of an object from successive frames and helps in increased accuracy in spite of motion blurs and cluttered image background.

B. *Particle Swarm Optimization (PSO)*

Moussa and Shoitan in this work has implemented Sequential Particle Swarm Optimization (PSO) for visual tracking, which tracks the objects by including significant features of the tracked objects [11]. This method resulted in increasing tracking performance because of its parameters that is flexible according to the fitness value of the objects and predicts the object's location correctly when it is in motion.

Nedjah has proposed an object tracking algorithm, which utilizes PSO technique, in order to detect the target object in motion from a video image series [12]. The entire video sequence is searched as an individual swarms which provides optimal solution.

C. *Compressive Visual Tracking*

Chen et al. [13] has proposed a scheme along with weight maps called as multi-sparse measurement matrix, which compresses the image but at the same time maintains the originality of the image features. The weight map merges a distinct weight as well as a characteristic weight to proficiently differentiate the aimed manifestation and position. Furthermore, a dispersion function is applied for the digital updating of the intended template letting to track together the position and extent of the target object.

Nguyen et al. [14] proposed a method which holds two steps one is effective Cholesky decomposition on GPU and FPGA. In order to improve the performance with respect the memory access, second is CS signal reconstruction applied on FPGAs and GPUs which helps to reduce the computation.

Li et al. [15] has proposed template matching dealing out phase along with the compressive tracking method, in demand to maintain the constant frame frequency and rise the strength of the tracker. This template comprises of all the available data and similarity metrics have been used to compare the available data with the regularly used images series.

D. *Kalman Filtering*

Kaderali in this work has implemented IMM cubature Kalman filter (IMM-CKF) in order to track the orbiting space objects [16]. This study utilizes the geometric association among the planetary object specifically space craft, space based optical (SBO) sensor, and the sun for tracking the space object. A situation which encompasses the aimed spacecraft and four SBO sensors is utilized to check efficiency of the IMM-CKF. A comparison was made between IMM-CKF and the normal cubature Kalman filter (CKF). The outcome designates that IMM-CKF is extremely vigorous than the CKF when the space object experiences a movement. Shantaiya et al. [5] has proposed multiple objects tracking from the video series using optical flow algorithm. This algorithm uses Kalman filtering to detect and track the moving objects in each frame, which helps in identifying moving objects with occlusion, blurred objects and so on. Ullah et al. [17] for the usage against non-linear systems proposed a novel method known as Unscented Extended Kalman Filtering (UEKF). This new method of Kalman filtering is same as traditional Kalman filtering except, for every running non-linear sample, the deterministic sample is caught with non-linear mean and linear covariance. This new method offered better performance when compared to that of conventional Kalman filtering.

E. *Convolutional Neural Network-based Visual Tracking*

Xiao and Pan has researched, how CNN filers helps in tracking moving objects by increasing the depth of the CNN [20]. It was found that, by making the depth to 16-19 layers, the proposed ConvNet showed better performance than the traditional visual tracking methodologies when evaluated against state-of-arts results. Mahmoudi et al. [18] has proposed CNN based online moving object tracking algorithm, in which the tracking missed error rates are reduced by employing truncated structure loss function and temporal selection mechanism for discriminating positive and negative samples. Liu et al. [19] has proposed online CNN model for tracking visual objects. For hierarchical feature learning, and to reduce the dependability of CNN, k-Means is applied. Regression model is involved to notice the positive samples of the goal visual object. The investigational outcomes showed that, the planned model executed very well when compared to another Online CNN model. Li and Yang proposed a model based on rich feature hierarchies of CNNs cultured from a large-scale datasets and train a liner correlation filter on each convolutional layer and conclude the goal location with a coarse-to-fine searching method [20], yields outcomes favorably against the state-of-the-art approaches in relations of robustness and accuracy.

Object tracking techniques in computer vision, Incremental Model Algorithms, Dense Spatio-temporal Context Learning, PSO for visual tracking, Compressive Visual Tracking with weight maps and efficient signal reconstruction, Kalman Filtering for tracking orbiting space objects, and CNN-based Visual Tracking are just a few of the advanced techniques for visual tracking that are examined in this literature review. To improve tracking performance, these approaches use a variety of strategies, including CNN filters, optical flow, Bayesian frameworks, Principal Component Analysis, and Cholesky decomposition. The review illustrates their uses in various contexts and shows how well they work to increase accuracy and resilience when compared to state-of-the-art outcomes and conventional tracking approaches.

Numerous strategies have been investigated by researchers, such as incremental model algorithms, Bayesian frameworks, comparative examinations of tracking methods, novel object identification and tracking algorithms, and the use of optimization strategies like Particle Swarm Optimization (PSO). Also, there is an emphasis on improving tracking performance by utilizing deep learning techniques, namely CNNs, multi-sparse measurement matrices, compressive tracking, and Cholesky decomposition. The main difficulty, despite the variety of approaches, is creating dependable and effective object tracking systems that can deal with things like motion blur, crowded backgrounds, and shifting object appearance.

III. Problem Statement

From the above discussed literatures, it is found that the challenge involves tackling the difficulty of multi-object tracking in dynamic environments, where a large number of objects must be reliably and precisely tracked despite occlusions, visual discrepancies, and intricate movement patterns [21]. The goal is to improve tracking accuracy and resilience by combining CNNs, PSO, Kalman Filtering, and Compressive Sensing. The issue statement's primary objective is to develop and evaluate an improved multi-object tracking system that employs these techniques in order to progress object tracking and computer vision applications and achieve high tracking accuracy and reliability in challenging circumstances. The method used in the study is called Multiple Object Tracking, or MOT. In order to overcome the aforementioned problems, the current study establishes a dependable and real-time tracking device that is capable of handling the difficulties associated with multiple object tracking in a variety of instances. This is achieved by using an effective compressible tracking infrastructure based on CNN models in conjunction with Kalman filtering and PSO algorithm.

IV. Proposed CNN-FCT Model for Object Tracking

The CNN-FCT Methodology combines a number of essential elements, each of which has a unique function in tackling the difficulties involved in multi-object recognition in dynamic and complex situations. The effectiveness of the methodology is largely due to its novel features, which include the use of Particle Swarm Optimization (PSO) to improve predictions, Fast Compressive Tracking (FCT) for object tracking, Segmentation with Otsu thresholding, Kalman Filtering, and Convolutional Neural Networks (CNN) for object detection and classification. This all-encompassing strategy outperforms separate approaches and has promise for robotics, autonomous systems, and surveillance. Fig. 1 depicts the proposed CNN-FCT methodology.

Object Detection & Classification (CNN)
Multi-Object Tracking Output

Fig. 1. Proposed CNN-FCT Methodology.

A. Data Collection

The MOT challenge 2017 dataset is used for example video clips in order to evaluate the suggested approach. In all, 11245 frames are included in its 14 series of detections, seven of which are used for testing and the other seven for training [22].

B. Kalman Filtering

In the predictive tracking and filtering process, Kalman Filtering is an essential part. Kalman filtering improves the estimated item positions using dynamic measurements and predictions by implementing a recursive method. This guarantees, even in situations where objects appear, disappear, or are obscured, that their trajectories are monitored precisely. The Kalman Filter is used to improve object tracking accuracy. The Kalman Filter gives an ideal estimate of the object's state, efficiently minimizing the effects of noise and uncertainties, by integrating noisy and uncertain observations with predictive models. As fresh measurements come in, it continually updates its estimation in order to dynamically respond to changing conditions. Smooth and precise tracking is made possible by the Kalman Filter's capacity to combine historical data and forecasts with current measurements, especially in conditions characterized by noise, occlusions, and fluctuations in object speed. It is essential to attaining accurate and consistent object tracking results because of its iterative process of prediction, update, and state estimation, which acts as a strong mechanism to preserve the trajectory and location of the tracked item. Kalman filtering, which is especially effective at managing noisy data, helps to lower the number of false positives and negatives and ensure accurate estimations of the object state. The system is robust in dynamic circumstances because of its capacity to adapt to changing surroundings and retain continuity between frames. This is made possible by its sequential frame processing capabilities. By offering temporal context for object tracking when combined with CNN Compressive Sensing, Kalman Filtering enhances the capabilities of CNNs and produces a more precise, accurate, and real-time multi-object detection system that performs well in demanding and dynamic settings.

C. Segmentation

To successfully separate items from the background, the segmentation module uses Otsu thresholding. By separating foreground and background pixels with the best possible threshold, this method enhances object localization. Otsu thresholding improves the segmentation process, making it possible to extract features for later stages of the approach with greater accuracy. Otsu thresholding, a popular image segmentation approach, distinguishes between object areas and background in a video stream, which is crucial for object tracking. With the help of automation, the ideal threshold value that reduces intra-class variation in object and background areas may be found. By transforming grayscale or color frames into binary images, where pixels are classed as either object or background based on their intensity values, Otsu thresholding efficiently separates items of interest in object tracking. Otsu thresholding allows subsequent object tracking algorithms to precisely detect and follow the movements of objects over time, improving the accuracy and robustness of the tracking process. This is accomplished by segmenting the video frames into discrete zones. It is given in Eq. (1) below.

$$\sigma_z^2 = W_x\sigma_x^2 + W_y\sigma_y^2 \tag{1}$$

In this equation, W_y stands for the weight of the frontal image and σ_y^2 for its variation, whereas W_x stands for the weight of the background image and σ_x^2 for its variation. With the use of this approach, researchers may determine which pixels in an image serve to balance the foreground and background, as well as how many of them overall there are in comparison to both the background and foreground pixels. The average and variance are then calculated for the suitable backdrop and foreground. The weight and variation were then used to establish the various thresholding level values.

D. FCT for Object Tracking

For effective and real-time object tracking, Fast Compressive Tracking (FCT) integration is essential. Using compressive sensing techniques, FCT is able to track and rebuild objects over several frames. This method offers strong tracking capabilities and is especially useful in situations where objects are obscured or move suddenly. Feature correspondence and transformation techniques are used in FCT, a unique approach to object tracking, to improve the accuracy and resilience of tracking in complicated visual situations. In order to build object correspondences, this technique first extracts and matches characteristic features from successive frames. An adaptive transformation procedure then adjusts for variations in object appearance, size, and orientation. FCT is a potential approach for multi-object tracking in real-world applications because it combines feature-based matching with transformation-based modelling to address issues including occlusions, illumination changes, and object deformations. By offering a more robust and flexible framework for monitoring objects across a variety of applications, including robotics, autonomous systems, and surveillance, this method has the potential to substantially enhance the fields of computer vision and object tracking.

Fast Compressive Tracking (FCT), a ground-breaking technique for reliable and effective object tracking in video sequences, has gained prominence. FCT presents a revolutionary method for collecting and describing the look of objects, building on the concepts of compressive sensing, enabling real-time tracking even in difficult circumstances. FCT makes use of a condensed image of the object's appearance. Online learning of this condensed model is effective and adapts to changes in object appearance and background noise. The distinguishing strength of FCT is its robustness to occlusions, changes in illumination, and deformations while still successfully separating the object from the backdrop. FCT is particularly suited for high-speed applications like robotics, surveillance, and interactive systems since it can achieve amazing tracking speeds while drastically decreasing computing overhead. Compressive sensing's effective signal capture combined with FCT's adaptable appearance modelling results in a significant improvement in object tracking. Algorithm 1 explains the object tracking.

Algorithm 1: Multi-Object FCT Algorithm

```
Input: A representative model from $Y^t, Y, t_{th}$ frame.
Step 1: retrieve $v(Y^t)$ by selecting the searching range " $\kappa_y \geq 1$ and looking for step ʊs≥ 1".
Step 2: classifier CNN equations are used, the tracking location $I_{(t-1)}$ is achieved with the best predicted outcome.
Step 3: retrieve $v'(Y^t)$ by selecting the searching range " $\kappa'_y \geq 1$and $\leq \kappa_y$ and looking for step ʊ's≥ 1 and≤ ʊs".
Step 4: By using $v'(Y^t)$ to CNN equations, the tracking location $I_{(t)}$ is achieved with the best predicted outcome.
Step 5: Now, extract the features from the two sets $v\,(Y^t)$ and $v'(Y^t)$ .
Step 6: Apply the sampled feature to the SVM classifier in the SVM equation now.
Output: Object is tracked at $I_{(t)}$.
```

E. Object Detection and Classification with CNN

Utilizing Convolutional Neural Networks (CNN), the approach performs exceptionally well in object classification and feature extraction. Because CNNs are skilled at extracting hierarchical representations from incoming data, the model can recognize complex patterns and features. This improves the methodology's ability to recognize and classify objects accurately, making it appropriate for a wide range of item kinds and intricate situations. The way of recognizing and classifying things inside images and video frames has been completely transformed by the state-of-the-art computer vision. CNNs are able to identify things with great precision because of their inherent ability to automatically learn hierarchical properties from input. Using this method, a CNN model is trained on large datasets to identify particular classes or objects. The trained CNN is used to input images during the inference phase, when it searches the whole scene for objects and then gives them class labels. Numerous real-world uses for this technol8ogy exist, such as in driverless cars, spying, the interpretation of medical images, and more. Its capacity to manage intricate situations like object occlusions and changing object sizes and orientations makes it a potent instrument in the field of computer vision, opening the door for sophisticated applications in a variety of sectors.

CNNs are used for object identification and classification in computer vision applications, such as multi-object tracking and real-time situations. These applications benefit from hierarchical feature extraction, spatial hierarchies, and robustness to fluctuations. CNNs are an invaluable tool for applications requiring precise and effective object detection in a variety of visual settings because to their versatility and adaptability. In the field of object tracking, CNNs are used to locate and identify objects inside video frames, giving not only their locations but also the labels that go along with them. Even in a variety of tough visual environments, the CNN can reliably distinguish between multiple object categories thanks to its capacity to learn intricate features and patterns from large training data. CNNs are adept at classifying objects; they give labels according to traits they have learnt and are adaptable to different categories. Training is accelerated by utilizing transfer learning, particularly in situations when task-specific data is scarce. With improved designs like SSD or YOLO, CNNs find applications in real-time activities and exhibit robustness to fluctuations in object appearance.

The input is fed to the CNN network, as a combination of two cropped regions from two next frames as explained in Algorithm-2. Then it is propagated through five layers of CNN layer, where researchers remove all the remaining layers from the pooling layers to store only precise information of the cropped pair of input images. Researchers produce a couple of frames (CF_t, CF_{t-1}) with target center $\left(a+\frac{w}{2}\,;b+\frac{h}{2}\right)_{t-1}$,and size $(p_w\,, p_{sh})_{t-1}$, where, $t-1$ stands for the directory of preceding frame and p describes the exploration range.

The collected areas are resized into $m_i * m_i$ with scale factor $(sx; sy)$ which is well-defined beforehand affording with the real size of images, and nourished into a CNN model to attain the 1^{th} Convolutional beginnings. Tracking information linked list is presented to discover novel substances of attention incoming the image which is a sequence of protuberances N depicting noticed objects which emerges in frames with the same ID from the initial to the final. Each node N_t comprises the objects in CF_t. Every object has ID which is identified by its aspects. When the similar object emerges over again, it goes on the olden ID in its place of a new one. Hence, the tracking information linked list can be applied to resolve obstruction issues and to forecast misrepresented objects. The suggestion is made by the PSO algorithm.

Algorithm 2: CNN based Classification Algorithm

Input: A pair of cropped frames $(CF_t; CF_{t-1})$ target center $(a+\frac{w}{2}; b+\frac{h}{2})_{t-1}$, and
size $(p_w; p_{sh})$

Step 1: Resize the cropped pairs $m_i * m_i$ with scale factor $(s_x; s_y)$

Step 2: The resized cropped image is fed to the CNN network to obtain 1^{th} convolution activation

Step 3: The precise features are extracted from the cropped inputs by removing all the images in the pooling.

Output: Classified object linked list obtained with Node N_t and associated objects O_t with ID for every node.

F. PSO for Enhancing Predictions

To improve and refine the predictions produced by the approach, Particle Swarm Optimization (PSO) is utilized. Accuracy and flexibility are enhanced through parameter optimization of the model by PSO. Ensuring that the model dynamically adapts to changing conditions is especially useful in situations when abrupt changes take place. PSO is essential for object tracking since it improves predictions after CNN classification. Following the CNN's classification and identification of the objects in the video frames, PSO enters to improve the original predictions by maximizing the predicted object locations and trajectories. By utilizing PSO's optimization skills, the tracking algorithm may fine-tune the anticipated item positions based on elements like motion models, historical data, and real-time measurements. This improves the initial forecasts' accuracy and allows them to be adjusted to the tracking scenario's dynamic nature. In order to account for uncertainties and imperfections caused during object categorization and initial tracking, PSO's repeated optimization procedure refines the anticipated locations. Its combination with other methods, such CNN-based object recognition and Kalman Filtering, results in a hybrid strategy that provides a thorough plan for precise and adaptable forecasts in multi-object tracking situations. Real-time applications are made easier by PSO's computational efficiency, which guarantees fast and rapid prediction generation. This is important in dynamic contexts where timely and accurate forecasts are necessary for making wise decisions.

PSO is attracting more academics because of its versatility and resilience, particularly for challenges in dynamic environments, it is a population-based stochastic optimization technique. Idea of PSO is the particles fly around randomly over the image searching for the best value in each round. The fittest value of the particle in its entire search at every round is called P_{Best}. The fitness function is applied to all particles, and the fitness value (best solution) is estimated and stored. The fitness value of the current optimal particle is referred to as “P_{best}”. PSO maximises the best population value gained as far as any particle in the neighbourhood, and its location is known as l_{best}.

When all of the generated populations are measured as topological neighbors by a sensitive particle, the best value is chosen among the executed population, and that sensitive best value is recognized as the best solution as g_{best}. The PSO is always attempting to change the speed of each particle towards its p_{best} and l_{best}. The speed is determined by arbitrary terms, which have arbitrarily generated quantities for the speed towards the p_{best} and l_{best} locales. The preceding stages are depicted as an Algorithm 3.

Algorithm 3: PSO Algorithm for fast visual tracking objects

```
Input: at $t_{th}$ frame of the image.
   Swarm size $(N)$, Maximum number of Iteration (M), L_rate$(L\_r)$ , acceleration coefficients $(C_1)$ ,$(C_2)$, prior width $(w)$ and height$(h)$
Initialize the image size $(n)$
For $i = 1\ to\ n$ // $i = 1, 2, 3 \ldots \ldots n$// starting with 1
        Initialize the swarm particles randomly      $SP_j = [\, X_{s1}, X_{s2}, X_{s3}, X_{s4} \ldots X_{sn}]$
// $j = 1,2,3, \ldots . N_{sp}\ j = 1,2,3, \ldots . N$, $X_1 = [x, y, w, h]$, $x$– starting x-axis, $y$-starting y-axis
      Calculate the fitness of each particle (i.e., compute the ratio classifier for all the samples
determine the $p_{best}$ and $g_{best}$ for the current round (“iteration”).
While $(t < M)$
for $j = 1\!: N_p$ //starting with_2
                    evaluate and update the velocity of the particles
                                        $V_j(t+1) = w(t+1) * V_j(t) + C_1 * rand * (P_{best} - SP_j) + C_2 * rand * (g_{best} - SP_j)$
                 $P_j(t+1) = p_j(t) + velocity\ (t+1) * lrate$ // “revise updated position”
end for // “end for 2”
    Calculate the fitness of particles $(new\_fit)$
                 revise the $P_{best}$ and $g_{best}$
        // $P_{best}$
if $(new_{fit} > P_{best}\ fit)$then
$P_{best}\ \_sol = P_j$ ;
$P_{best}\_fit\ = new\_fit$
else
                              do nothing
end if
        // $G_{best}$
if $g_{best}\_fit < max(new\_fit)$) then
$g_{best}\_Sol = P_j(index\ of\ Max(new\_fit))$
 $g_{best}\ Fit = Max(new\_fit)$
end if
end while // Repeat until the maximum num. of iterations is reached.
End for // until n frames are reached.
```

V. Experimental Results

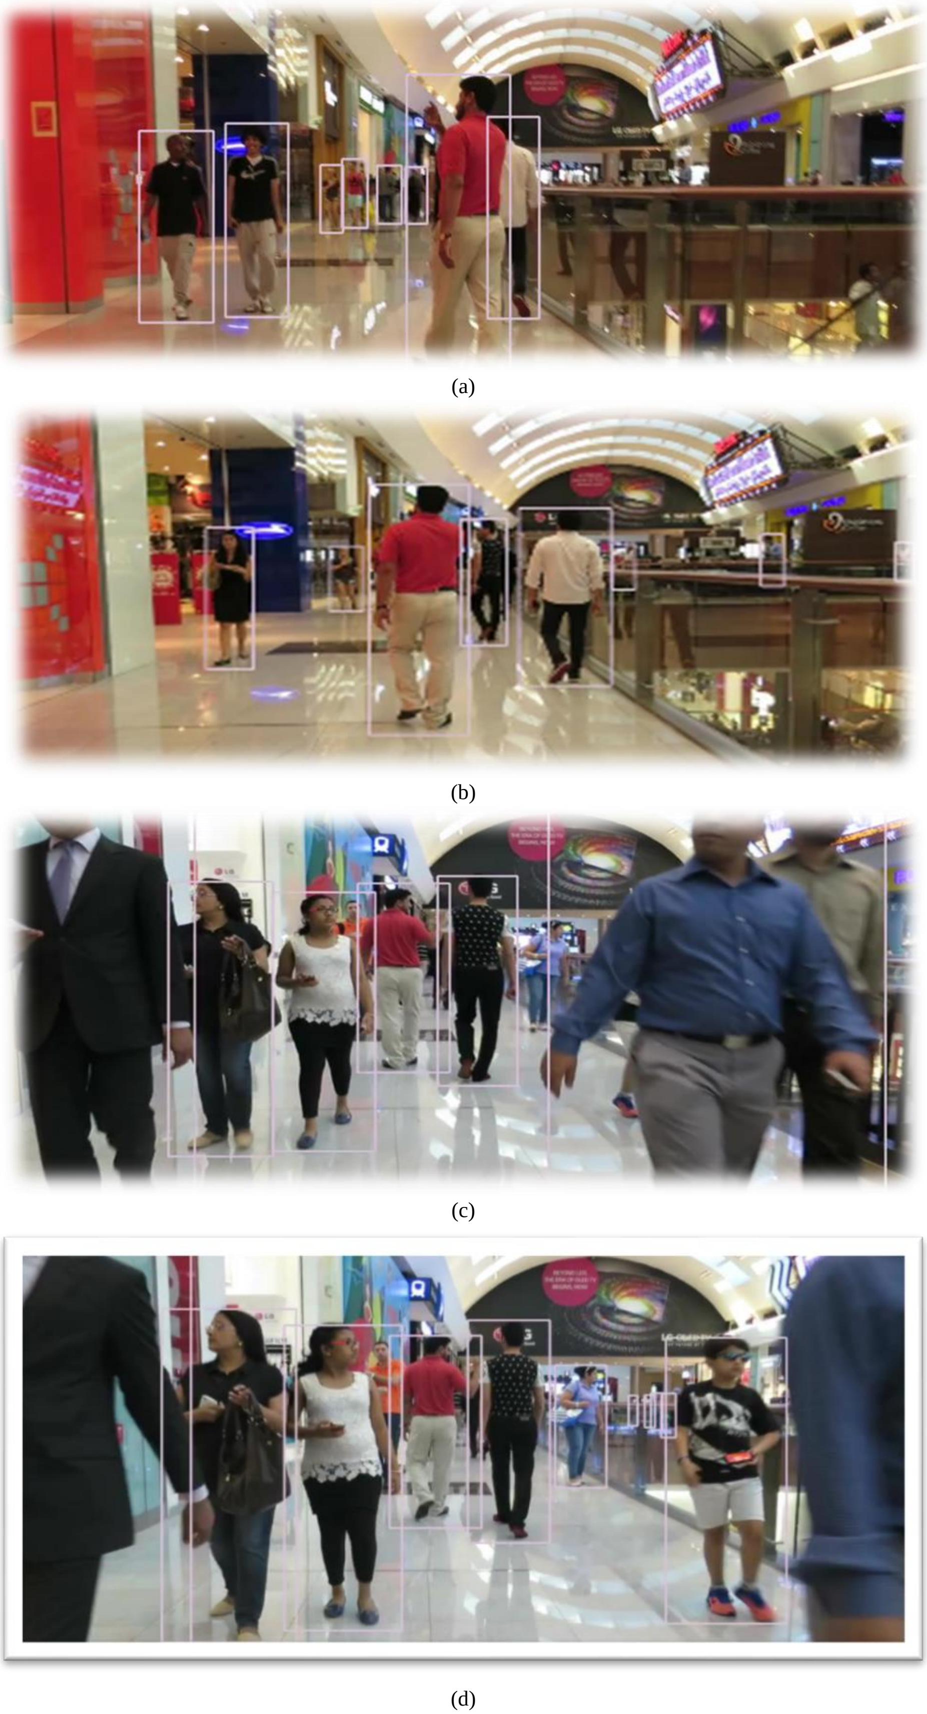
To assess the proposed methodology, MOTchallenge 2017 dataset is utilized for sample video clippings. It contains encompasses 14 series of detections, seven for training and seven for testing, thereby on a whole comprising 11245 frames. The investigations are executed in OpenCV environment, in which python is applied as the programming language.

A. Tracking Samples of the Proposed CNN-based Fast Compressive Tracking Methodology

1) Detection of people in a busy shopping mall- sample video for complete occlusion: The detection people in a shopping mall in highly occluded condition are depicted in Fig. 2(a) – (d). The video sample consists of 30 Frames Per Second (FPS), with 75 tracks and 12389 detection boxes. From Fig. 2(a) and (b) researchers can show that, the proposed methodology was able to track and detect people whose motion is unpredictable.

From Fig. 2(c) and (d) it can discovered that, the man in blue shirt has completely occluded a small boy whose shoes are only visible in the Fig. 2(c). In the frame i.e., Fig. 2(d), the boy is easily detected by the proposed methodology from which researchers can give assurance that the novel methodology is capable of detecting objects even in complete occlusion.

2) Tracking people in busy street- sample video for sudden arrival and fading of the object: Fig. 3(a), 3(b) and 3(c) depicts the example of sudden arrival and fading of the goal object. This sample video comprises of 30 FPS, with 83 tracks and 47557 detection boxes.



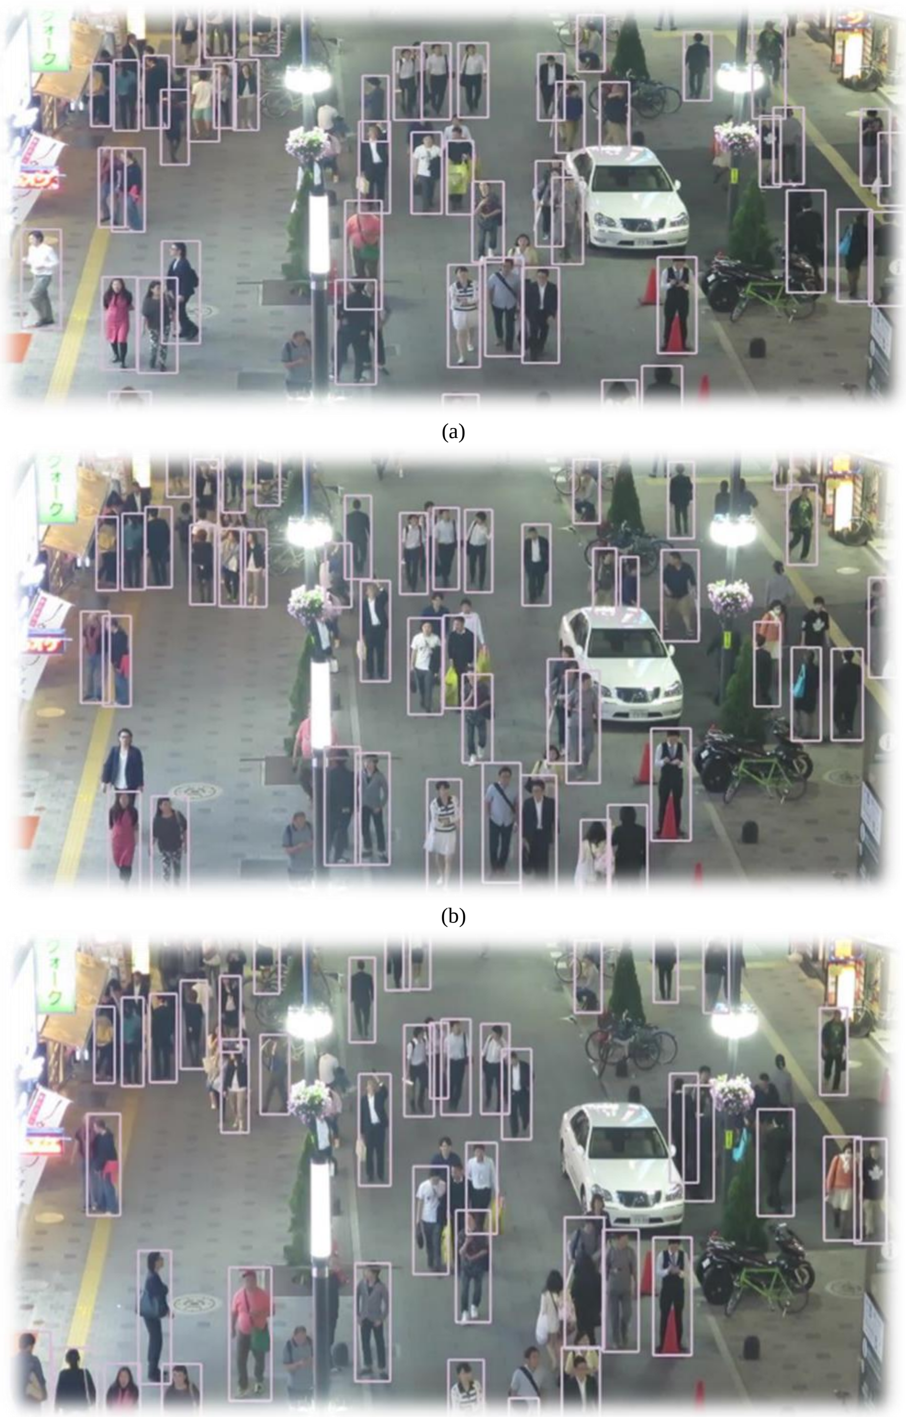
(a)

(b)

(c)

(d)

Fig. 2. (a) – (d) Detection of people in shopping malls at various frames.



(a)

(b)

(c)

Fig. 3. (a)-(c) Example of sudden appearance and disappearance of target object.

From the Fig. 3(a), it can be found that in the third street lamp, a man wearing a black hat is standing near the post. In the next Fig. 3(b), he was hidden behind the post. After sometimes, he is again appearing and tracked in the Fig. 3(c). Thus the proposed methodology was able to track objects with sudden appearance and re-appearance behavior.

Researchers are evaluating using MOT as a performance metric suite, which comprises MOT_A (Multi-Object Tracking Accuracy) and MOT_P (Multi-Object Tracking Precision) as the chief metrics The MOT_A collects “three error causes: False Positives (FP), False Negatives (FN) and Identity Switches (IDs)”. “*Gt* is the sum of the goals in each edge. Researchers also investigate about the sum of courses of Ground_Truth (GT), Mostly_Tracked (MT), Mostly_Lost (ML), Fragment (FM), Partially_Tracked trajectories (PT), and Multiple Object Tracking Accuracy with log 10 (*IDs*) (MOTAL), False_Alarms per Frame (FAF). Researchers also acknowledge the assessment metrics Recall (Rcll) and Precision (Prcn)”. Each technique's rate is restrained in frames per second (FPS). The subsequent table compares several object followers in the MOT2017 encounter dataset to the planned scheme.

The above Table I make a comparison between the existing multi-objects tracking to that of the proposed methodology. The comparison was made taking two datasets which was used as sample video sequences for the experimental purpose namely, shopping mall dataset and busy street dataset. From the table it can be concluded that, the proposed methodology showed better performance against MOT2017 dataset state-of-arts methods when compared to that of existing object tracking methodologies.

The graphical depiction of the comparison between the proposed CNN-FCT and M-FCT is shown in the following graphs. Fig. 4 compares the Accuracy, Robustness and efficiency of the proposed methodology with that of M-FCT. It was found that, CNN-FCT showed enhanced performance measures when compared to that of M-FCT.

Fig. 5 depicts the MOT accuracy between CNN-FCT and M-FCT, whereas Fig. 6 depicts the Most Tracked and Most Least measures of the proposed and existing methodologies. As the proposed CNN-FCT tracks object even if the object is fully occluded or appears and re-appears randomly, the MOT Accuracy is higher than that of M-FCT. Even though M-FCT is better when compared to conventional object tracking methods, its track loss rate is higher when compared to that of CNN-FCT. Hence from the comparisons, it can be evident that the proposed methodology performed well against all recently proposed multi-object tracking algorithms, especially in case of complete occlusion and object appearance and disappearance scenario.

B. *Performance Metrics Evaluation*

Quantitative indicators that evaluate accuracy and effectiveness are referred to as metrics of performance. These measurements are employed to assess and contrast various tracking approaches or algorithms. Here are a few performance measures that are frequently employed in object tracking such as recall, mAP, F1-score, Peak Signal to Noise Ratio (PSNR) and Root Mean Square Error (RMSE).

1) Recall: The proportion of real optimistic outcomes that a model correctly organizes as being optimistic is known as recall. The proportion of true positives to the entire of true positives and false negatives is secondhand to calculate it. It is given in Eq. (2) below:

$$\text{Recall} = \frac{\text{TP}}{\text{TP+FN}} \tag{2}$$

TABLE. I MOT2017 CHALLENGE DATASET MULTI-OBJECT TRACKING VERSUS THE PROPOSED METHODOLOGY

Datasets	Methods	MOT-A	MOT_P	MTrack	MLost	FP(+ve)	FN (-ve)	IDs (/Rcll)	FM(/Rcll)	Speed
Mall dataset	ACF [30]	33.7	76.5	7.2%	54.2%	5,804	112,587	2,418 (63.2)	2,252 (58.9)	1.3
	ZF [30]	33.2	75.5	7.8%	54.4%	6,837	114,322	642 (17.2)	731 (19.6)	0.3
	CNN-FCT (proposed)	**40.9**	**88.8**	**9.8%**	**34.0%**	**3,356**	**83,108**	**567 (11.78)**	**670 (18.4)**	**12.5**
Busy Street dataset	ACF [30]	29.7	75.2	5.3%	47.7%	17,426	107,552	3,108 (75.8)	4,483 (109.3)	0.2
	ZF [30]	26.2	76.3	4.1%	67.5%	3,689	130,54	365 (12.9)	638 (22.5)	22.2
	CNN-FCT (proposed)	**38.4**	**90.34**	**9.7%**	**36.0%**	**3,378**	**85,108**	**572 (12.78)**	**620(18.4)**	**13.6**

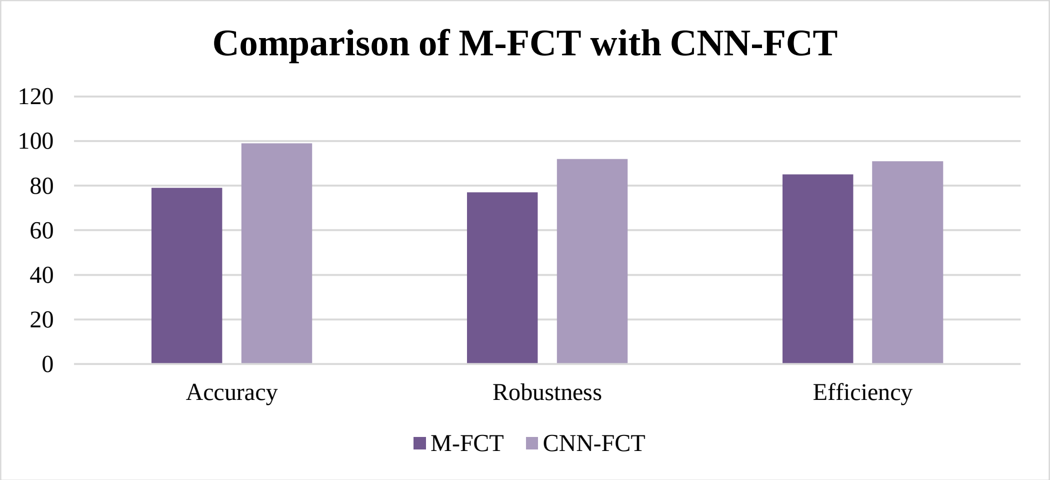


Fig. 4. Performance metrics comparison graph.

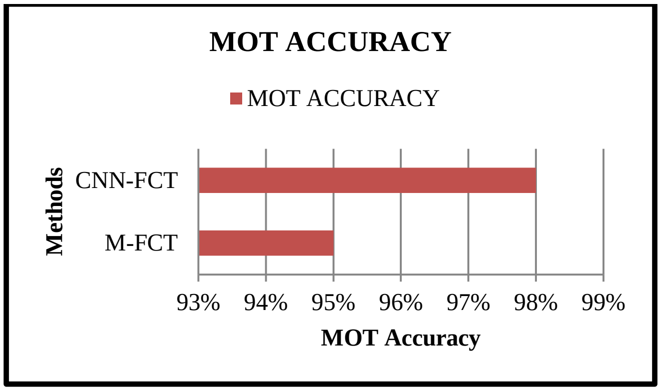

Fig. 5. Mot accuracy.

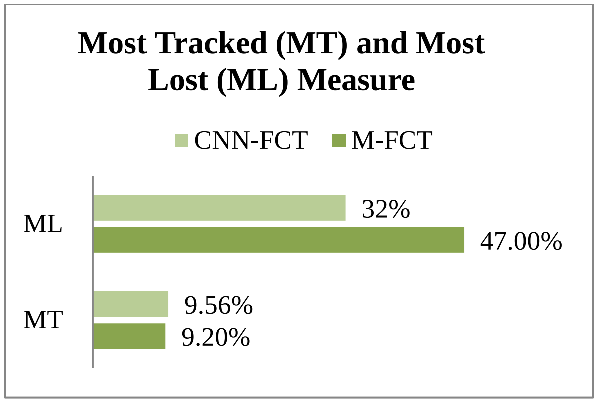

Fig. 6. ML and MT measures.

2) mAP: The mean over every category is then calculated by mAP after calculating the standard deviation of precision for every class. Its equation is given in Eq. (3) below,

$$mAP = \sum_{p=1}^{P} \frac{Average\ Q(p)}{P} \quad (3)$$

3) F1 Score: The F1 score is an individual statistic that syndicates precision and recall. It is the vocal average of these two metrics. It is frequently employed in binary categorization jobs where the proportion of both positive and negative instances is unbalanced. Its equation is given in Eq. (4) below,

$$\text{F1-Score} = \frac{\text{2 x Precision x Recall}}{\text{Precision+Recall}} \quad (4)$$

4) Root Mean Square Error (RMSE): A standard metric for assessing the effectiveness of models of regression is RMSE. By taking into account the squared variations, it calculates the average variance among the expected and actual outcomes. When greater errors are more important, RMSE is especially helpful since it draws attention to more significant discrepancies. It is given in Eq. (5) below,

$$RMSE = \sqrt{\sum_{j=1}^{M} \frac{\|x(j)-\hat{x}(j)\|}{N}} \quad (5)$$

Here, j is represented as the variable; M is represented as the non-missing data points; $x(j)$ is represented as the actual observation time series; $\hat{x}(j)$ is represented as the estimated time series.

5) Peak Signal to Noise Ratio (PSNR): A commonly used statistic for assessing the effectiveness of video or image compression methods is PSNR. It calculates the difference among the highest possible signal strength and the background noise power. It is given in Eq. (6) below,

$$PSNR = \frac{10\ log_{10}\ (peak\ value)^2}{MSE} \quad (6)$$

TABLE. II COMPARISON TABLE OF RECALL, MAP, F1 SCORE

Method	Recall	Map	F1 score
Clustering Method [23]	71	53	61
YOLOV4 DNN Model [24]	93	96	93
YOLOV3 Model [25]	41	46	53
Proposed CNN-FCT Model	95	96.9	95.3

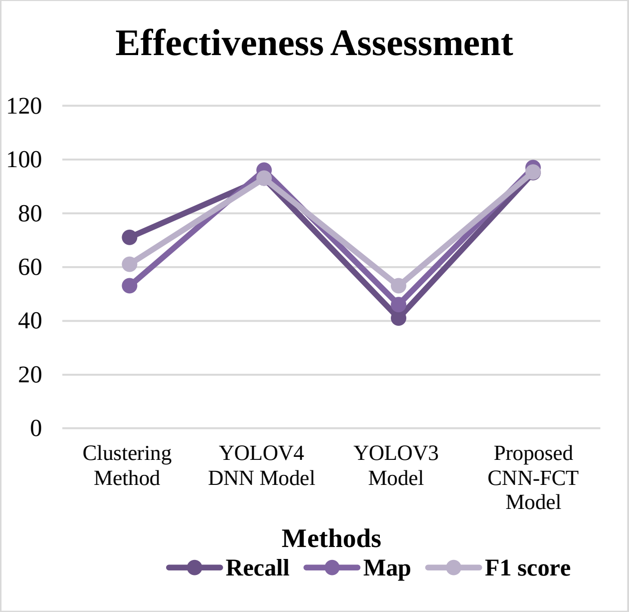

Fig. 7. Effectiveness assessment of Recall, mAP and F1-Score.

Table II makes the assessment among the existing methods recall, mAP and F1 score with the proposed CNN-FCT method. The proposed model produces greater recall, mAP and F1 score points and Fig. 7 depicts the comparison graph of the existing methods recall, mAP and F1 score with the proposed CNN-FCT method.

Other metrics like RMSE and PSNR also takes place and the below Table III shows the assessment table of it and Fig. 8 shows the comparison graph of the existing methods RMSE and PSNR with the proposed CNN-FCT method.

TABLE. III COMPARISON TABLE OF RMSE AND PSNR

Method	RMSE	PSNR
CNN Method [26]	24.09	30.38
OTSU Algorithm [27]	43.18	29.16
Proposed CNN-FCT Model	18.25	35.72

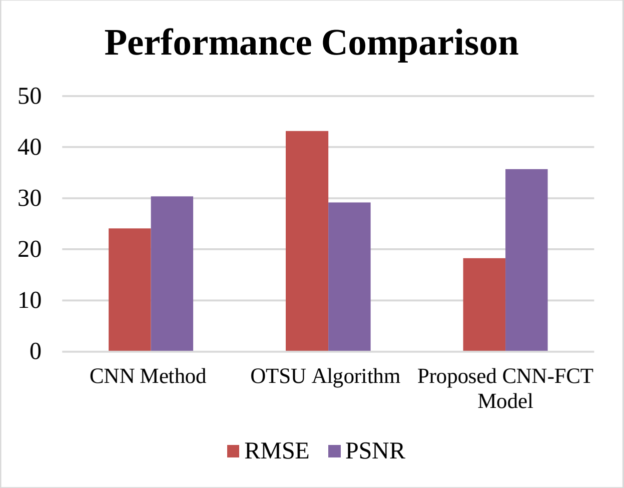

Fig. 8. Comparison graph of RMSE and PSNR.

The phrase fitness improvement over iteration in this context refers to the detection method's use of an optimization iteration procedure that enhances the precision and effectiveness of various item monitoring. A Convolutional Neural Network (CNN) model, which serves as an extractor of features for representing the objects in the video frames, is at the core of the approach. The CNN algorithm extracts the object's features after estimating the object's location in the initial frame during the tracking procedure. The predicted location of the first frame might not be completely precise, leading to a less-than-ideal initial solution. The Kalman Filter and PSO algorithm are used to modify the object's projected position at every iteration, and the fitness metric is calculated as well. This fitness statistic measures how closely the predicted position of the object matches the actual or intended position. Fig. 9 shows the fitness improvement graph.

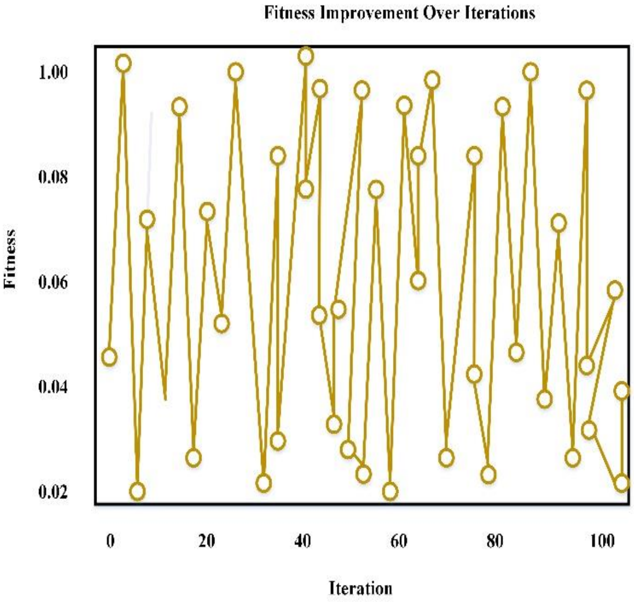

Fig. 9. Fitness improvement over iteration graph.

The graph contrasting the efficacy of a model with and without Accuracy, Recall, mAP (mean Average Precision), and F1 score optimization offers insightful information about the importance of focused improvement in particular machine learning tasks. The algorithm undergoes training in the with optimization case primarily deals with the goal of enhancing The key performance indicators for applications like object identification and classification are accuracy, recall, mAP, and F1 score. The graph shows a stronger upward trend as a result of the model's constant fine-tuning to maximize these metrics. When there is no optimization, the algorithm is trained without giving these metrics any special consideration, which results in more or less noticeable improvements in Accuracy, Recall, mAP, and F1 score. The graphs of accuracy, recall, mAP, and F1 score with and without optimization are displayed in Fig. 10.

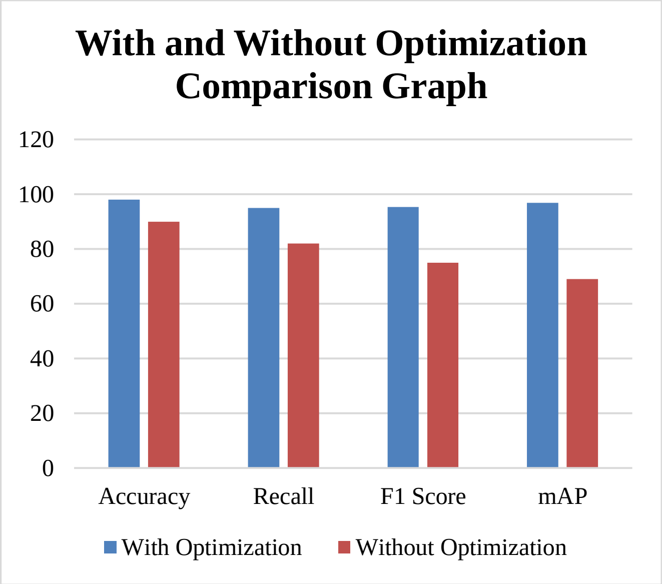

Fig. 10. With and without optimization comparison graph of accuracy, Recall, mAP, F1 score.

C. Discussion

In order to improve object tracking, the research article suggests a Fast Compressive Tracking approach based on Convolutional Neural Network (CNN) models. The CNN model is fed two sets of the dimensionally decreased object characteristics using this method. The CNN algorithm analyses the input frames via consecutive layers of the CNN model, removing the salient characteristics from the input frames. The Particle Swarm Optimization (PSO) technique is used by the CNN model's output coating to record the positions of the monitored targeted image features. The intended image is then classified using a Support Vector Machine (SVM) classifier based on the monitored positions. Here, the planned CNN based fast visual tracking architecture is depicted in Fig. 1. The Multi Object FCT algorithm is given in Algorithm 1. CNN based Tracking algorithm is given in Algorithm 2. Then, PSO algorithm for fast visual tracking object is given in Algorithm 3. In the results section, the detection people in a shopping mall in highly occluded condition are depicted in Fig. 2(a) – (d). The video sample consists of 30 Frames Per Second (FPS), with 75 tracks and 12389 detection boxes. From Fig. 2(a) and (b) researchers can show that, the proposed methodology was able to track and detect people whose motion is unpredictable. Then, Fig. 2(c) and (d) it can discover that, the man in blue shirt has completely occluded a small boy whose shoes are only visible in the fig. 2(c). Fig. 2(d), shows the boy is easily detected by the proposed methodology from which researchers can give assurance that the novel methodology is capable of detecting objects even in complete occlusion. Fig. 3(a), 3(b) and 3(c) depicts the example of sudden appearance and disappearance of the target object. This sample video comprises of 30 FPS, with 83 tracks and 47557 detection boxes. After that, Table I makes a comparison between the existing multi-objects tracking to that of the proposed methodology. The comparison was made taking 2 datasets which was used as sample video sequences for the experimental purpose namely, shopping mall dataset and busy street dataset. Fig. 5 depicts the MOT accuracy between CNN-FCT and M-FCT, whereas Fig. 6 depicts the Most Tracked and Most Least measures of the proposed and existing methodologies. Table II makes the comparison between the existing methods recall, mAP and F1 score with the proposed CNN-FCT method. The proposed model produces greater recall, mAP and F1 score points and Fig. 7 depicts the comparison graph of the existing methods recall, mAP and F1 score with the proposed CNN-FCT method. Table III displays the assessment table of it and Fig. 8 displays the assessment graph of the existing methods RMSE and PSNR with the planned CNN-FCT method [26] [27]. Fig. 9 shows the fitness improvement graph and it is used to determine a performance achievement's advantages or flaws. Fig. 10 shows the with and without optimization graph of Accuracy, Recall, mAP and F1 score because it is important to remember that these conclusions are hypothetical considering the limited facts at hand [23] [24] [25].

Compared to previous multi-object identification techniques, the CNN-FCT Methodology works well because it addresses these drawbacks. Real-time tracking may be difficult for traditional methods, particularly in situations where there is occlusion or abrupt object movements. In order to overcome these drawbacks, the CNN-FCT Methodology incorporates Kalman Filtering, FCT, CNN, and PSO. This results in improved accuracy, flexibility, and resilience while dealing with changing environmental circumstances. As a promising development in the realm of multi-object identification, the methodology stands out for its capacity to tackle a variety of obstacles.

The proposed CNN-FCT technology in addition to displaying the experimental results and performance metrics. The theoretical advances and computing efficiency attained by the optimization processes have immediate real-world applications in object tracking scenarios such as surveillance systems, traffic monitoring, and human activity analysis. Because of the durability exhibited in dealing with hard conditions such as occlusion and the unexpected appearance/disappearance of objects, this technology is particularly helpful for practical application in dynamic contexts. Enhanced measures such as accuracy, recall, mAP, and F1 score directly contribute to improving the dependability and efficacy of object tracking systems across multiple domains. The proposed methodology shows itself as a viable tool for real-world applications by stressing these practical consequences, addressing the demand for improved and efficient object tracking systems.

VI. Conclusion and Future Work

The combined strategy of using Particle Swarm Optimization (PSO), Kalman Filtering, Convolutional Neural Networks (CNNs), and Compressive Sensing has shown to be very successful in addressing the difficulties involved in multi-object tracking and identification in dynamic environments. By using CNNs for accurate object recognition, compressive sensing for well-tuned representations, Kalman Filtering for flexibility, and PSO for the best forecasting accuracy, this synergistic system performs better than individual techniques. The joint application of these methods showed excellent tracking performance under difficult conditions, such as complex motion patterns, occlusions, and visual discrepancies. This suggested methodology has notable practical benefits. With a tracking accuracy of 98%, the system demonstrates its potential for practical use, especially in fields that demand advanced multi-object recognition and tracking. In addition to advancing computer vision, the study establishes a strong basis for further advancements in multi-object tracking systems. It is important to recognize some restrictions, though. Real-time monitoring in resource-constrained contexts requires further optimization of the computational efficiency of the program. Investigating transfer learning and domain adaptation can improve the system's generalization in a variety of tracking environments. Three-dimensional object tracking would benefit from the addition of depth information, and more research is necessary to determine how robust the method is against inclement weather and abrupt changes in illumination. Future work can concentrate on optimizing the methodology for real-time application, increasing scalability to support a larger number of objects and a wider range of surroundings, and combining it with creative algorithms. The above efforts would certainly improve the capabilities of the methodology and increase its application across many areas. To sum up, our research offers significant understandings of the theoretical and practical aspects of multi-object tracking systems, opening new avenues for further investigation and development in computer vision. The suggested CNN-FCT methodology performs well in a variety of settings, but it is important to recognize its possible advantages as well as its limitations with regard to different kinds of data. To further improve adaptability and meet the particular obstacles presented by various circumstances, future study could investigate algorithm adaptations or parameter tailoring for certain data kinds.

Comparative Analysis of Weighted Ensemble and Majority Voting Algorithms for Intrusion Detection in OpenStack Cloud Environments

Pravin Patil, Geetanjali Kale, Nidhi Bivalkar, Agneya Kolhatkar
Department of Computer Engineering, Pune Institute of Computer Technology, Pune, Maharashtra, India

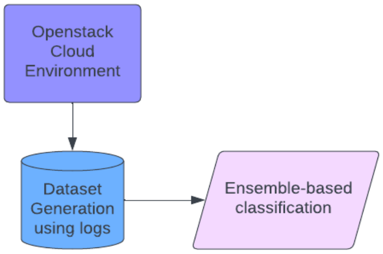
Abstract—**In the ever-evolving landscape of cybersecurity, the detection of malicious activities within cloud environments remains a critical challenge. This research aims to compare the effectiveness of two ensemble algorithms, the weighted ensemble algorithm and the majority voting algorithm, in the context of intrusion detection within an OpenStack cloud environment. To conduct this study, a dataset was generated using a network of 10 virtual machines, simulating the complex dynamics of a real cloud infrastructure. Various attack scenarios were simulated, and system metrics including CPU usage, memory utilization, and network traffic were monitored and logged. The weighted ensemble algorithm combines the predictions of multiple individual models with varying weights, while the majority voting algorithm aggregates predictions from multiple models. Through a rigorous experimental setup, these algorithms were applied to the generated dataset, and their performance was evaluated using standard metrics such as accuracy, precision, recall, and F1-score. These findings provide valuable insights into the strengths and weaknesses of ensemble algorithms for intrusion detection in cloud environments. It highlights the importance of selecting appropriate algorithms based on specific security requirements and threat profiles. Different attack scenarios may require different algorithmic approaches to achieve optimal results. Overall, this study contributes to the understanding of ensemble techniques in cloud security and offers a foundation for further research in optimizing intrusion detection strategies within dynamic and complex cloud environments. By identifying the strengths and weaknesses of different ensemble algorithms, cybersecurity professionals can make informed decisions in selecting the most suitable approach to enhance the security of cloud environments.**

Keywords*—*Intrusion detection; ensemble algorithms; cloud security; openstack; weighted ensemble; majority voting

I. Introduction

The advancement of computing has ushered in transformative technologies, with cloud environments being at the forefront. These digital ecosystems offer unparalleled convenience, scalability, and connectivity, fundamentally reshaping the storage and processing of data. However, along with these advantages comes the pressing challenge of securing data within interconnected cloud systems. These systems, while efficient, create pathways for a diverse range of cyber threats that require robust and adaptable intrusion detection mechanisms. In the pursuit of fortifying cloud security, traditional intrusion detection approaches have played a crucial role [1], [3]. Nevertheless, these methodologies face limitations as attackers continuously evolve their tactics. Rule-based systems prescribe inflexible attack patterns, signature detection relies on pre-identified attack signatures, and anomaly detection, while effective against new attacks, often yields high false positive rates. To overcome these limitations, the integration of ensemble techniques into intrusion detection systems (IDS) has emerged as a promising strategy. Ensembles amalgamate the insights of multiple models to enhance accuracy and robustness, enabling systems to adapt to evolving attack strategies. Within the realm of ensembles, two methods stand out prominently: the weighted ensemble and the majority voting algorithms.

This research embarks on a comprehensive exploration of these two algorithms within the dynamic framework of OpenStack cloud environments. OpenStack, renowned as an open-source cloud platform, provides an intricate architecture and susceptibility to real-world cyber threats, making it an ideal evaluation ground for ensemble techniques. At the heart of our investigation lies the question of which ensemble algorithm, between the weighted ensemble and majority voting, demonstrates superior performance in the field of intrusion detection within OpenStack environments. To address this question, our methodology involves meticulously simulating a wide range of attack scenarios within the OpenStack ecosystem. By creating a synthetic environment consisting of virtual machines that mimic the complexities of cloud ecosystems, we subject our algorithms to various cyber-attacks. This deliberate diversification encompasses different tactics and vectors, resulting in a comprehensive evaluation of the algorithms' resilience and adaptability. Furthermore, during these simulations, we diligently record and analyze intricate system metrics. This detailed dataset sheds light on how the algorithms behave under dynamic attack conditions, enhancing our understanding of their effectiveness and response. In essence, the main contribution of this research lies in the empirical evaluation of the weighted ensemble and majority voting algorithms. Through rigorous experimentation and thorough analysis of the results, we uncover valuable insights into their operational dynamics, strengths, and limitations. Additionally, our findings have practical implications for the real-world deployment of these algorithms within intrusion detection systems. Fig. 1 gives an overall research workflow.



Openstack Cloud Environment
Dataset Generation using logs
Ensemble-based classification

Fig. 1. Workflow.

This research paper unfolds in several sequential sections following the introduction. The Related Work section delves into existing intrusion detection systems, thereby establishing the groundwork for ensemble techniques. Following this, the Data Collection section provides an in-depth account of the creation of a synthetic dataset, designed to simulate a wide range of cyber-attacks within an OpenStack environment. Subsequently, in the Classification Algorithms section, ten different supervised learning models are introduced, serving as the foundation for subsequent evaluations of ensemble techniques. The obtained results yield a comprehensive performance analysis, comparing various metrics such as accuracy, precision, recall, and F1 score and further implications of those results are discussed. Finally, the Conclusion synthesizes the findings, highlighting the strengths of the research and proposing potential avenues for future investigations.

II. Related Work

The continuous pursuit of enhancing intrusion detection systems has propelled researchers to explore a diverse range of methodologies. Traditional approaches encompass rule-based systems, signature detection, and anomaly detection. Rule-based systems prescribe static attack patterns, yet struggle to accommodate the dynamic nature of evolving attack strategies.

Signature detection relies on predefined attack signatures, rendering it ineffective against novel attacks that evade established patterns [1], [4]. Wie et al. and W. Hu et al. used the AdaBoost Classifier for a Network IDS [5], [6]. A. Rai et al. designed optimized IDS using deep neural networks and the GradientBoost Classifier [7].

Ensemble methods leverage the collective insights of multiple models to enhance accuracy and resilience, enabling systems to adapt to emerging attack tactics. Notably, the weighted ensemble and majority voting algorithms have emerged as formidable contenders within the realm of ensemble-based intrusion detection. The weighted ensemble algorithm hinges on the principle of model weighting, dynamically assigning importance to individual model predictions [8]. This adaptability empowers the algorithm to excel across diverse attack scenarios, optimally adjusting the influence of each model based on its performance characteristics.

Conversely, the majority voting algorithm capitalizes on the synthesis of predictions from multiple models [9]. By establishing a consensus among models, this approach fosters robustness, mitigating the impact of errors arising from individual models. Several studies have explored the applications of ensemble techniques for intrusion detection [8], [2] [10], [9], [11], [12].

There has also been significant research on the applications of these classifiers on multi-tenant systems [8], [9]. While these previous studies have enriched the discourse on ensemble-based intrusion detection, the comparative assessment of the weighted ensemble and majority voting algorithms remains a relatively unexplored area, particularly within the dynamic context of OpenStack cloud environments [4]. It is within this realm that our research finds its foundation, systematically evaluating the performance of these algorithms in a relevant cloud security landscape. Previous studies have shed light on the potential of ensemble techniques. However, these studies often lack a comprehensive analysis of the strengths and weaknesses of the algorithms. The specific limitations of each method, particularly within the OpenStack environment, have not been thoroughly addressed. To bridge this gap, our research undertakes an extensive comparative analysis of the weighted ensemble and majority voting algorithms. By subjecting these algorithms to attack scenarios within OpenStack cloud environments, we aim to discern their nuanced responses and understand their operational dynamics in the face of complex threats. Through this exploration, our study strives to offer practical insights into the adaptability and effectiveness of these algorithms, enabling informed decision-making for intrusion detection in multi-tenant distributed systems.

III. Data Collection

The research methodology encompasses a seamless continuum from data collection to model training. System metrics are meticulously collected from a simulated OpenStack cloud, replicating real-world dynamics during attacks. The raw data undergoes thorough preprocessing, including cleaning and feature engineering, transforming the metrics into meaningful attributes for insightful analysis. The refined dataset is used to train weighted ensemble and majority voting models. The models undergo iterative adjustments and fine-tuning to optimize their intrusion detection capabilities. This integrated process establishes a robust evaluation framework for ensemble algorithms within the intricate context of OpenStack cloud scenarios.

A. *Dataset Generation*

In our pursuit of conducting a comprehensive evaluation, we systematically undertook the task of creating a virtual cloud environment utilizing the OpenStack framework. This task utilized the computational resources of two laptops, one with 8GB of RAM and the other with a substantial 32GB. Within this setup, we deployed ten strategically distributed virtual machines (VMs) across the laptops, each serving as a control node or a compute node. These roles mirrored the dynamics of a real-world cloud ecosystem and facilitated a highly realistic evaluation [13]. To further enhance the realism of our evaluation, we simulated cyber-attacks on this virtual cloud environment, with a focus on the control node, a vital component of the cloud infrastructure. The attacks encompassed a wide range of threats, including Cross-Site Request Forgery (CSRF), XML External Entity (XXE) Injection, Brute Force, Cross-Site Scripting (XSS), Open Redirect, Directory Traversal, SQL Injection, Command Injection, and Remote Code Execution. Each attack category had the potential to impact various critical parameters within the cloud environment. Each attack category had distinct implications for the cloud environment, leading to specific performance metrics. Each attack category had the potential to influence these system performance metrics, resulting in nuanced impacts on the operational landscape of the cloud environment.

1) CSRF could compromise data integrity and disrupt user interactions, potentially affecting transaction success rates and request latencies [14].

2) XEE could impact system behaviour and data confidentiality, potentially influencing system response times and memory utilization [15].

3) Brute Force attacks on authentication mechanisms could have system-wide consequences, impacting authentication failure rates and overall system availability.

4) XSS could undermine user interactions and data integrity, posing threats to user session durations and engagement metrics.

5) Open Redirect vulnerabilities could impact user navigation experiences, potentially affecting click-through rates and user satisfaction levels.

6) Directory Traversal exploits could influence file access rates and disk I/O operations.

7) SQL Injection could jeopardize data confidentiality and system availability, influencing query execution times and database throughput.

8) Command Injection could manipulate system commands, potentially affecting CPU usage and system response times.

9) Remote Code Execution posed severe risks to system integrity and availability, potentially impacting memory usage and network traffic rates.

The execution of these attacks was randomized to ensure a diverse range of threat scenarios. To capture the dynamics of the cloud environment during attacks, we utilized the Netdata REST API service to collect real-time system metrics. These metrics were meticulously organised into a structured CSV format for subsequent analysis. The extent of our evaluation is evident in the execution of a total of 10,000 attack instances, showcasing the rigorous and dedicated nature of our study. This comprehensive exploration serves as a robust foundation for analyzing the performance of ensemble algorithms in real-world scenarios.

The distribution of attack and non-attack instances is clearly shown in Table I.

The dataset utilized in this study comprises a diverse range of system metrics and attributes collected from a simulated OpenStack cloud environment. With a total of 63 distinct parameters, each column represents a specific system parameter or feature [16]. These parameters encompass various measurements related to CPU utilization, memory consumption, disk activity, network behaviour, process behaviour, firewall activity, and more. Each row in the dataset corresponds to a specific time instance during simulated attack scenarios. A value of 1 or 0 is assigned to categorise the instances, where 1 denotes an attack instance and 0 represents a non-attack instance. For attack instances, an additional column specifies the type of attack executed, providing valuable insights into the nature of each attack scenario.

TABLE I. DATASET DISTRIBUTION

Attack Instances	10000
Non-attack instances	90000
Total instances	100000

B. *Oversampling and Undersampling*

The ratio of attack to non-attack instances is 1:9 causing the dataset to be slightly imbalanced. To improve the performance of classification algorithms, we employed two essential techniques: Synthetic Minority Over-sampling Technique (SMOTE) and Random Under-sampling. SMOTE generates synthetic instances for the minority class by interpolating existing instances, effectively balancing class proportions [17]. This technique mitigates the risk of the model favouring the majority class due to its higher representation. Conversely, Random Under-sampling reduces the majority of class instances randomly, aligning class distributions [18]. By employing SMOTE and Random Under-sampling, we aimed to strike a harmonious balance between class representations, enabling the models to train on a more equitable dataset.

IV. CLASSIFICATION ALGORITHMS

The dataset is split into training and testing data in a ratio of 1:4. 10 different supervised learning algorithms are trained on this data comprising 17998 non-attack instances and 2002 attack instances.

A. *Supervised Classification Algorithms*

1) Logistic regression: Logistic Regression is a linear classifier that estimates instance probabilities by identifying an optimal hyperplane separating different class data points. It is particularly essential when assuming a linear relationship between input features and the outcome.

2) Support Vector Machine (SVM): Support Vector Machine aims to find the hyperplane that maximizes the margin between data points of different classes, thereby enhancing the separation between classes. SVM is particularly effective in handling complex datasets and can handle non-linear decision boundaries through kernel transformations.

3) k-Nearest Neighbours (KNN): KNN is a powerful instance-based classification algorithm that focuses on the local neighbourhood of data points. It assigns a class label to a new instance based on the majority class of its k closest neighbours. This algorithm is beneficial for capturing the local characteristics of data, making it effective for tasks with irregular data distributions and localized patterns.

4) Random forest: Random Forest is a versatile ensemble learning technique that addresses overfitting and improves predictive performance. It constructs multiple decision trees during training and combines their outputs to make predictions. By doing so, it mitigates the risk of overfitting associated with individual decision trees and provides robust results across a variety of datasets.

5) Gradient boosting: Gradient Boosting is a powerful ensemble algorithm that constructs a strong predictive model by iteratively improving upon the errors of previous iterations. It sequentially builds a series of weak learners, often decision trees, and places emphasis on instances that were misclassified earlier. This approach is particularly advantageous for capturing complex relationships and delivering high predictive accuracy.

6) Adaptive Boosting (AdaBoost): AdaBoost is a boosting algorithm that iteratively trains weak learners and combines them into a robust ensemble model. What makes AdaBoost instrumental is its ability to adapt to difficult instances by assigning higher weights to misclassified instances in the previous iteration. This adaptability enhances the model's performance and is particularly beneficial when dealing with imbalanced class distributions [5].

7) Naive bayes: Naive Bayes is a probabilistic classification algorithm that makes an instrumental simplifying assumption: feature independence given the class. Despite this assumption, it's highly efficient, making it suitable for large datasets. Naive Bayes excels in text classification and tasks where the independence assumption approximately holds, showcasing its instrumental role in such contexts.

8) Decision tree: Decision Trees are simple yet effective models that recursively partition data based on feature attributes. They're instrumental in understanding the hierarchy of decisions within a model. However, they're prone to overfitting, which can be mitigated through ensemble methods like Random Forest or Gradient Boosting, making them an essential foundational element in machine learning.

9) Multi-Layer Perceptron (MLP): Multi-Layer Perceptron is an instrumental neural network architecture composed of multiple layers of interconnected neurons. Its ability to capture complex patterns in data makes it highly versatile across various domains. However, its instrumental application requires thoughtful architecture design and hyperparameter tuning to prevent overfitting and ensure effective learning [19].

10)XGBoost: XGBoost is an advanced gradient boosting library instrumental for improved model performance. It incorporates regularization techniques, optimized tree pruning, and effective handling of missing data [20]. XGBoost's instrumental role lies in its capability to provide robust results with minimal overfitting, making it a go-to choice for boosting-based ensemble methods.

All classification algorithms have been trained on the same data with default parameters. The data has been scaled using the standard scaler. The decision function shape for the SVM algorithm is One-vs-Rest by default and max iterations for Logistic Regression have been set to 1000 to account for the size of the dataset. Now let us explore the two ensemble-based classification algorithms in consideration for this comparative analysis.

B. Ensemble-based Classification Algorithms

1) Weighted ensemble classifier: A weighted ensemble classifier is a machine learning technique that combines the predictions of multiple base classifiers, each with its own assigned weight (see Fig. 2). The weights reflect the strengths and weaknesses of each base classifier, and they determine the contribution of each classifier's prediction to the final ensemble prediction. By giving more weight to the predictions of more accurate or reliable classifiers, and less weight to those of less accurate ones, the weighted ensemble aims to improve the overall performance of the ensemble. The weights of the classifiers were decided using cross-validation f1 scores and came out to be in the range of 0.0872 for KNN to 0.1049 for AdaBoost.

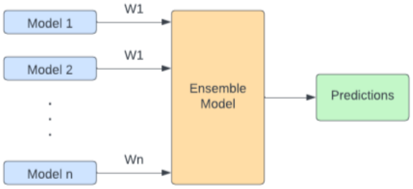


Fig. 2. Weighted ensemble classifier.

2) Majority voting ensemble classifier: The Majority Voting ensemble method is a powerful technique used to enhance the accuracy and robustness of machine learning models [9]. It involves combining the predictions of multiple individual models to make a final prediction. In Majority Voting, each model's prediction is considered a "vote" for a specific class label. The class label that receives the most votes becomes the ensemble's final prediction. This method leverages the wisdom of the crowd by aggregating the predictions of multiple models, which can lead to more accurate and reliable results. Fig. 3 diagrammatically shows its working. One of the key advantages of Majority Voting is its ability to reduce variance and errors. Even if some individual models make incorrect predictions, the ensemble can still provide accurate results if the majority of the models are correct. In cases where there is a tie in the votes, various strategies can be employed to handle it.

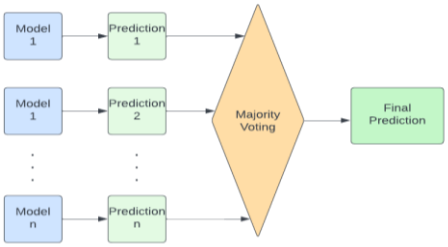

Fig. 3. Majority voting classifier.

V. Results and Discussion

In this section, we will conduct a detailed examination of the Weighted Ensemble and Majority Voting algorithms, specifically in the context of identifying potential attacks within OpenStack cloud configurations and being able to extend them to broader multi-tenant environments in the future. We will evaluate the effectiveness of these algorithms using various metrics such as accuracy, F1 score, precision, recall, and confusion matrices. By analyzing these metrics, we aim to gain insights into how well these algorithms distinguish between attack and non-attack instances in an OpenStack cloud environment. Furthermore, this section also discusses the reasoning behind choosing Majority Voting and Weighted Ensemble as the two algorithms in this comparison.

A. Performance Metrics

1) Confusion matrix: A confusion matrix provides a detailed breakdown of a model's predictions by comparing them against actual class labels. It includes four metrics: true positives (TP), true negatives (TN), false positives (FP), and false negatives (FN). True positives represent the instances that were correctly predicted as positive by the model, while true negatives represent the instances that were correctly predicted as negative. False positives are instances incorrectly predicted as positive, and false negatives are those incorrectly predicted as negative. From these metrics, other evaluation metrics can be derived.

2) Accuracy: Accuracy is the ratio of correctly predicted instances to the total instances in a dataset, offering an overall performance assessment across all classes, particularly effective for balanced datasets. Nevertheless, in imbalanced class scenarios, accuracy might be skewed by the majority class. In such cases, metrics like precision, recall, and F1 score offer deeper insights into performance, particularly for identifying attacks in intricate multi-tenant setups.

$$Accuracy = \frac{(TP + TN)}{(TP + TN + FP + FN)} \tag{1}$$

3) Precision: Precision evaluates the proportion of true positive predictions out of all positive predictions made by the model (see Eq. (2)). It is an important metric when the cost of false positives is high, as it indicates how trustworthy the positive predictions are. A high precision value indicates a low rate of false alarms.

$$Precision = \frac{TP}{(TP + FP)} \tag{2}$$

4) Recall: Recall calculates the proportion of true positive predictions from all actual positive instances in the dataset. It is valuable when the cost of false negatives is high, as it measures how effectively the model captures all actual positives. A high recall value indicates that the model is good at identifying positives. However, a high recall value may come at the cost of more false positives.

$$Recall = \frac{TP}{(TP + FN)} \tag{3}$$

5) F1 Score: The F1 score is a balanced metric that takes into account both precision and recall. It is particularly valuable when the dataset is imbalanced and there is a need to consider false positives and false negatives. The F1 score is calculated as the harmonic mean of precision and recall, helping to strike a balance between them and providing a more comprehensive assessment of a model's performance.

$$F1\ Score = 2 \times \frac{(Precision \times Recall)}{(Precision + Recall)} \tag{4}$$

B. Performance

The performance results obtained from the Weighted Ensemble and Majority Voting classifiers based on the above performance five metrics are given in Table II.

The Weighted Ensemble Classifier holds a slight performance edge over the Majority Voting Classifier in accuracy, recall, and F1 score. Although the latter has higher precision, the difference between the two precision values is not as significant as that of the two recall values. It is also noteworthy that the Majority Voting Classifier incurred an extra 1161-second runtime compared to the Weighted Ensemble. Consequently, the Weighted Ensemble Classifier emerges as the more efficient and effective choice overall.

Table III and Table IV show the confusion matrices of both classifiers for a more in-depth review of the results.

TABLE II. Results

Algorithms	**Performance Metrics**			
	Accuracy	**Precision**	**Recall**	**F1 Score**
Weighted Ensemble	0.9942	0.9876	0.9535	0.9703
Majority Voting	0.9926	0.9920	0.9336	0.9619

TABLE III. Confusion Matrix for Weighted Ensemble

Weighted Ensemble	**Actual**		
	20000 logs	**Non-attack**	**Attack**
Prediction	**Non-attack**	17974	24
	Attack	93	1909

TABLE IV. Confusion Matrix for Majority Voting

Majority Voting	**Actual**		
	20000 logs	**Non-attack**	**Attack**
Prediction	**Non-attack**	17983	15
	Attack	133	1869

TABLE V. F1 Scores after Oversampling

Algorithm with oversampling	**F1 Score**
Weighted Ensemble	0.9711
Majority Voting	**0.9702**

From these matrices, one can see that the two algorithms performed very similarly. The Weighted Ensemble could classify more attack instances correctly whereas the Majority Voting Classifier could classify more non-attack instances correctly. The Weighted Ensemble does have one disadvantage which is that it requires the calculation of weights as an extra step before the classification process. Furthermore, we have also extracted performance results after using SMOTE and RandomUndersampler on the data to get a balanced dataset [17], [18].

Table V clearly shows that oversampling reduced the performance gap between the two algorithms but the Weighted Ensemble still has slightly higher performance. Add to this, the fact that the Weighted Ensemble did not require the extra pre-processing step of Oversampling and Undersampling.

C. Discussion

Now, we delve into the evaluation of classification algorithms, and their comparison with Weighted Ensemble and Majority Voting with a particular emphasis on the stability of predictions. To simulate scenarios involving unseen data, random test-train dataset splits are utilized. A key metric used to assess the consistency of algorithmic performance is the standard deviation of F1 scores for each split.

Notably, the KNN algorithm stands out as it exhibits the lowest standard deviation (see Fig. 4), demonstrating a remarkable level of consistency across diverse dataset splits. However, its performance pales in comparison to other algorithms as shown in Fig. 5. From Fig. 4 it is evident that both the Weighted Ensemble and Majority Voting techniques prove to be the strongest contenders, displaying low standard deviations and highlighting their stability. One could argue that the Random Forest algorithm displays similar levels of stability but Fig. 5 clearly shows the lower F1 score as compared to Majority Voting and Weighted Ensemble.

This discussion provides valuable insights into the realm of intrusion detection algorithms. These algorithms carry the dual responsibility of accurately classifying threats while avoiding the pitfall of overfitting specific threat types.

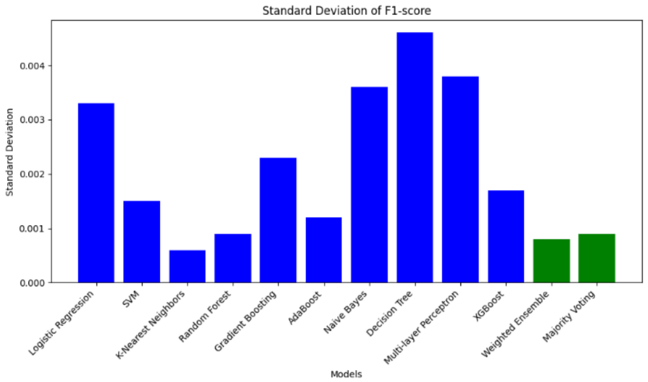

Fig. 4. Standard deviation of f1 scores of algorithms.

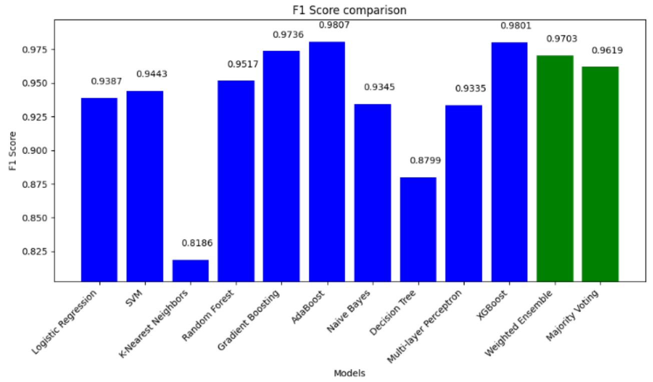

Fig. 5. Comparison of f1 scores of algorithms.

VI. Conclusion

Thus, we comprehensively compared the Weighted Ensemble and Majority Voting algorithms for intrusion detection in OpenStack cloud environments. Our analysis aimed to assess their ability to identify attacks and non-attacks and their real-world applicability. Through extensive evaluation, both algorithms demonstrated strong performance in distinguishing between attack and non-attack instances, highlighting their effectiveness as ensemble-based intrusion detection methods. While the Weighted Ensemble algorithm showcased a slight edge in terms of accuracy, recall, and F1 score, it is important to note that both algorithms demonstrated comparable performance. Additionally, the runtime analysis revealed that the Weighted Ensemble algorithm exhibited faster processing times compared to the Majority Voting algorithm, highlighting its potential efficiency advantage during real-time intrusion detection scenarios. However, it is essential to consider that real-time performance is influenced by various dynamic factors specific to the operational environment. Although one outperforms the other, both these algorithms display high performance along with stability which underscores their resilience in addressing challenges posed by unseen security threats.

Our study contributes to the ongoing discourse on enhancing cybersecurity within multi-tenant cloud environments. The findings underscore the role of ensemble techniques as valuable tools for bolstering intrusion detection capabilities. As the landscape of cyber threats evolves, future research could explore further optimizations and extensions to ensemble algorithms, aiming to refine their performance in real-world cloud environments. In conclusion, our investigation advances the understanding of ensemble-based intrusion detection, facilitating more informed decisions for ensuring the security and resilience of cloud infrastructures.

Rural Homestay Spatial Planning and Design Based on Bert BiLSTM EIC Algorithm in the Background of Digital Ecology

Zhibin Qiu, Junghoon Mok*
Department of Space Design, Hanseo University,
Seosan 31962, Korea

***Abstract*—There is a promising development prospect in the digital ecosystem. In this context, the spatial planning of rural homestays has also received widespread attention. The research aims to better explore the advantages and determine the development direction of rural homestays, while providing two-way demand support for consumers and managers. Therefore, this study combines bidirectional long-term and short-term memory networks, pre-trained models, and emotional information attention mechanisms in deep learning. A new emotional analysis model is proposed. Then it is applied to the spatial planning of homestays near Chengdu Normal University and Chengdu Neusoft University. The experimental results show that the accuracy, recall, and F1 values of the new emotion analysis model proposed in this research reach 94%, 93%, and 94%, respectively. In terms of consumer satisfaction with the spatial location of homestays before and after the renovation, the average score of homestays near Chengdu Normal University increases by 21% compared to before the renovation. The average score of homestays near Chengdu Neusoft University increases by 40% compared to before the renovation. In summary, the new emotional analysis model proposed in this research has certain feasibility and effectiveness in the planning of rural homestay spatial location, providing new ideas for homestay spatial location planning.**

Keywords—Rural homestay; spatial planning; deep learning; emotional analysis; bidirectional long short term memory network

I. Introduction

As a key support project for the tourism industry, rural homestays have been consistently popular in recent years [1]. With the changing demand for tourism and vacation methods, the market size of the homestay industry is constantly expanding. The rise of new homestays has gradually replaced traditional farmhouses and inns [2]. Featured homestays are constantly emerging. For example, urban-rural integration and distinctive homestay planning meet personalized pursuits and experiences [3]. Abroad, homestay platforms such as Airbnb have established a huge network of accommodation resources worldwide. This specialized operational transformation further improves the quality and image of homestays [4]. In Japan, the homestay policy supports the transformation of private housing into homestays. But the operational safety and good environment of homestays need to be guaranteed [5]. However, there are currently many problems in the planning and design of homestay spaces in the Chinese market, such as unreasonable layout and inability to meet consumer needs. Inappropriate planning methods may cause a series of negative reactions.

In view of this, the research explores in the context of digital ecology and innovatively proposes the integration of Bidirectional Long ShortTerm Memory (BiLSTM), Natural Language Processing and specific elements of spatial planning. Meanwhile, considering the growth and change of the rural lodging industry, a lodging spatial location planning and design model is finally proposed. The aim is to solve the unreasonable spatial location planning in domestic homestays, provide effective advice and guidance for the spatial location planning and design of homestays, and promote the development of rural homestays. This study is divided into six sections. Section I is an introduction to the overall content. Section II outlines the related works. Section IV is about performance testing of rural homestay spatial planning model. Discussion and conclusion is given in Section V and Section VI respectively.

II. Related Works

BiLSTM is a deep learning algorithm that can effectively process sequence data. In recent years, this algorithm has achieved significant results in fields such as natural language processing and image recognition. Singla P et al. proposed an integrated model that combines wavelet transform with bidirectional long-term and short-term memory deep learning networks to predict solar irradiance at all levels within 24 hours. Wavelet transform decomposes the input time series data into different intrinsic model functions to extract its statistical features. To improve prediction accuracy, the sequences of intrinsic model functions are reduced through comprehensive experimental analysis. Wavelet decomposition components are merged. Next, each intrinsic model function subsequence is assigned a trained BiLSTM network for prediction. Finally, the predicted values of each subsequence reconstructed from the BiLSTM network are used to provide the final solar irradiance prediction at all levels. The research results indicate that the R2 value of the proposed model is 0.94. Compared to the benchmark model, prediction performance increases by 47% [6]. To predict the capacity of photovoltaic energy, Liu B et al. proposed a multi factor installed capacity prediction model based on bidirectional short-term memory grey correlation analysis. The solar photovoltaic installed capacity in China from 2020 to 2035 is predicted using this model. The research results indicate that the constructed model has high prediction accuracy. It can accurately predict China's solar photovoltaic installed capacity from 2020 to 2035, reaching 2833GW by 2035 [7]. Human activity recognition has become an important research field in human behavior analysis, human-computer interaction, and ubiquitous computing. To improve the accuracy of deep learning models in processing time series data, Challa S K et al. proposed a robust classification model for human activity recognition. This model combines convolutional neural networks and bidirectional long-term and short-term memory for design. The proposed multi branch CNN-BiLSTM network can automatically extract features from raw sensor data and minimize data preprocessing. CNN-BiLSTM can learn local features and long-term dependencies in sequence data, which helps improve the feature extraction process. The performance is evaluated using three benchmark datasets. It achieves accuracy of 96.05%, 96.37%, and 94.29% on these datasets, respectively. The experimental results show that the method combining multi-branch CNN-BiLSTM networks outperforms the other compared methods [8].

Spatial planning and design commonly referred to as "spatial design" or "spatial planning". It refers to the process of creating an indoor space that combines functionality and aesthetics in an orderly manner. Space planning and design is the allocation of appropriate functional areas for a specific environment, determining the layout and interaction of these areas. There are currently many related studies. Design space exploration provides intelligent adjustment methods for complex optimization parameters in modern advanced comprehensive space design tools. Due to the long hardware compilation time, advanced comprehensive parameter tuning is a time-consuming process. Gautier Q et al. utilized a design space exploration framework to address multiple conflicting optimization objectives and actively sought Pareto optimal solutions. The research results indicate that the adopted processing framework can achieve optimal spatial design faster. In addition, the design space exploration framework can also customize the regression model based on specific problems, thereby obtaining the model that best reflects the application design space [9]. Wu W et al. proposed a novel data-driven technology. This technology can automatically and efficiently generate floor plans for residential buildings with given boundaries. The proposed data-driven technology can mimic human spatial design processes. Firstly, the room position is determined, and then the wall position is determined, while adapting to the input building boundary. Finally, based on the spatial location of the building, a plan structure diagram is obtained. A large number of experimental results indicate that the proposed data-driven technology is effective. This technology can realistically simulate the floor plans of different floors of a building. In many cases, the floor plan generated by the research method is almost identical to the actual design plan [10].

In summary, many experts have completed a series of studies using BiLSTM, including various data prediction, action recognition, model optimization, etc [11]. For spatial planning and design problems, scholars often start with optimizing complex parameters in space. Various models are used to tune parameters to achieve the expected spatial optimization goals. For buildings like rural homestays, there is a lack of research on integrating deep learning models into the spatial planning and design of homestays. Therefore, based on the BiLSTM algorithm, an improved sentiment analysis model is proposed by combining the Bert model and emotional attention mechanism. The aim is to quickly and accurately understand customer evaluations and emotional tendencies for homestay operators, provide decision-making support, and promote the healthy development of the homestay industry.

III. Rural Homestay Spatial Planning based on Bert-BiLSTM-EIC Algorithm

There are still many problems in the current spatial planning and design of homestays, such as traffic positioning, location planning, and consumer preferences. In response to these issues, the first section constructs a new emotional analysis model through a bidirectional long-term and short-term memory network, Bert model, and emotional information attention mechanism. It effectively extracts relevant suggestions from consumers for the geographical location planning of homestays. The second section applies the model to the spatial planning of homestays near two universities, exploring the feasibility of this method.

A. Construction of a Homestay Sentiment Analysis Model Based on Bert-BiLSTM-EIC Algorithm

In recent years, the sentiment analysis method that combines Long Short Term Memory (LSTM) with deep learning has the highest popularity. LSTM updates the time record timing of cell structure through an additive calculation method, avoiding the time step feature retained when the previous state data has a significant impact on this state data, as shown in Fig. 1[12].

In Fig. 1, at time t, a value $f(t)$ between 0 and 1 is output through the internal states of $h(t-1)$ and $x(t)$, representing a trade-off between fully retained or discarded states. The activation function is the sigmoid function. The formula for the input gate is shown in Eq. (1).

$$i_t = \sigma\left(W_i \cdot x_t + U_i \cdot h_{t-1} + b_i\right) \qquad (1)$$

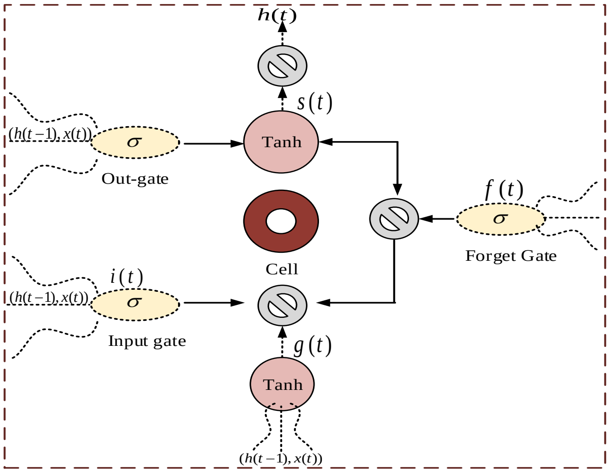

Fig. 1. LSTM network structure diagram.

In Eq. (1), i_t represents the output of the input gate. W_i and U_i represent the weight and bias of the input gate, h_{t-1} denotes the previous state. The input gate represents the information stored in $h(t-1)$ and $x(t)$ within the cell. The output gate is shown in Eq. (2).

$$o_t = \sigma\left(W_o \cdot x_t + U_o \cdot h_{t-1} + b_o\right) \quad (2)$$

In Eq. (2), x_t denotes the output data, σ denotes the sigmoid function. W_o and U_o denote the weight and bias of the output gate, respectively, and b_o denotes the learnable parameters. The information of the output gate is usually obtained by multiplying the result of the tanh activation function with $h(t-1)$ and $x(t)$ through the sigmoid activation function [13]. The forgetting gate is shown in Eq. (3).

$$f_t = \sigma\left(W_f \cdot x_t + U_f \cdot h_{t-1} + b_f\right) \quad (3)$$

In Eq. (3), f_t denotes the output of the forgetting gate, W_f and U_f denote the weight and bias of the forgetting gate, respectively, and b_f denotes the learnable parameter. The error function calculates the partial derivative of the weighted input of the neuron. The backpropagation error transmitted by time to the previous state is shown in Eq. (4).

$$\delta_k^T = \prod_{j-k}^{t-1} \delta_{o,t}, {}^T W_{oh} + \delta_{f,t}, {}^T W_{fh} + \delta_{i,t}, {}^T W_{ih} + \delta_{s,t}, {}^T W_{sh} \quad (4)$$

In Eq. (4), δ_k^T refers to the error of the objective function k with respect to T. W_{oh}, W_{fh}, W_{ih} and W_{sh} refer to the weights that go sequentially from unit o, f, i and s to unit h, respectively. $\delta_{o,t}$ refers to the error of the o th unit at the moment of t. $\delta_{f,t}$ refers to the error of the f th unit at the moment of t. $\delta_{i,t}$ refers to the error of the i th unit at the moment of t. $\delta_{s,t}$ denotes the error of the s th unit at the moment of t. The error formula for error propagation upwards is shown in Eq. (5).

$$\frac{\partial E}{\partial net_t^{l-1}} = (\delta_{o,t}{}^T W_{ox} + \delta_{f,t}{}^T W_{fx} + \delta_{i,t}{}^T W_{ix} + \delta_{s,t}{}^T W_{sx}) of\,'(net_t^{l-}1) \quad (5)$$

In Eq. (5), W_{ox}, W_{fx}, W_{ix} and W_{sx} refer to the weights from cell o, f, i and s to the formula cell x, respectively. The rest of the algebra is consistent with the previous explanation. However, due to the complexity and massive content of comments on homestays, relying on a single network model often leads to low efficiency and computational errors [14]. Therefore, BiLSTM with bidirectional channels is needed to process sequence data. On the basis of BiLSTM, Bert word embedding and EIC emotional information attention mechanism are introduced. The Bert-BiLSTM-EIC model is proposed. The structure diagram of the Bert-BiLSTM EIC model is shown in Fig. 2.

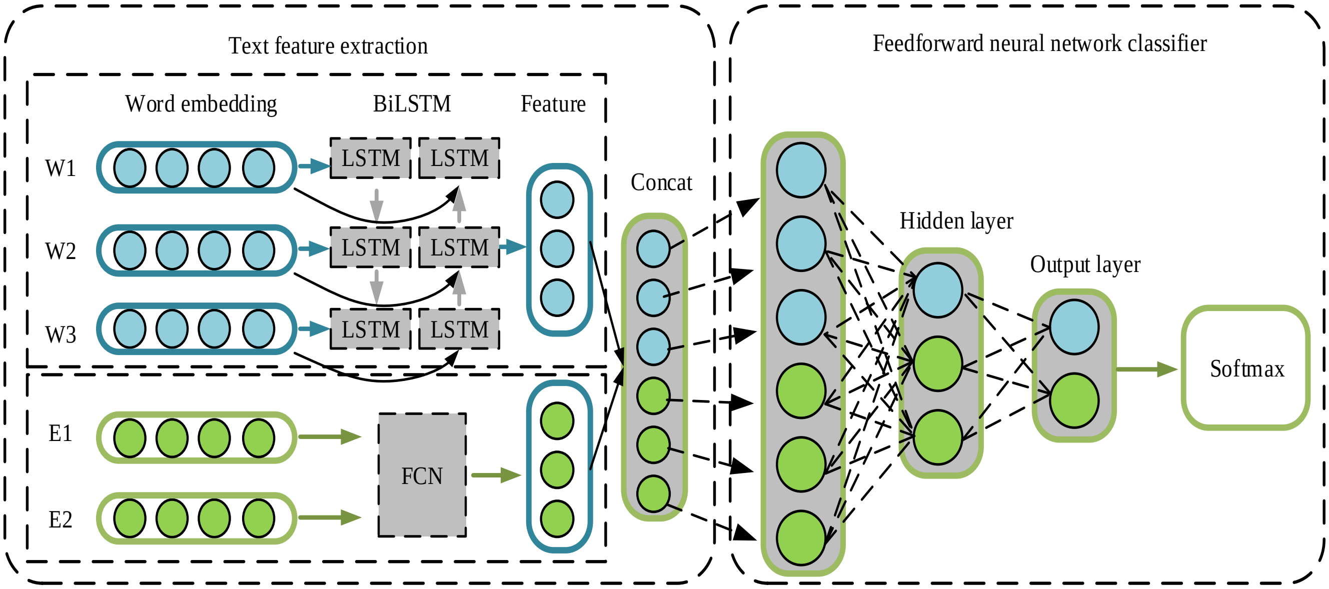

Fig. 2. Bert-BiLSTM-EIC network architecture diagram.

In Fig. 2, the Bert training model is used as the first stage. BiLSTM-EIC is used as the second stage. BiLSTM-EIC includes semantic information channels and emotional information channels. Firstly, Bert passes each input individual word through a Token embedding layer to convert each word segment into a fixed dimensional vector form. Secondly, BiLSTM-EIC extracts the emotional features of the statement, fuses the feature information and inputs it into the fully connected layer. Finally, softmax calculates the attribution probability. The Bert word embedding layer is shown in Eq. (6).

$$R_w = w_1 \oplus w_2 \oplus L \oplus w_n \tag{6}$$

In Eq. (6), R_w represents the input semantic word vector. w_1, w_2, w_3 represent different semantic participles. The word set after segmentation is used as input for the semantic channel. The Bert model obtains the semantic word input vector. The calculation of emotional channels is similar to the input of semantic channels. The calculation is shown in Eq. (7).

$$R_e = e_1 \oplus e_2 \oplus L \oplus e_m \tag{7}$$

In Eq. (7), R_e represents the input emotional information vector. e_1, e_2, e_3 represents different emotional participles. The semantic and emotional vectors are input into a network composed of forward and backward LSTM for sequence encoding to achieve information extraction and fusion, thereby improving the predictive ability of the model [15]. The calculation for model prediction is shown in Eq. (8).

$$pre = soft\max(w_o * V^{s+e} + b_o) \tag{8}$$

In Eq. (8), w_o represents the weight coefficient. pre represents the predicted emotional category. b_o represents the offset coefficient. V^{s+e} denotes the sentiment feature vector. The prediction accuracy of this model is shown in Eq. (9).

$$CV_{(k)} = \frac{1}{k}\sum_{i=1}^{k} P_i \tag{9}$$

In Eq. (9), k represents the number of datasets. i represents the combination method. P_i represents the accuracy indicator. The loss function of this model is shown in Eq. (10).

$$f_{loss} = -\frac{1}{N}\sum_{i=1}\sum_{j=1}^{M} y_i^j \log \hat{y}_i^{\,j} + \lambda\|\theta\|^2 \tag{10}$$

In Eq. (10), N is the number of samples. M is the number of emotional labels. y is the emotional label value. $\hat{y}$ is the predicted value of the model. λ is the normalization term. The preference scoring of subsequent users is shown in Eq. (11).

$$H = \begin{bmatrix} ru_1^n \, L \; ru_k^n \\ L \\ ru_1^m \, L \; ru_k^m \end{bmatrix} \tag{11}$$

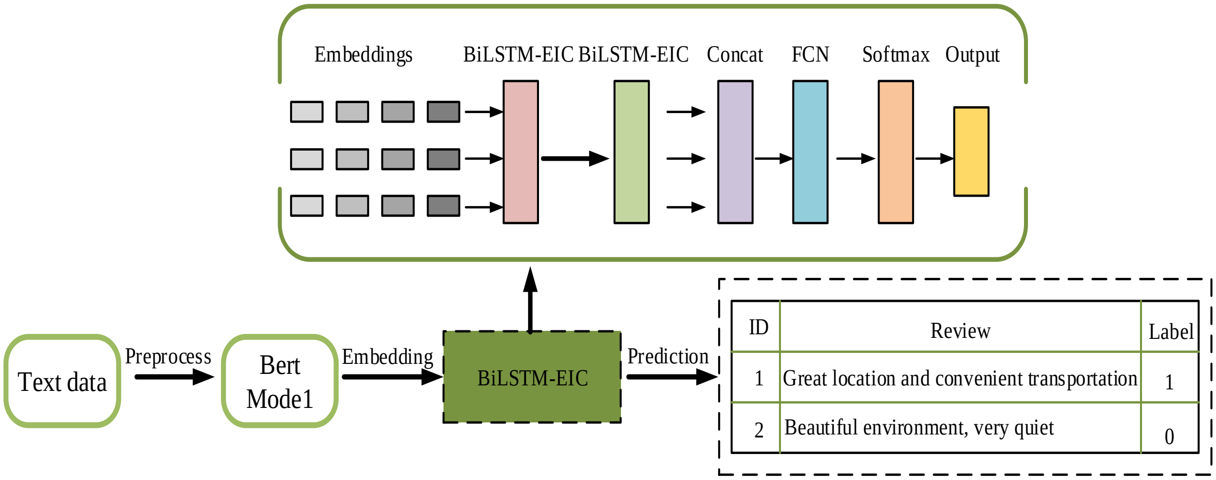
In Eq. (11), H represents the scoring set. n and m represent the regional category of homestays. k represents the number of homestays. At this point, the potential score is shown in Eq. (12).

$$R = \begin{bmatrix} r_1u_n \, L \; r_ku_n \\ K \\ r_1u_m \, L \; r_ku_m \end{bmatrix} \tag{12}$$

In Eq. (12), R represents the consumer record matrix. r_1u_n represents the number of homestay consumption in n. r_1u_m represents the number of homestay consumption in m. The location similarity of the two homestays is shown in Eq. (13).

$$similarity(h_1, h_2) = \frac{\cos(s_1, s_2 \, L \; s_3, s_4)}{e^{dis(h_1, h_2)}} \tag{13}$$

In Eq. (13), $dis(h_1, h_2)$ represents the distance between two places. s_1, s_2, s_3 and s_4 conveniently represents location, transportation, environment, and resource ratings. The sentiment analysis process combined with the BiLSTM-EIC model is shown in Fig. 3.



ID	Review	Label
1	Great location and convenient transportation	1
2	Beautiful environment, very quiet	0

Fig. 3. Emotion analysis flow of BiLSTM-EIC model.

In Fig. 3, step 1 inputs a comment dataset. Step 2 applies the Bert word embedding method to extract and embed sentences from the dataset into the tensor space. Step 3 inputs these different vectors into the BiLSTM model for semantic and feature extraction. Step 4 calculates and predicts feature information to obtain corresponding emotional results.

B. Spatial Location Planning of Rural Homestay Based on Emotional Analysis Model

After the epidemic, the national tourism industry has surged to a new height. The demand for homestays and accommodation requirements are gradually increasing [16]. According to the 2023 Homestay Industry Insight Report released by Feizhu Travel, the keywords for homestays in the hot search are shown in Table I.

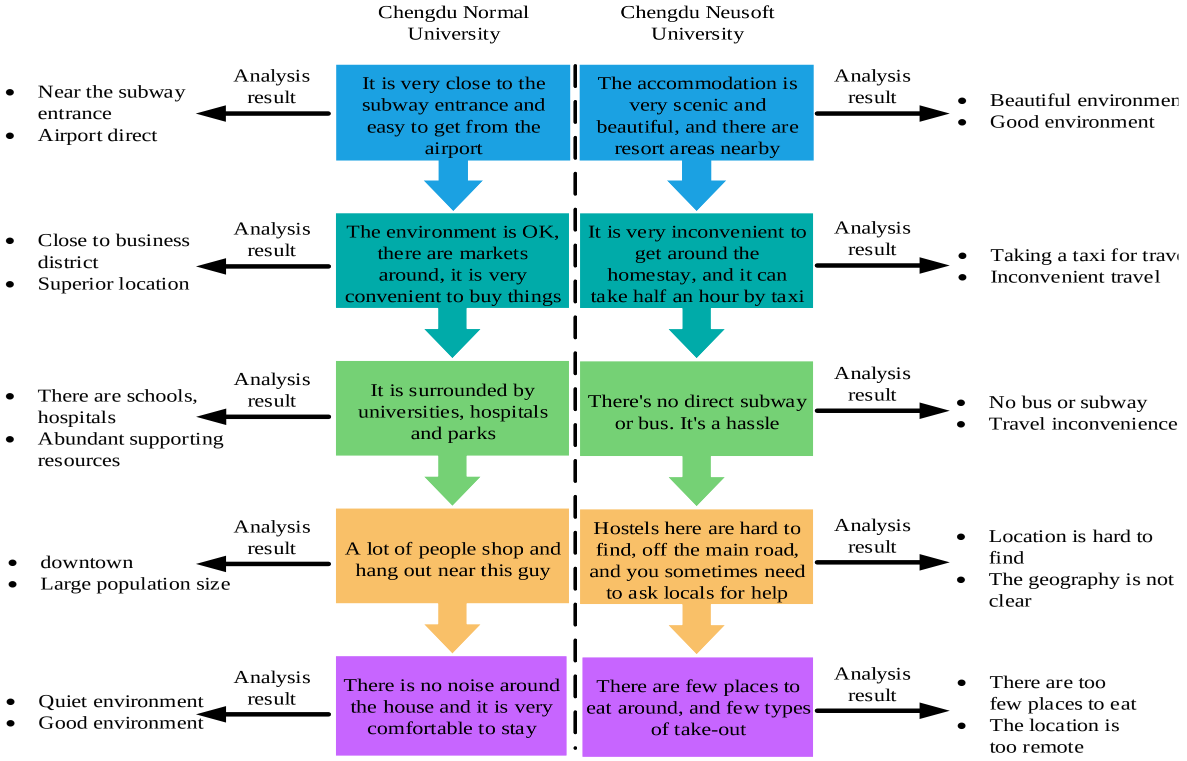
In Table I, the best search terms selected by the public include geographical location, homestay environment, and price. Geographical location has become the most perplexing choice factor for consumers. As a homestay manager, the success of site selection almost determines the subsequent operation of homestays [17]. The study used GIS and market research data to identify optimal sites, with relevant location parameters including geographic location, environmental parameters and plot parameters [18]. The location parameters include 10-20 kilometers from the city center, no more than five kilometers from major tourist attractions, and close to major highways or transportation hubs. Environmental factors include noise levels not exceeding 50 dB and an Air Quality Index (AQI) of less than 100 year-round.The plot parameter refers to a slightly sloping or flat, well-drained soil area within the model's applicability range of 2,000 square meters [19]. Aiming at the above hot semantic words, this study compares the spatial locations of B&B rentals near Chengdu Teachers College and Chengdu Neusoft College by combining the proposed sentiment analysis model after the relevant parameters are determined. Chengdu Normal University is located in the university town area of Wenjiang District, Chengdu City. It has convenient subway and public transportation, and commercial districts gather, belonging to the urban area [20]. Chengdu Neusoft College is located in Qingchengshan Town, Dujiangyan Irrigation Project City. There are buses but no subways. There are fewer business districts and more mountain views. It belongs to a rural area [21]. There are nearly 20000 comments on geographical location provided by Meituan APP for homestays in two places. After randomly selecting the comments, they are input into the sentiment analysis model for feature extraction. The data analysis is shown in Fig. 4.

In Fig. 4, in the context of massive review data, consumers maintain independent opinion on the geographical location characteristics of homestays. After data processing in the emotional semantic analysis model, four main emotional analysis focuses are identified, convenient transportation, superior location, quiet environment, and rich supporting facilities. Based on the above online comment sentiment analysis data, the spatial location planning of the two homestays is designed before and after improvement, as shown in Fig. 5.

In Fig. 5(a) and Fig. 5(c) are the spatial maps of homestays before the renovation design of two universities. Fig. 5(b) and Fig. 5(d) show the spatial planning of homestays after the renovation of two universities. From Fig. 5, the original homestays of Chengdu Normal University are relatively concentrated. They are located in the downtown area. Although the transportation is convenient and shopping is convenient, the living environment and comfort are slightly poor [22]. Therefore, after the renovation, green circles represent quiet and comfortable homestays. The red circle indicates homestays with convenient transportation and superior location. Due to the unique geographical location, Chengdu Neusoft College is mostly located near mountains [23]. Quiet and comfortable homestays have become a trend. Considering the previous trend of loose distribution of homestays, and the difficulties of commercial and transportation areas, this renovation mainly focuses on bus stops and the surrounding areas of rare commercial areas. Consumers can balance both.

TABLE I. HOMESTAY HOT SEARCH KEYWORD LIST

First level keywords	Secondary keywords	Hot search words
Geographical position	Convenient transportation	Convenient
	Superior location	Shortcut
	Security environment	Secure
	Surrounding facilities	Richness
Price distribution	Below 200 yuan	Cheap
	200-500 yuan	Moderate price
	500-1000 yaun	Slightly expensive
	Above 1000 yuan	Too expensive
Residential environment	Lighting	Good indoor lighting
	Ventilate	Good indoor air
	Soundproof	Sleep undisturbed
	Water quality	Clean
Homestay quality	General homestay	Not so bad
	Boutique homestay	Cost performance
	Trendy homestay	Generally not selected
Home style	Minority	Seldom choose
	Rural	Acceptable
	Neo-chinese style	Acceptable
	Simple style	Most popular
Star standard	Five star	Don't have to
	Four-star	Maybe
	Three-star level	Consider moving in
	Two-star level	Consider moving in
	One-star level	Will not check in
Characteristics of homestay	Landscape experience	Family or couple
	Rural experience	Relax
	Artistic experience	Experience
	Sports experience	Recreation
	Cultural experience	For fun



Chengdu Normal University
Chengdu Neusoft University
It is very close to the subway entrance and easy to get from the airport
Analysis result
Near the subway entrance
Airport direct
The accommodation is very scenic and beautiful, and there are resort areas nearby
Analysis result
Beautiful environmen
Good environment
The environment is OK, there are markets around, it is very convenient to buy things
Analysis result
Close to business district
Superior location
It is very inconvenient to get around the homestay, and it can take half an hour by taxi
Analysis result
Taking a taxi for trav
Inconvenient travel
It is surrounded by universities, hospitals and parks
Analysis result
There are schools, hospitals
Abundant supporting resources
There's no direct subway or bus. It's a hassle
Analysis result
No bus or subway
Travel inconvenience
A lot of people shop and hang out near this guy
Analysis result
downtown
Large population size
Hostels here are hard to find, off the main road, and you sometimes need to ask locals for help
Analysis result
Location is hard to find
The geography is not clear
There is no noise around the house and it is very comfortable to stay
Analysis result
Quiet environment
Good environment
There are few places to eat around, and few types of take-out
Analysis result
There are too few places to eat
The location is too remote

IV. Performance testing of rural homestay spatial planning model based on Bert-BiLSTM-EIC algorithm

The Bert module is used as the first part of the model training to improve its ability to be used to understand and extract contextually relevant features from the input text. This is followed by the BiLSTM layer, which is used to process the features extracted by the Bert layer to capture the long-term dependencies in the text. Finally the EIC layer is trained which is used for used for final sentiment classification based on the output of the first two layers. During the training process, the average length of the text in the training set is too long, while the amount of training data is large. Therefore, the study selectively set the Bert sequence length to 256, BiLSTM hidden layer unit to 128, and the EIC layer parameters to 64. Also, the learning rate of AdaGrade optimizer was set to 0.001, the batch size was set to 32, and the training period was set to five weeks.

Precision is the most intuitive performance metric, which indicates the ratio of instances correctly predicted by the model to the total number of instances. Recall measures the ratio of positive instances correctly identified by the model to all actual positive instances. Recall is particularly important in sentiment analysis because missing instances of positive or negative sentiment can lead to poor business decisions or misinterpreted user feedback. The F1 score is the reconciled average of accuracy and recall, which provides a balance between the two. The F1 score is particularly useful when classes are unevenly distributed or when the penalties for false positives and false negatives are the same. Compared to other metrics, these three metrics are commonly used in sentiment analysis models because they provide a comprehensive view of model performance and are easy to understand and communicate.

Firstly, a suitable experimental environment is established. Accuracy, recall, and F1 are used as evaluation indicators to test the sentiment analysis model fused with the Bert-BiLSTM-EIC algorithm. Secondly, time series, geographic similarity of homestays, and user satisfaction are used as indicators for actual performance testing.

A. *Performance Testing of Sentiment Analysis Model Based on Bert-BiLSTM-EIC Algorithm*

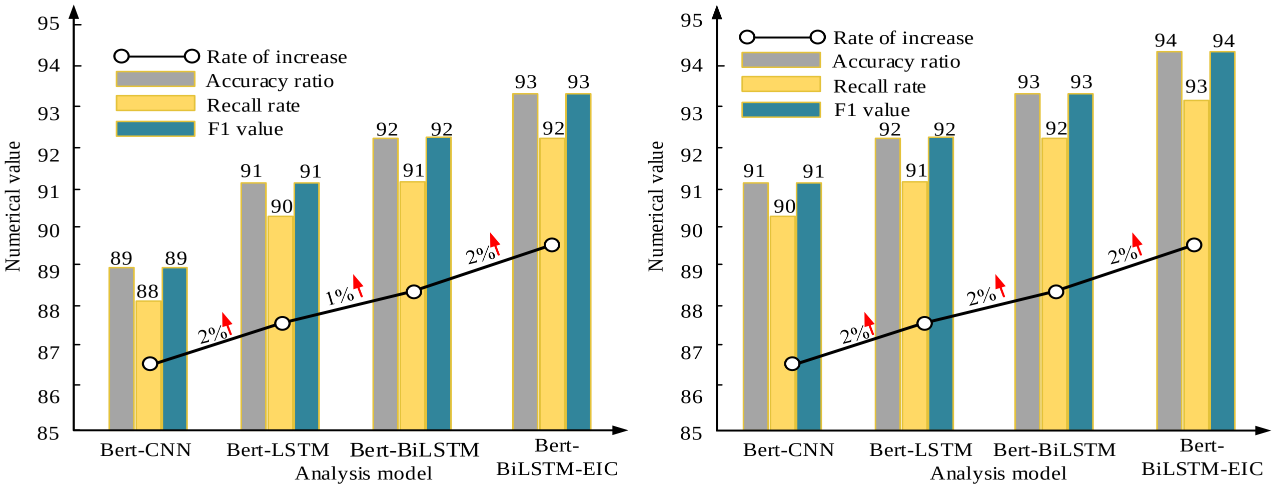
To verify the performance of the emotion analysis model proposed in this experiment, a suitable experimental environment platform is established. A guesthouse comment corpus, ChnSensiCorp, containing both Chinese and English corpora, is used as the dataset. At the same time, to ensure sufficient experimental data and the reliability of the results, a new dataset consisting of approximately 8000 positive comments and 3000 negative comments, totaling 11000, is developed by combining the review data of numerous travel softwares such as Feizhu, Ctrip, and Meituan. It is divided into a training set and a testing set according to 8:2. The specific experimental environment is shown in Table II.

Fig. 6(a) shows the accuracy, recall, and F1 values of four different analysis models in the training set. Fig. 6(b) shows the accuracy, recall, and F1 values of four different analysis models in the test set. From Fig. 6, the CNN model has the worst comprehensive experimental performance, and LSTM is good at capturing temporal features. It is slightly better than the CNN model. BiLSTM has better accuracy in capturing semantic features than LSTM. Based on the above results, the Bert-BiLSTM-EIC proposed in this study performs the best in all three aspects. Its accuracy, recall, and F1 values can reach up to 94%, 93%, and 94%, respectively. The overall score has increased by six percentage points compared to the CNN network. Therefore, the EIC emotional information attention mechanism can extract emotional word sets from text information in the set order, thereby improving the accuracy of semantic and emotional information retrieval and better capturing potential semantic features. To further verify the performance status of the Bert BiLSTM EIC analysis model proposed in this research, the loss function and accuracy are used as reference indicators during the training iteration process. The Bert-CNN model, Bert-LSTM model, Bert-BiLSTM, and Bert-BiLSTM-EIC model are used as experimental objects for testing. The specific test results are shown in Fig. 8.

Accuracy, recall, and F1 value are used as evaluation indicators. The emotion analysis model based on BiLSTM-EIC proposed in this research and three different analysis models, including Bert-CNN model, Bert-LSTM model, and Bert-BiLSTM, are compared and tested. The specific test results are shown in Fig. 6.

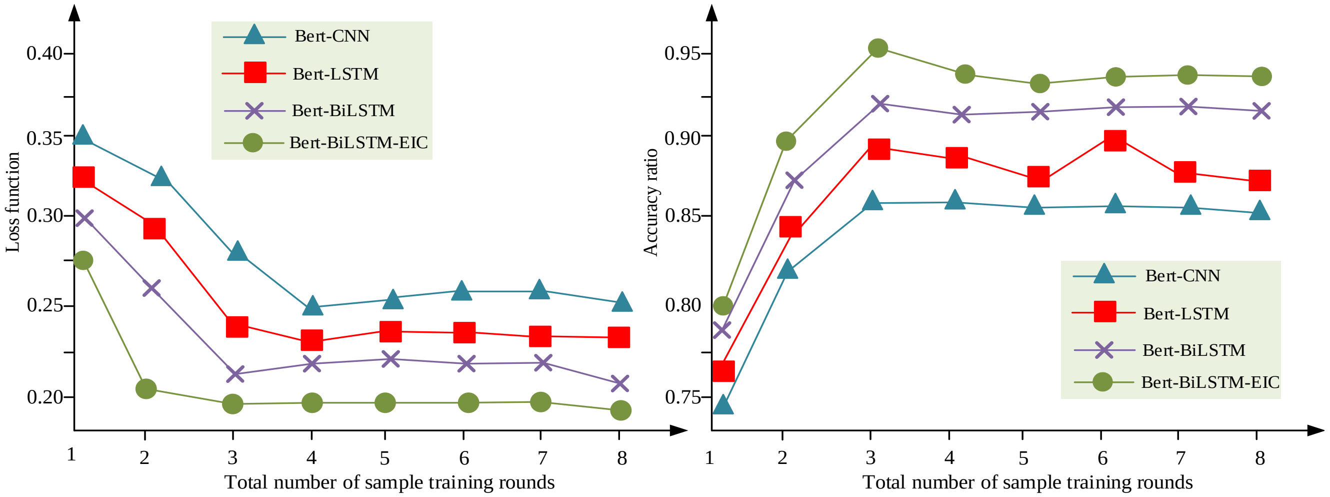
TABLE II. Experimental Environmental Parameters

Equipment environment and parameter items	Model and specific parameters
CPU	3.6GHz Intel Core i9
GPU	NVIDIA GeForce GTX 3066Ti 8G
Operating system	Windows10 64
Memory	32G
Deep learning library	TensorFlow
Amount of data for one training session	1 article
The total number of rounds required for training samples	5 rounds
Iterations	45000 times
Learning rate	0.001
Optimizer	AdaGrade



(a) Training set (b) Test set

Fig. 6. Graph of test results for four models.



(a) Loss rate comparison chart (b) Accuracy variation chart

Fig. 7. Comparison of loss function and accuracy of different models.

Fig. 7(a) shows the loss function curve for the four analytical models. Fig. 7(b) shows the accuracy curve changes of the four analysis models. In Fig. 7, the accuracy curve of the proposed Bert-BiLSTM-EIC analysis model has always been higher than the other three models. The loss rate is the lowest among the four analysis models. Throughout the entire iteration process, the performance of all four models decreases. At this point, the loss function is negatively correlated with accuracy. Although overfitting training can cause slight data fluctuations, the Bert BiLSTM-EIC analysis model tends to be more stable than the other three models. This model has a dual channel construction of semantic emotions. Therefore, the convergence speed during training is faster than the other three models.

B. *Application Test of Emotional Analysis Model in Rural Homestay Spatial Planning*

Generally speaking, the emotional consumption patterns of users are influenced by changes in time series. Therefore, based on the spatial location planning maps of Chengdu Normal University and Chengdu Neusoft University, the application effect of the sentiment analysis model in spatial planning is further demonstrated by drawing the emotional time series curves of consumers in the two places over the year. The detailed results are shown in Fig. 8.

Fig. 8(a) shows the changes in the number of reserved homestays, quiet environment homestays, and convenient transportation homestays in the vicinity of Chengdu Normal University during the year before the renovation. Fig. 8(b) shows the changes in the number of reserved homestays, quiet environment homestays, and convenient transportation homestays near Chengdu Normal University during the year after renovation. Fig. 8(c) shows the changes in the number of reserved homestays, quiet environment homestays, and convenient transportation homestays near Chengdu Neusoft College during the year before the renovation. Fig. 8(d) shows the changes in the number of reserved homestays, quiet environment homestays, and convenient transportation homestays near Chengdu Neusoft College after renovation during the year. According to Fig. 8(a) and 8(b), the demand is highest near Chengdu Normal University after the Spring Festival, from June to August, and in November. It may be due to the urgent need to rent a house after the New Year, the summer vacation from June to August for tourism, and an increase in traveling or taking the postgraduate entrance exam in November. From Fig. 8(c) and Fig. 8(d), near Chengdu Neusoft College, due to geographical location factors before the renovation, the average annual total rental volume does not fluctuate significantly. After the renovation, the total number of rented houses has increased by nearly 60. After analyzing consumer emotions, the designed homestay housing location is more favored by the public.

To better understand consumers' preferences for the geographical location of homestays, Eq. (12) is used to calculate the similarity of housing locations. The total rental volume and consumer selection evaluation of homestays after the renovation of the two places are used as the horizontal and vertical coordinates. The scatter plot of homestays in both locations is shown in Fig. 9.

Fig. 9(a) shows the location similarity of homestays near Chengdu Normal University. Fig. 9(b) shows the location similarity of homestays near Chengdu Neusoft College. From Fig. 9, public consumers near Chengdu Normal University prefer homestays with high similarity, that is, homestays with similar geographical locations. At the same time, the higher the similarity of homestay locations, the greater the rental volume is. Consumers have higher evaluation of their choices. However, near Chengdu Neusoft College, the geographical similarity of homestays is generally not high, and their geographical locations are relatively far apart.

To enable homestay operators to quickly and accurately understand customer evaluations and emotional tendencies, provide decision support, and improve service quality, the CSI (Customer Satisfaction Index) is used for evaluation. A satisfaction survey is conducted on consumers in both regions, with a score of 1-5 on the Likert scale from dissatisfied to satisfied. The data results are shown in Table III.

From Table III, the two homestays before and after the renovation have significantly improved in convenient transportation, superior location, quiet environment, and rich resource allocation. Especially in the vicinity of normal colleges, the popularity of homestays with quiet environment, convenient transportation, and superior location has generally increased. The average score increases by 21% compared to before the renovation. After planning the geographical location of homestays near the Soft College, the scores for convenient transportation and location increased significantly. The average score has increased by 40% compared to before the renovation. The proposed sentiment analysis model that integrates the Bert BiLSTM EIC algorithm has shown high feasibility in actual rural homestay spatial transformation testing. It has played a certain reference role in the subsequent spatial location planning of rural homestays.

V. DISCUSSION

For this study, the data results are further expanded through the following three areas of discussion. The first is the feasibility of the algorithm effect and application. This study demonstrates the potential of digital technology in rural revitalization and tourism development by combining the Bert-BiLSTM-EIC algorithms in the spatial planning and design of rural B&Bs. The Bert module shows superiority in understanding the preferences and feedbacks of the B&B customers, while the BiLSTM performs excellently in dealing with the time-series data such as the booking trend and the flow of guests. The EIC module is introduction further optimizes the decision-making process of spatial planning, making it more accurate and efficient. Secondly, the impact of digital ecology, in the context of digital ecology, this study highlights the importance of data-driven decision making. As more and more data becomes available, it enables the public to understand the needs and challenges of the rural lodging industry more fully. The digital ecology not only provides rich data resources, but also offers new perspectives on the sustainable development of rural B&Bs through the application of algorithms. The result exists a consistent recognition with the optimal row design of neighborhood houses proposed by Teng Y et al. [24]. Finally, the innovation of spatial planning and design, the study is able to solve the complex problems in spatial planning of rural lodging more effectively by utilizing the Bert-BiLSTM-EIC algorithm. For example, the algorithm helps identify the optimal spatial layout and spatial location distribution of the B&B, while taking into account the emotional needs of different users. This approach brings innovation to traditional spatial planning and design, making it more data-driven and result-oriented. The result also has similarities with the algorithmic application in landscape classification by Zhang D et al. [25].

However, despite the positive results of this study, there are some challenges and limitations. First, access to high quality and relevant data remains a challenge. Second, the algorithmic models need to be continuously adjusted and optimized to adapt to changing market and environmental conditions. Finally, applying these techniques to rural lodging in different regions may require targeted adaptation to specific local needs and conditions. For example, sentiment analysis may be more focused on community services and quality of life feedback in rural areas, while in urban areas it may be more focused on business services and the experience of city life. Regardless of the application scenario or geographic location, the main means of studying the proposed model is to obtain key information through public and customer sentiment analysis, and then classify and identify it through algorithmic modeling, as well as give key solutions for spatial planning and positioning. In terms of expansion, the multilingual utility and scalability of the model needs to be further enhanced.

Follow-up research could explore the application of this algorithmic framework to broader areas of rural revitalization, such as agricultural production, rural education and health services. Further research on the adaptability and effectiveness of the algorithm in different cultural and geographical contexts is also necessary.

VI. Conclusion

The current spatial location planning of rural homestays lacks systematicity and scientificity. Therefore, a sentiment analysis model integrating Bert BiLSTM EIC algorithm is proposed based on deep learning networks. This model is applied to the spatial planning of homestays near Chengdu Normal University and Chengdu accuracy, recall, and F1 values of the model can reach 94%, 93%, and 94%. The comprehensive score has increased by 6% compared to the traditional CNN model. In the loss function test, the model has the lowest loss rate, the best stability, and the fastest convergence speed among the four analytical models. In the statistics of the homestay housing resources in the two regions over the year, the demand is highest after the Spring Festival, June August, and November. In the consumer satisfaction scores before and after the renovation of the two places, the average score of homestays near Chengdu Normal University increases by 21% compared to before the renovation. The average score of homestays near Chengdu Neusoft College increases by 40% compared to before the renovation. In summary, the proposed sentiment analysis model that integrates the Bert BiLSTM EIC algorithm has high accuracy and feasibility in the spatial location planning of rural homestays, which can effectively improve the spatial layout optimization and service quality of rural homestays. However, there are many limiting factors in the actual planning of homestays, such as local policies, population size, etc. Therefore, this is also an area for further improvement in subsequent experiments. For example, a detailed analysis of local policies, such as Neusoft University. For the Bert-BiLSTM-EIC algorithm, the land use regulations, building codes, and tourism promotion policies, was included in the experiment. Simulate the impact of different policy changes on B&B spatial planning in order to evaluate planning options under different policy environments. Or integrate data such as population size, population density, and population movement into the model to better understand the needs and constraints of the target area. Use the model to simulate the impact of different population dynamics on B&B planning, such as population movement during peak and off-season, and long-term population trends.

Robot Human-Machine Interaction Method Based on Natural Language Processing and Speech Recognition

Shuli Wang, Fei Long*
Foreign Language School, Harbin University of Commerce, Harbin, 150028, China

***Abstract*—With the rapid development of artificial intelligence technology, robots have gradually entered people's lives and work. The robot human-machine interaction system for image recognition has been widely used. However, there are still many problems with robot human-machine interaction methods that utilize natural language processing and speech recognition. Therefore, this study proposes a new robot human-machine interaction method that combines structured perceptron lexical analysis model and transfer dependency syntactic analysis model on the basis of existing interaction systems. The purpose is to further explore language based human-machine interaction systems and improve interaction performance. The experiment shows that the testing accuracy of the structured perceptron model reaches 95%, the recall rate reaches 81%, and the F1 value reaches 82%. The transfer dependency syntax analysis model has a data analysis speed of up to 750K/s. In simulation testing, the new robot human-machine interaction method has an accuracy of 92% compared to other existing methods, and exhibits excellent robustness and response sensitivity. In summary, research methods can provide a theoretical and practical basis for the improvement of robot interaction capabilities and the further development of human-machine collaboration.**

***Keywords*—Human-computer interaction; speech recognition; natural language processing; lexical analysis; syntactic analysis**

I. Introduction

Natural language processing is an important branch of computer science and artificial intelligence that deals with techniques that enable computers to understand, interpret and generate human language. Speech recognition, on the other hand, is the technology that converts human speech into text. With the continuous development of natural language processing and speech recognition technology, robot human-machine interaction has gradually become a research hotspot [1]. There are three common human-machine interaction methods for language robots, the earliest of which was the use of rule-based human-machine interaction methods, that is, language recognition and response through pre written rules [2]. But this method requires manual writing of a large number of rules and has poor adaptability. Then, statistical human-machine interaction methods are used to identify and understand speech inputs by establishing language and speech models [3]. But this method requires a large amount of corpus for training, which is time-consuming and not accurate. Finally, the human-machine interaction method of deep learning is utilized, which automatically extracts speech and text features through deep learning models, effectively improving the performance of language recognition [4]. With the increasing demand of people, the human-machine environment has become even more harsh, so simple deep learning models can no longer meet high requirements for completing human-machine interaction tasks. In the existing research, the design of robot human-robot interaction system that combines natural language processing technology and language recognition technology is still in the minority, and only proposes, for example, a sentiment analysis robot that can better understand the user's emotions and respond accordingly by analyzing the pitch, speed, volume of speech, and the emotional color of text. Or multimodal interaction robots provide a more natural interaction experience by analyzing the user's voice, text and body language. Despite the success of these human-robot interaction system designs in the existing market, they still face challenges such as dealing with complex and variable natural language understanding challenges and maintaining high accuracy and adaptability in diverse and dynamic environments. Therefore, the research attempts to combine natural language processing and speech recognition to propose a novel approach to human-computer interaction. The method improves the two major steps of lexical analysis and syntactic analysis, and introduces structured perceptual machine and transfer-dependent syntactic analysis for improvement respectively, to enhance the computational performance of each module, and to achieve the goal of enhancing the recognition accuracy of human-computer interaction. The study aims to explore the latest progress of natural language processing and speech recognition technologies in the field of robot human-robot interaction, analyze the limitations of existing technologies, and look forward to the future development trend. Therefore, this study attempts to combine natural language processing with speech recognition and proposes a new human-computer interaction method. This method improves the two major steps of lexical analysis and syntactic analysis to enhance the recognition accuracy of human-computer interaction. This study is divided into five sections. Section I is an introduction to the overall content of the article. Section II is an analysis and summary of research on others. Section III introduces how the improved lexical analysis model and syntactic analysis model are constructed. Section IV tests the performance of the new human-computer interaction system. Section V is a summary of the paper.

Studying the application of natural language processing and speech recognition in robot human-robot interaction is crucial for improving the level of intelligence and user experience of interaction technology. It can not only improve the efficiency of communication between people and robots, but also provide better assistive tools for specific groups (e.g., people with disabilities). In addition, this research is also

*Corresponding Author.

valuable for understanding human language and communication patterns, and can contribute to the development of knowledge in related fields. The results of the above research can reveal the efficacy and limitations of natural language processing and speech recognition technologies in different contexts and provide an empirical basis for theoretical models. For example, by analyzing the performance of robots in different linguistic contexts, the research can help us better understand the impact of language complexity on the performance of the technology. Meanwhile research findings can stimulate new research questions, such as how robots deal with dialects or non-standard languages, or how to deal with metaphors and humor in language more effectively.

II. Related Works

With the advancement of artificial intelligence technology, robots have begun to play an important role in various fields. However, one of the key challenges in making robots more intelligent and humane is how to achieve natural and smooth interaction between robots and humans. Currently, many scholars have conducted in-depth research in this field. Freire Obregon D et al., in order to further improve the recognition performance of biometric verification in human-computer interaction, used independent interest frameworks to improve the accuracy of robot audio recognition. By using high confidence image facial recognition to avoid errors caused by similarity in appearance, its accurate resolution after simulation testing is higher than traditional methods, providing a new method for robot recognition technology [5]. Ko et al. introduced a nonverbal social behavior dataset to improve the recognition and learning efficiency of robots in different scenarios. This dataset includes human body index and bone data, which robots use sensors to identify and analyze, and guide subsequent behavioral operations. The learning rate of robots under this dataset has significantly improved, and their behavior inference and response abilities have significantly improved [6]. Kim et al. conducted opinion interviews with 70 ordinary users in order to further optimize the evaluation indicators of food aid robots and improve user experience. The collection of over 500 suggestions on robot interface design and security provides more solutions for the usability, emotional value, and functional construction of food aid robots [7]. Roda Sanchez L et al. proposed an intelligent system that combines the Internet of Things and human-machine action collaboration to improve the efficiency of product manufacturing processes in the context of digital industry. This system is centered around human-computer interaction, reflecting the natural interaction between IoT inertial measurement unit equipment and robotic arms. The system meets the basic requirements of modern digital industrial manufacturing in terms of real-time performance, success rate, and acceptable level [8].

The development of speech recognition technology began in the 1950s, with initial research mainly based on spectral analysis and pattern matching of audio signals. However, due to limitations in computing power and data volume at the time, the accuracy and stability of speech recognition were not satisfactory. With the development of technology, speech recognition technology has made significant breakthroughs in many disciplinary fields. Alsayadi et al. proposed an automatic language recognition system based on convolutional neural networks to address the issue of distinguishing between Arabic language recognition techniques with and without inflections. The system is tested on a standard Arabic single speaker corpus. The results show that recognition techniques with neural networks are superior to traditional recognition techniques, reducing word error rates by 5.24% [9]. Lin's team designed a recognition technique that combines recursive neural network embedding blocks to extract advanced features in order to reduce speech loss caused by radio communication propagation. This technology integrates multi language speech recognition into a single model, thus avoiding class imbalance. The Chinese and English character error rates of this technology are 4.4% and 5.6%, respectively, which are significantly better than other methods [10]. Dong et al. proposed a significant time series method using connectionist time classification to address the issues of delayed response time and emotional noise in continuous emotional speech recognition technology. This method treats sentence labels as a chain of emotional significant events and non-emotional significant event states. This method can continuously improve the performance of emotion recognition, and when the consistency of significant emotional events is high, this improvement is more significant [11]. Yerigeri et al. proposed a mechanical and efficient speech emotion recognition technology that utilizes stress level analysis to explore the impact of stress on people's emotional changes. This technology utilizes learning algorithms to evaluate auditory and visual cues, and uses a pressure speech database for performance analysis. The overall performance of this technology is good, with an accuracy rate of 90.66% for stress related emotion recognition [12].

In summary, many academic teams have conducted extensive research in the field of robot interaction design and recognition technology, and have achieved remarkable results. Overall, the research status of robot human-machine interaction method design is constantly developing and innovating, involving the intersection and integration of multiple disciplines. This study attempts to apply natural language processing technology and speech recognition technology to the design of robot human-machine interaction, exploring how these technologies can be applied to intelligent robots to achieve more natural and convenient human-machine interaction.

III. Design of a Robot Human-Machine Interaction Method Model Combining Natural Language Processing and Speech Recognition

The natural language processing technology in robot human-machine interaction methods enables machines to understand human intentions and instructions by analyzing and understanding human language [13]. Speech recognition technology converts human speech input into text or commands, thereby achieving interaction with machines. The first section of this study will improve and innovate speech recognition technology, and the second section will improve natural language processing methods.

A. Design of Lexical Analysis Model Based on Structured Perception Machine in Natural Language Processing

The most common ways of human-computer interaction are verbal communication and behavioral communication. Speech communication involves speech recognition, while behavioral communication involves image recognition. And verbal communication is nothing more than the simplest way of interaction. The existing processing methods for natural language include lexical analysis, syntactic analysis, semantic analysis, speech recognition, and speech synthesis. Lexical analysis is the most important step in natural language processing. This step consists of three parts, namely Chinese word segmentation, part of speech tagging, and entity naming recognition. For Chinese, the results of lexical analysis will directly affect subsequent natural language processing. Perception machine is a basic binary classification algorithm proposed by American scientist Frank Rosenblatt in 1957 [14]. The goal of the perceptron is to linearly classify input data into two different categories. The perceptron model is shown in Fig. 1.

In Fig. 1, w represents the normal vector and b represents the intercept. The processing of classification problems by perceptron models is called decision boundaries. The neighborhood differentiation of this model is obvious, and the feasibility of linear implementation is high. In a space, from input to output, the perceptron model calculates the formula as shown inEq. (1).

$$f(x) = sign(w \cdot x + b) \tag{1}$$

In Eq. (1), x represents a point in the input space. b represents offset. w represents the weight value. $w \cdot x$ represents the weight of the point. $sign$ represents a symbolic function. This function is shown in Eq. (2).

$$\mathrm{si}\,gn(x) = \begin{cases} +1 \longrightarrow x \geq 0 \\ -1 \longrightarrow x < 0 \end{cases} \tag{2}$$

In Eq. (2), +1 or -1 are usually used as indicators of input and output, and the geometric interpretation of the perceptron model is shown in Eq. (3).

$$w \cdot x + b = 0 \tag{3}$$

In Eq. (3), $w \cdot x + b$ belongs to the set of all linear classification models in the feature center of the perceptual model. It corresponds to a hyperplane in the feature space. Part of speech tagging is a typical type of structured prediction. The structured prediction scoring of the perceptron model is shown in Eq. (4).

$$\hat{y} = \arg\max_{y \in Y} score_{\lambda}(x, y) \tag{4}$$

In Eq. (4), λ represents the prediction model. Y represents all selectable structures. Usually for linear models, structured perceptron is used as a training algorithm, and the classifier can assist in predicting problems such as sequence annotation. The structured prediction is shown in Eq. (5).

$$\hat{y} = \arg\max_{y \in Y} (w \cdot \phi(x, y)) \tag{5}$$

In Eq. (5), x and y represent independent variables. $\phi(x, y)$ represents a characteristic function. After the product of the new feature vector and weight points, the highest output structure is used as the decoding of the sequence annotation problem. The decoding process of this method is described in Eq. (6).

$$\delta_{t,i} = \begin{cases} w \cdot \phi(s_{0,} s_i, x_1), i = 1, \cdots, N \\ \max_{1 \leq j \leq N} (\delta_{t-1} + w \cdot \phi(s_j, s_i, x_t)), i = 1, \cdots, N \end{cases} \tag{6}$$

In Eq. (6), N represents the corresponding state. s represents the score. j belongs to any one of the state sets. t represents the time. The maximum score calculation is shown in Eq. (7).

$$S = \max_{1 \leq i \leq N} \delta_{T,i} \tag{7}$$

In Eq. (7), S represents the maximum score. T represents the corresponding time set under this score. i represents the optimal path. When there is a local optimal solution, the maximum score at this point corresponds to the label under that path, which is the i-value. In summary, this study integrates the structured perceptron model into the natural language processing of human-computer interaction, and proposes a new natural language processing framework for human-computer interaction, as shown in Fig. 2.

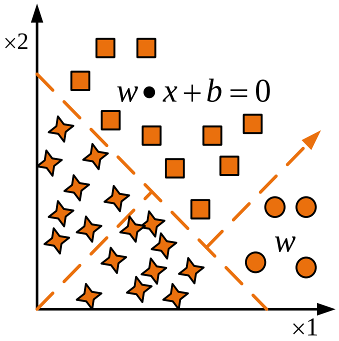

Fig. 1. Perceptron model.

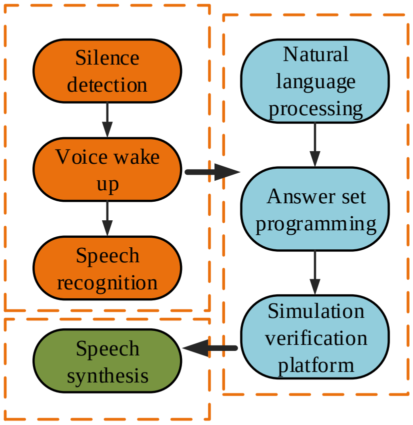

Fig. 2. Human-computer interaction natural language processing framework.

In Fig. 2, the natural language processing framework is mainly divided into three parts. Firstly, the language detection and recognition section provides information on the sounds emitted by external users. The second step is to convert the extracted sound information into linear features, which are labeled by programming data. Finally, the structure aware machine algorithm performs lexical analysis on these labeled data and converts them into communicative text.

B. Design of Key Information Speech Recognition Method Based on Dependency Syntactic Analysis

Natural language is constantly changing and cannot be represented by simple linear symbols. Meanwhile, due to the extremely complex construction of natural language, robot acquisition analysis is still too abstract. Therefore, this study continues to focus on constraint transformation of structured prediction results and remove abstraction. Natural language processing is generally manifested as the relationship between words in a sentence. Dependency syntax analysis defines this relationship as a binary nonequivalence relationship, namely the master-slave relationship [15]. To more vividly display the dependency relationships between words, the dependency tree is obtained by dividing the words in order, as shown in Fig. 3 [16].

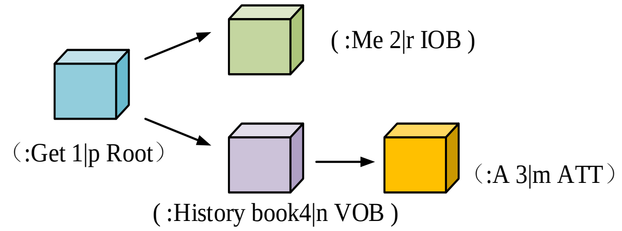

Fig. 3. "Get me a history book" depends on the syntax tree.

In Fig. 3, there are four phrase relationships in the sentence "Help me get a history book". Among them, "get" has the strongest interdependence with "me" and "history Book", while "a" has the lowest interdependence. There are two common implementation methods for dependency syntax analysis, namely the combination graph or transfer analysis method. By combining the dependency syntax analysis of graphs, using independent assumptions and establishing a model, the optimal branch solution can be found in the entire dependency tree model [17]. As shown in Eq. (8).

$$Score(x,d) = \sum_{p \subseteq d} Score_{subtree}(x, p) \tag{8}$$

In Eq. (8), w represents the weight vector. p represents a branch that conforms to the hypothesis. The analysis method of combining graphs completely depends on the maximum number of dependencies allowed in the tree. The strength of obtaining effective information in a simultaneous graph model depends on the number of features used. Under normal operation, the graph model utilizes a feature extractor to extract features for each word and transmit them to the classification scorer as scores for dependency relationships.

Based on the characteristics of dependency parsing, an improvement was made on its state machine, and conditional analysis was introduced to obtain the transfer dependency parsing algorithm [18]. The corresponding machine state under this algorithm is shown in Eq. (9).

$$s(x)_0 = ([x_0]_\sigma, [x_1 \cdots x_k]_\beta) \tag{9}$$

In Eq. (9), σ represents the stack. β represents the queue. x represents a sentence. k represents the tail element of the queue. $s(x)_0$ represents the initial state. The set of state transitions in transfer dependency syntactic analysis roughly includes move in actions, left reduction, and right reduction. The move in action is shown Eq. (10).

$$(a, x_i | \beta, A) \Rightarrow (a | x_i, \beta, A) \tag{10}$$

In Eq. (10), A represents the set of constructed dependent edges. x_i represents the state of being pushed onto the stack. Ensure that the queue is in a non-empty state and push the elements in the queue onto the stack. The calculation formula for left reduction is shown in Eq. (11).

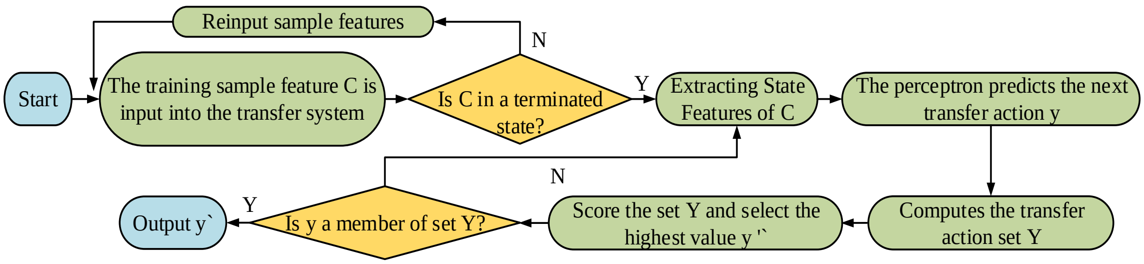
$$([x_0 \cdots x_k, x_j, x_i], \beta, A) \Rightarrow ([x_0 \cdots x_k, x_i], \beta, A \cup (i,, j) \tag{11}$$

In Eq. (11), i and j each represent a new element. When the element in the stack is greater than 1, the two elements at the top of the stack are introduced into the set (j,i), and then the i element is re pushed onto the stack. The calculation formula for rightward reduction is shown in Eq. (12).

$$([x_0 \cdots x_k, x_j, x_i], \beta, A) \Rightarrow ([x_0 \cdots x_k, x_i], \beta, A \cup (j,i) \tag{12}$$

In Eq. (12), i and j each represent a new element. When the elements in the stack are greater than 1, the two elements at the top of the stack are introduced into the set (j,i), and then the j element is re pushed onto the stack. For example, in the short sentence "You drink water", there is a subject verb relationship between the words "you" and "drink", and a verb object relationship between "drink" and "water". Therefore, machines need two steps to establish a syntactic dependency tree during learning.

The analysis process of transfer dependency syntax analysis roughly includes transfer system, feature extraction, and action sequence transformation. The transfer system mainly covers some executable actions and their conditions. Feature extraction selects object features through manually set feature templates that combine single words, two words, and three words. The transformation of action sequences is commonly divided into static specification transfer and dynamic specification transfer [19]. To improve the persuasiveness and feasibility of machine learning, a training process for machine learning was proposed by selecting dynamic norm transfer and combining it with a structured perceptron model, as shown in Fig. 4.



Reinput sample features
N
Start
The training sample feature C is input into the transfer system
Is C in a terminated state?
Y
Extracting State Features of C
The perceptron predicts the next transfer action y
N
Output y`
Y
Is y a member of set Y?
Score the set Y and select the highest value y '`
Computes the transfer action set Y

Fig. 4. Machine learning transfer dependency parsing training flow.

In Fig. 4, from the perspective of data structure, state judgment has been added in both the training sample input to the transfer system stage and the selection of the highest scoring feature stage, indicating that the entire process of machine learning is robust and feasible. Because after selecting features and scoring in the model, the results are usually directly output. But the process introduces attribution judgment for actions, thereby reducing the chances of self-error and increasing accuracy.

C. Construction of a Robot Human-Machine Interaction Model Combining Natural Language Processing and Speech Recognition

The first two chapters have already introduced the implementation steps of lexical analysis and syntactic analysis. This time, we will elaborate on the design of the human-machine part of the robot in the human-machine interaction model [20]. Assuming that the position of the robot is composed of an initial inertial coordinate system and a carrier reference coordinate system, the coordinate representation of the mobile robot is shown in Fig. 5.

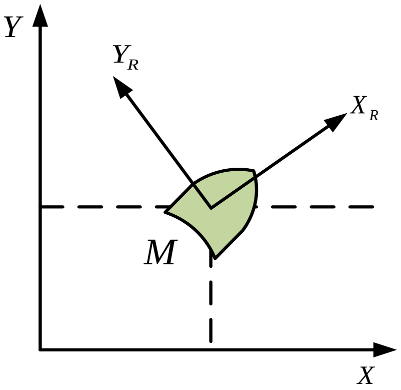


Fig. 5. Robot moving coordinate representation.

In Fig. 5, XOY represents the inertial coordinate system. $X_R MY_R$ represents the carrier coordinate system. The representation of robots in three-dimensional coordinates changes over time. If the position at time k is inferred from the position at time $k+1$, the motion model is shown in Eq. (13) [21].

$$X_r(k+1) = f(X_r(k), u(k)) \tag{13}$$

In Eq. 13, u represents the navigation weight value. f represents the state transition function. In the initial inertial coordinate system, the position vector at time $k+1$ is represented as the motion model of the robot, as shown in Eq. (14).

$$\begin{bmatrix} x(k+1) \\ y(k+1) \end{bmatrix} = \begin{bmatrix} \cos\theta - \sin\theta \\ \sin\theta, \cos\theta \end{bmatrix} \begin{bmatrix} x(k) \\ y(k) \end{bmatrix} \tag{14}$$

In Eq. (14), θ represents the heading. x and y represent the horizontal and vertical coordinates of the mobile robot, respectively. At this point, the input variable of k is $[v_r, w_r]$, where v_r represents speed. w_r represents angular velocity. After constructing the robot movement model, a new robot human-machine interaction method flow is proposed by combining the improvement scheme of natural language processing module and speech recognition module, as shown in Fig. 6 [22].

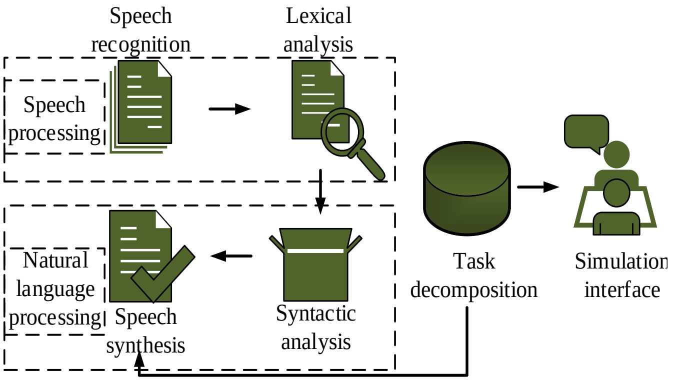

Fig. 6. New human-computer interaction process.

In Fig. 6, speech recognition and natural language processing are the two main parameter analysis modules. The speech recognition module serves as the main input part of the entire human-computer interaction process. The speech synthesis and simulation interface is the output part. In each stage, semantic recognition and synthesis are responsible for recognizing and expressing sounds, while simulation interfaces are responsible for verifying the effectiveness of interaction results [23].

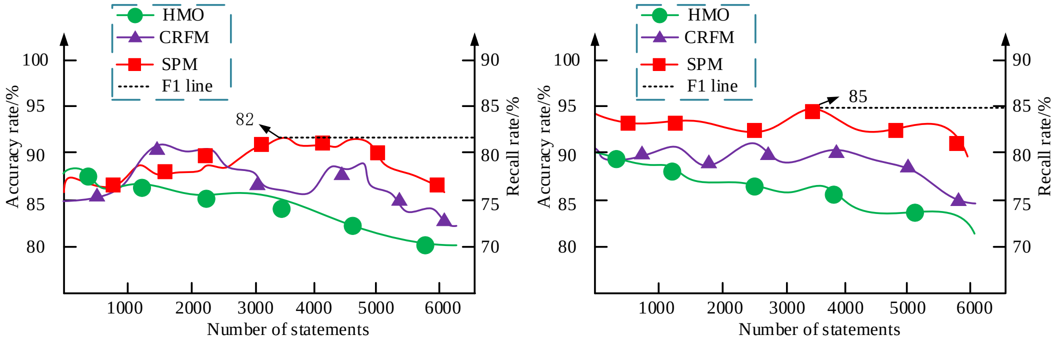
IV. Performance Testing of a Robot Human-Machine Interaction Model Combining Natural Language Processing and Speech Recognition

The first step is to establish a suitable experimental environment, set various experimental parameters and indicators, and create a reliable experimental corpus. Further extracting key feature information into robot human-machine interaction systems through natural language processing of structured perceptron models and speech recognition through transfer dependency syntax analysis. The accuracy (P), recall (R), and comprehensive evaluation index F1 value are used as evaluation indicators to conduct performance tests on the human-machine interaction model.

A. Performance Testing of Natural Language Processing Models and Speech Recognition Models

To verify the performance of the proposed new human-computer interaction model, natural language processing and speech recognition modules were tested separately. The computer system used in the experiment is Window10, the development environment is Pycharm, the language is Pyuthon3.7, and the CPU is (Intel ® Core TM i7-9700CPU@3.00GHz × 8), GPU is (NVIDIA GeForce RTX 3060 SUPER). The data source is the BCC Modern Chinese Corpus of Beijing Language and Culture University. This corpus includes over 30000 pieces of corpus information from various fields. According to an 8:2 ratio, the corpus information is divided into a training group and a testing group.

In natural language processing experiments, P value, R value, and F1 value are used as reference indicators to compare the performance of existing hidden Markov models, conditional random field models, and research models. The hidden Markov model is represented by HMO, the conditional random field model is CRFM, and the structured perceptron model is SPM. The experimental test results are shown in Fig. 7.



(a) Training set

(b) Test set

Fig. 7. Test results of different lexical analysis models.

Fig. 7 (a) and Fig. 7 (b) show the test results curves of three models in the training and testing sets. In Fig. 7, the performance of the training and testing sets of the three models shows a slow downward trend. However, the test P-values, R-values, and F1 values of the hidden Markov model perform the worst in both the training and testing sets. The combination of structured perceptron models proposed in the study performed the best, with an accuracy of up to 95%, a recall rate of up to 81%, and an F1 value of up to 82% in the test set.

Lexical analysis, as the most crucial step in natural language processing, provides the foundation for all subsequent speech processing steps. The accuracy of its analysis directly affects the efficiency of subsequent processes. Therefore, tests are conducted on the P-value, R-value, and F1 value of the three subtasks in the sequence annotation of the structured perceptron model, namely word segmentation, part of speech annotation, and named entity recognition. The results are shown in Fig. 8.

In Fig. 8, after inputting instructions from the BCC modern corpus, the average score of part of speech tagging in the structured perceptron model is the highest at 97.9%. Compared to word segmentation, its F1 value is not significantly different, but it surpasses word segmentation in terms of accuracy and recall. Due to the relatively single corpus tested, the three scores for named entity recognition are generally low.

Regarding the speech recognition process, considering that the sentences involved in human-computer interaction design in the BCC corpus are relatively fixed to be closer to life and simulate real-life communication more realistically, this study used the CTB8.0 corpus for model training and comparison. Using P value, R value, and F1 value as reference indicators, comparative tests are conducted on the probabilistic context free grammar (RCFG), semantic feature analysis (SFA), and transfer dependency syntactic analysis models. The transfer dependency parsing model is represented by TDSA, and the test results are shown in Fig. 9.

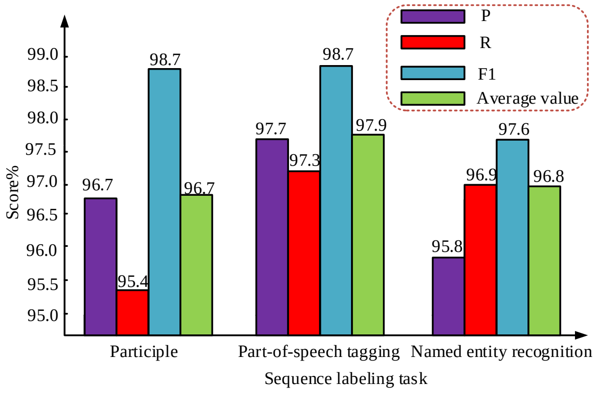


Fig. 8. Sequence annotation results of structured perceptron model.

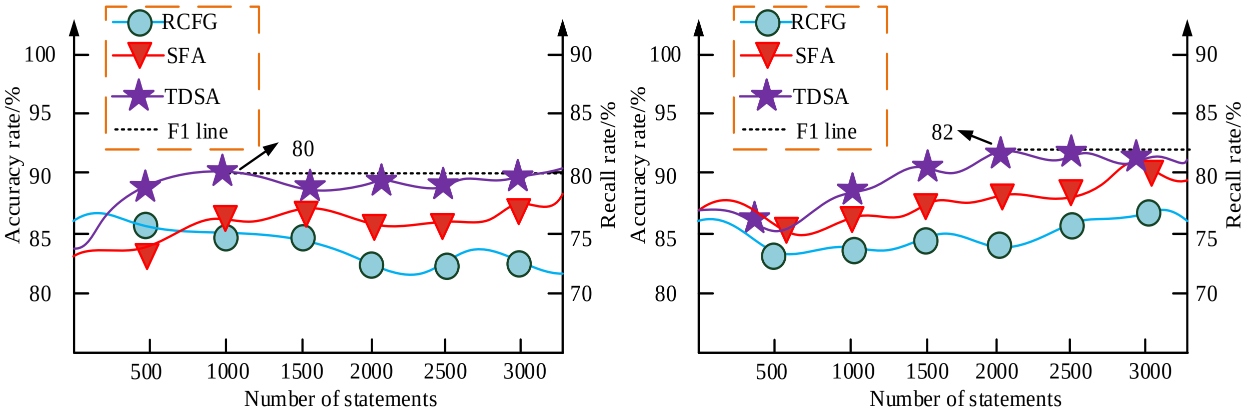


(a) Training set (b) Test set

Fig. 9. Test results of different syntactic parsing models.

Fig. 9(a) and Fig. 9(b) show the test results of three syntactic parsing models in the training and testing sets. According to Fig. 9, in a specific corpus training environment, the accuracy of the research model is close to 90%, and compared to other models, this method has the best training results. In the test set results, the maximum P-value of the transfer dependency parsing model is close to 93%, the maximum R-value is close to 83%, and the F1 value is close to 82%.

To delve deeper into the actual performance of syntactic analysis of these three types of models, accuracy, analysis speed, and running memory are used as reference indicators, and the CTB8.0 corpus continues to be used as the test object. Table I shows the specific test results.

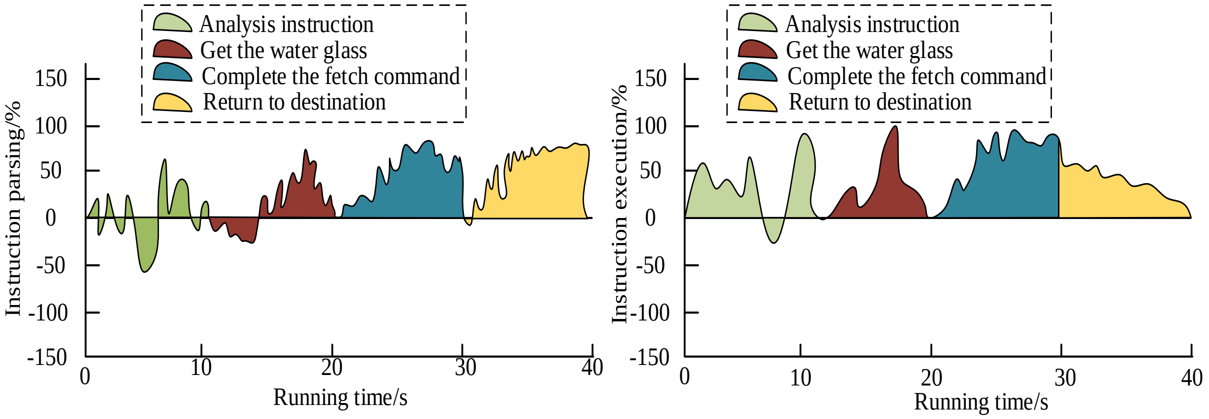
In Table I, among the three syntactic analysis models, the RCFG model has low accuracy, analysis speed, and running memory. Compared to RCFG, the accuracy and analysis speed of SFA have been improved. However, its running memory is small and not suitable for statement analysis in larger information environments. The accuracy of the research model can reach up to 96.77%, with a data analysis speed of up to 750K/s and a running memory of 126M. This can indicate that the transfer dependency syntactic analysis model proposed in this study has good practical application performance.

B. *Simulation Performance Testing of Robot Human-Machine Interaction Model*

Combining, Fig. 5, Eq. (13), and (14) for the design of the human-machine part of the robot, a human-machine interaction system using speech recognition has been built this time. It is tested using a universal Chinese textbook corpus and simulated with simple texts from daily family life. This study takes instruction parsing and execution as reference indicators, and uses the text "Give me a water cup" as the initial instruction for analysis and testing. A positive score indicates correct analysis and execution of instructions, while a negative score indicates error analysis and execution of instructions. The simulation results are shown in Fig. 10.

TABLE I. ACTUAL TEST RESULTS OF THREE SYNTACTIC ANALYSIS MODELS

Task		Accuracy/%	Speed/K/s	Memory/M
RCFG	Training set	94.31	580.00	77.00
	Test set	96.77	640.00	82.00
SFA	Training set	95.69	620.00	45.00
	Test set	96.83	650.00	68.00
TDSA	Training set	96.31	710.00	118.00
	Test set	97.28	750.00	126.00



（a）Robot command parsing situation （b）Robot command execution

Fig. 10. Robot human-computer interaction instruction execution.

Fig. 10(a) and Fig. 10(b) show the analysis accuracy and execution accuracy curves of the "Give Me a Water Cup" command executed by the human robot. In Fig. 10, the robot first performs command analysis after receiving voice commands. After disassembling the analysis results, it goes to retrieve the water cup. After completing the retrieval of the water cup, it returns to its destination. Due to the complex environment in the home environment and the presence of various interference factors in robot analysis, error analysis occurred in the instruction analysis stage for approximately two seconds. At the same time, within 10 seconds, an error action with a negative execution rate occurred. But overall, the performance during the subsequent 30 seconds of picking up the water cup and returning was relatively satisfactory.

In order to further explore the practical application performance of the robot human-machine interaction method, execution speed, execution accuracy, sensitivity, and robustness are used as reference indicators this time. This study discusses the proposed human-machine interaction method and compares it with existing robot little i human-machine interaction systems, robot Echo human-machine interaction systems, and robot Hanna human-machine interaction systems on the market. Table II shows the experimental results.

TABLE II. EXECUTION DATA OF DIFFERENT HUMAN-COMPUTER INTERACTION SYSTEMS

Human-computer interaction method	Execution time /s	Execution accuracy rate /%	Response sensitivity /%	Robustness /%
Robot little i	32	67	81	69
Robot Echo	52	88	84	54
Robot Hanna	45	74	76	83
The method proposed in this study	35	92	86	92

In Table II, the human-machine interaction execution time of little i robot is the shortest, and the execution accuracy of Echo robot is the highest. Based on the above data, it is found that the proposed human-machine interaction method combining structured perceptron and transfer dependency syntax analysis has much higher robustness and response sensitivity than other systems. Its accuracy is 92%, indicating that the combination of lexical analysis and syntactic analysis human-machine interaction method has the best execution effect in a certain speech recognition environment.

V. CONCLUSION

In order to further improve the accuracy and effectiveness of robot human-machine interaction systems, this study proposed a new method based on traditional speech recognition interaction systems. It combined a structured perceptron model and a transfer dependency syntactic analysis model for a new type of human-computer interaction. The experiment showed that the testing accuracy of the structured perceptron model in this method was as high as 95%, the recall rate was as high as 81%, and the F1 value was as high as 82%. In the testing of the transfer dependency syntactic analysis model in speech recognition, the maximum P value was close to 93%, the R value was close to 83%, and the F1 value was close to 82%. At the same time, the data analysis speed was up to 750K/s and the running memory was 126M. In the simulation testing experiment of the proposed new human-computer interaction method, although there were brief erroneous data analysis, the overall task execution rate was high. Compared to other robot human-machine interaction systems on the market, the accuracy of this method could reach 92%, and its robustness and response sensitivity were excellent. It can be seen from the above test results that, compared with the same type of language recognition interaction models, the new HCI model proposed by the study, which combines the structured perceptual machine model and the transfer dependency syntactic analysis model, is more adaptable to complex and randomly changing interaction scenarios, and the advantages of the model of this method are not only manifested in the aspects of very high accuracy, recall and F1 value, but also has an absolute leading advantage in the analysis speed and running memory. The model of this method not only shows its advantages in terms of very high accuracy, recall and F1 value, but also has absolute leading advantages in analysis speed and operation memory. Therefore, it can be said that the proposed model in the study is in the leading position in all the indexes, and can bring great impetus to the field of speech recognition human-computer interaction. In summary, the proposed new human-computer interaction method could timely and accurately respond to user instructions after correctly recognizing them, and could automatically detect and avoid erroneous voice data analysis. In addition, the high accuracy and efficiency data provided by the current study can be used as a benchmark to help future researchers optimize existing models. By analyzing and understanding the advantages of structured perceptual machines and transfer-dependent syntax, future research can build on these success factors to further improve the model. In a large number of corpus datasets, the test results of lexical analysis and syntactic analysis performed better. However, this study only focused on optimizing and improving the field of speech recognition, and had not yet introduced image analysis technology in human-computer interaction. Further research can be conducted on this basis, combined with image recognition technology, for in-depth exploration. This research provides new insights into robotic human-robot interaction systems in the field of natural language processing and speech recognition, and the results pave the way for future research. Future research can build on the current high accuracy and efficiency data for further model optimization, and delve into the causes of error data to reduce the occurrence of errors. In addition, explorations incorporating image recognition technology will open up a more comprehensive human-computer interaction experience. Cross-domain applications, such as healthcare, education or customer service, are also important directions for future research. Meanwhile, the ability to adapt to different cultural and linguistic environments, improve user experience and interaction design, and test the system's durability and application performance in long-term and real-world environments are all areas of interest. Finally, as technology evolves, research on ethical, legal, and privacy issues is indispensable to ensure the safe and responsible use of technology. Through these multiple perspectives, we are able to advance not only on the technological level, but also on the application, ethical, and legal dimensions that drive the overall development of the field.

Investigating of Deep Learning-based Approaches for Anomaly Detection in IoT Surveillance Systems

Jianchang HUANG*, Yakun CAI, Tingting SUN
College of Science and Technology, Hebei Agricultural University, Huanghua 061100, China

***Abstract*—Anomaly detection plays a crucial role in ensuring the security and integrity of Internet of Things (IoT) surveillance systems. Nowadays, deep learning methods have gained significant popularity in anomaly detection because of their ability to learn and extract intricate features from complex data automatically. However, despite the advancements in deep learning-based anomaly detection, several limitations and research gaps exist. These include the need for improving the interpretability of deep learning models, addressing the challenges of limited training data, handling concept drift in evolving IoT environments, and achieving real-time performance. It is crucial to conduct a comprehensive review of existing deep learning methods to address these limitations as well as identify the most accurate and effective approaches for anomaly detection in IoT surveillance systems. This review paper presents an extensive analysis of existing deep learning methods by collecting results and performance evaluations from various studies. The collected results enable the identification and comparison of the most accurate deep-learning methods for anomaly detection. Finally, the findings of this review will contribute to the development of more efficient and reliable anomaly detection techniques for enhancing the security and effectiveness of IoT surveillance systems.**

Keywords*—*Internet of Things; surveillance systems; anomaly detection; deep learning; video analysis

I. Introduction

The Internet of Things (IoT) has revolutionized various domains, including video surveillance systems, by enabling the integration of smart devices and connectivity [1, 2]. IoT video surveillance systems leverage the power of networked cameras and sensors to provide comprehensive monitoring and security solutions [3, 4]. These systems capture and process vast amounts of video data, requiring efficient techniques for analyzing and detecting anomalies in real time [5].

Video-based anomaly detection plays a vital role in IoT video surveillance systems as it enables the automatic identification of abnormal events or behaviors that deviate from expected patterns [6-8]. By leveraging computer vision algorithms, anomaly detection algorithms can detect and alert operators to potential security threats, safety violations, or irregular activities, enhancing the overall security and situational awareness of the surveillance system [9, 10].

In recent years, there have been significant advancements in video-based anomaly detection technologies. Traditional approaches relied on handcrafted features and rule-based algorithms, which often had limitations in handling complex scenarios and achieving high detection accuracy. However, with the emergence of deep learning techniques [11-13], there has been a paradigm shift in anomaly detection approaches [14]. Deep learning algorithms, such as Generative Adversarial Networks (GANs), Recurrent Neural Networks (RNNs) [15], as well as Convolutional Neural Networks (CNNs) [16], have illustrated remarkable capabilities in learning discriminative representations and capturing intricate spatio-temporal patterns from video data.

Deep learning-based approaches have demonstrated superior performance in anomaly detection applications [17, 18]. They have the ability to automatically learn and extract relevant features directly from raw video data, enabling more robust and accurate anomaly detection. However, despite the promising results, there are still several research gaps and limitations that require to be addressed to exploit the potential of deep learning in this field fully.

This review paper aims to address the current limitations and research gaps in deep learning-based anomaly detection for IoT video surveillance systems. It will review and analyze the most recent methods and advancements in the field, focusing on identifying and exploring these research gaps. The paper investigates deep learning-based approaches and methodologies to tackle these challenges, aiming to enhance detection accuracy, address complex scenarios, and improve real-time performance. Additionally, extensive experimental evaluations and performance analyses will be conducted to validate the effectiveness of the suggested methods. By addressing these aspects, this review paper will contribute to the existing literature and provide valuable insights for researchers, practitioners, and system developers working on deep learning-based anomaly detection in IoT video surveillance systems.

This study delves into recent advancements in deep learning methodologies within the context of anomaly detection, examining various categories, including Recurrent Neural Networks (RNNs), Convolutional Neural Networks (CNNs), Autoencoders, Graph Convolutional Networks (GCNs), and Generative Adversarial Networks (GANs). By comprehensively exploring each deep learning category in subsequent sections, this research endeavors to not only unravel the intricacies of these methods but also to propose strategies for enhancing interpretability. Addressing the challenges posed by limited training data and concept drift, the study aims to contribute insights and methodologies that facilitate a clearer understanding of deep learning models, ensuring their effectiveness in the ever-evolving landscape of IoT environments.

The motivation behind this comprehensive review paper stems from the imperative need to address the current limitations and research gaps in deep learning-based anomaly detection for IoT video surveillance systems. By focusing on identifying anomaly in videos, the paper aims to investigate the deep learning-based approaches and methodologies that not only enhance detection accuracy but also address the challenges posed by limited training data and the dynamic nature of evolving IoT environments. The overarching goal is to improve real-time performance in complex scenarios.

The research contributions of this study are summarized as follows,

1) The review paper systematically identifies and discusses the existing research gaps and limitations in deep learning-based anomaly detection for video surveillance systems.

2) The paper introduces novel approaches that address the identified research gaps and limitations, aiming to enhance detection accuracy, address complex scenarios, and improve real-time performance in video-based anomaly detection.

3) The paper conducts extensive experimental evaluations and performance analyses to validate the effectiveness of the suggested methods, comparing them with existing state-of-the-art techniques and demonstrating their contributions regarding improved detection accuracy and real-time capabilities.

The rest of this paper is as follows, Section II review of related works. Section III discuss about research methodology. Section IV outlines the performance metrics. Section V presents results and discussion. Finally, this paper concludes in Section VI.

II. Related Work

The authors in [19] present a study on video anomaly detection with compact feature sets for online performance. The research methodology involves developing a framework that extracts compact yet discriminative features from video data to detect real-time anomalies. Key features of the study include the use of deep learning techniques for feature extraction, the incorporation of temporal information for enhanced anomaly detection, and the focus on online performance to ensure timely detection. The findings demonstrate that the suggested approach achieves efficient as well as accurate anomaly detection while reducing the computational complexity. However, one limitation highlighted in the study is the potential trade-off between the compactness of feature sets and the detection accuracy, which requires careful optimization. Overall, this research provides valuable insights into developing efficient video anomaly detection systems with compact feature sets for real-time applications.

In study [20], the application of neural networks for anomaly detection in videos is presented specifically in the context of video surveillance applications. The study presents a comprehensive overview of various neural network approaches, such as RNNs and CNNs, for analyzing video data and identifying anomalies. The findings highlight the effectiveness of neural networks in detecting anomalies in video surveillance data, showcasing their ability to capture complex spatial and temporal patterns. The paper emphasizes the potential of neural networks to enhance video surveillance systems by providing accurate and efficient anomaly detection capabilities, paving the way for improved security and monitoring in various real-world applications.

A thorough survey of deep learning-based techniques for video anomaly detection was published in study [21]. The research methodology involves an extensive examination of existing literature in the field, focusing on deep learning approaches applied to video anomaly detection. The key features of the study include categorizing and analyzing various deep learning methods, such as CNNs, RNNs, Autoencoders, GANs, and GCNs, in terms of their application, strengths, and limitations. The findings highlight the effectiveness of deep learning techniques in detecting anomalies in video data while acknowledging the challenges and limitations associated with each approach. This review serves as a valuable resource for researchers and practitioners, offering insights into the current state-of-the-art deep learning methods and their implications in video anomaly detection.

This paper in [4] focuses on anomaly detection using edge computing in video surveillance systems. The research methodology involves implementing an edge computing framework for real-time video analysis and anomaly detection. Key features of the study include utilizing edge devices to process video data locally, reducing latency and bandwidth requirements, and applying deep learning algorithms for anomaly detection. The findings demonstrate the effectiveness of edge computing in improving real-time anomaly detection performance. However, the study acknowledges limitations such as limited computational resources on edge devices and potential challenges in scaling the system. Overall, this research provides insights into leveraging edge computing for video surveillance anomaly detection while recognizing the associated limitations.

Finally, in study [22], a taxonomy of deep models for anomaly detection in surveillance videos offers a comprehensive review and performance analysis. The study systematically categorizes various deep learning models based on their thematic attributes and provides a detailed examination of each category's strengths, limitations, and performance metrics. The findings highlight the effectiveness of deep models in detecting anomalies in surveillance videos, showcasing their ability to capture intricate spatial and temporal patterns. The paper emphasizes the importance of selecting appropriate deep-learning architectures based on the specific requirements of surveillance applications. Overall, this research provides valuable insights into the state-of-the-art deep learning approaches for anomaly detection in surveillance videos, facilitating informed decision-making for implementing robust and efficient surveillance systems.

As results, the papers contribute to advancing video anomaly detection using deep learning while addressing critical challenges and needs in the field. The research in [16] emphasizes real-time performance by introducing a framework with compact feature sets, addressing the need for efficiency; however, the potential trade-off between compactness and accuracy requires careful consideration. The study in [17] contributes to improved interpretability by exploring neural networks for video surveillance, capturing complex patterns, although it does not explicitly tackle challenges related to limited training data or concept drift. The survey in [18] categorizes deep learning methods, providing a comprehensive overview but leaves room for deeper exploration of strategies for handling limited training data and concept drift. The research in [4] focuses on real-time performance through edge computing, acknowledging challenges in scalability and limited resources, indicating potential limitations. Lastly, the study in [19] offers taxonomy of deep models, aiding interpretability, but specific strategies for addressing limited training data and concept drift could be further investigated. While each paper makes notable contributions, future research should continue to bridge gaps and enhance the interpretability, handling of limited training data, addressing concept drift, and ensuring real-time performance in deep learning-based video anomaly detection systems.

III. Research Methodology

This study intends to investigate the recent deep learning methods in video-based anomaly detection methods. Various methods have been explored in different categories. These categories are RNNs, CNNs, Autoencoders, GCNs as well as GANs. The detail of each deep learning category is discussed.

The investigation delves into the inner workings of each model, scrutinizing the learned representations and features that contribute to their predictions. Techniques such as feature visualization, activation mapping, and attention mechanisms are employed to elucidate the influential aspects of input data on model outputs. Moreover, the study scrutinizes model training procedures, optimization techniques, and generalization capabilities, aiming to understand how these factors impact the interpretability of the models. By assessing robustness, handling concept drift, and employing post-hoc explanation methods like SHAP and LIME, the research aims to provide a holistic understanding of deep learning models, making them more transparent and interpretable. Through this multifaceted investigation, the study aspires to contribute valuable insights and methodologies to address the challenges posed by limited training data and the dynamic nature of evolving IoT environments, ultimately facilitating the deployment of interpretable deep learning models in practical anomaly detection scenarios.

A. Convolutional Neural Networks (CNNs)

The CNNs have emerged as a powerful deep learning technique for analyzing visual data, particularly images and videos [14, 23, 24]. They are specifically designed to capture spatial dependencies and hierarchical patterns present in visual data, making them highly effective for tasks such as image classification, object detection, and even video-based anomaly detection. In the context of anomaly detection, CNNs can learn to detect unusual patterns or events in videos, enabling the development of systems that can automatically identify anomalies or abnormal behavior in various domains, including surveillance, industrial monitoring, and healthcare.

Several existing methods leverage CNNs for video-based anomaly detection, showcasing the effectiveness of this approach. One popular approach uses spatiotemporal CNNs [25, 26], which capture temporal and spatial information by incorporating 3D convolutions [27, 28]. These models excel at detecting anomalies that involve motion or dynamic patterns. Another approach is the use of deep feature learning, where CNNs are pre-trained on large-scale image datasets and then fine-tuned for anomaly detection on video data. By leveraging pre-trained CNN models, these methods can effectively extract high-level features from videos, enabling robust anomaly detection.

B. Recurrent Neural Networks (RNNs)

The RNNs are a class of deep learning models specifically designed to process sequential data by capturing temporal dependencies [28, 29]. They have gained significant attention in various domains, consisting of video analysis, natural language processing, and speech recognition. In the context of video-based anomaly detection, RNNs have shown great promise [30]. By considering the temporal context of video sequences, RNNs can effectively capture long-term dependencies and learn complex patterns, enabling the detection of anomalies or abnormal behavior in videos.

There are several existing RNN-based methods that leverage the power of sequential modeling for video-based anomaly detection. These methods have demonstrated their effectiveness in capturing temporal patterns and detecting video anomalies. Some notable examples include Long Short-Term Memory (LSTM) [31, 32], Gated Recurrent Unit (GRU) [33, 34], and Convolutional Recurrent Neural Network (CRNN) [35].

One widely used RNN-based method for video-based anomaly detection is LSTM. The LSTM is designed to address the vanishing gradient problem that can occur in traditional RNNs [32]. By incorporating memory cells and gating mechanisms, LSTM can capture long-term dependencies and effectively learn temporal patterns. In the context of anomaly detection, LSTM models can be trained on normal video sequences and learn to forecast the next frame based on the prior frames. Anomalies can be detected by measuring the deviation between the predicted frame as well as the actual frame. LSTM has been successfully applied in diverse domains, like surveillance [36], where it has shown promising results in detecting anomalous events like abnormal behavior or unusual object movements.

C. Autoencoders

Autoencoder Networks are a class of neural networks that are designed for data compression and unsupervised learning [37, 38]. Autoencoders consist of a decoder network that reconstructs the input data from the latent representation as well as an encoder network that maps the input data into a lower-dimensional latent space [25]. This architecture enables autoencoders to learn efficient representations of the input data by capturing the most salient features. In the context of video-based anomaly detection, autoencoders can be leveraged to detect anomalies by reconstructing normal video frames accurately, as well as identifying deviations from the learned representation.

There are several existing autoencoder-based methods that have been applied to video-based anomaly detection, showcasing the effectiveness of this approach. Some notable examples include Variational Autoencoders (VAE) [39], Stacked Autoencoders (SAE) [40], and Convolutional Autoencoders (CAE) [38, 41].

Incorporating a probabilistic interpretation, variational autoencoders (VAEs) are a type of autoencoder that may provide fresh samples from the learned latent space. VAEs model the latent space as a probability distribution and learn to encode and decode data based on this distribution. In the context of anomaly detection, VAEs can be trained on normal video frames and learn to generate new frames that adhere to the learned distribution. Anomalies can be detected by measuring the reconstruction error or by evaluating the likelihood of the generated frames. VAEs have shown promising outcomes in detecting video anomalies, such as unusual activities or objects that deviate from the learned normal behavior.

Convolutional Autoencoders (CAEs) are a variant of autoencoders specifically designed for handling image and video data. CAEs utilize convolutional layers in the encoder and decoder networks to capture spatial dependencies and preserve the structure of the input data. By learning a compact representation of normal video frames, CAEs can effectively reconstruct the input frames and identify anomalies according to deviations from the learned representation. CAEs have been successfully applied in video-based anomaly detection tasks, such as detecting abnormal events or behavior in surveillance footage or industrial monitoring. The ability of CAEs to capture both local and global features from video frames makes them suitable for detecting complex anomalies that involve spatial patterns. Therefore, Autoencoder Networks offer a powerful approach to video-based anomaly detection by learning efficient representations of normal video frames and detecting deviations from the learned representation. Existing autoencoder-based methods, such as Variational Autoencoders (VAEs) and Convolutional Autoencoders (CAEs), have demonstrated their effectiveness in capturing the salient features of video data and detecting anomalies based on reconstruction errors or generated samples. These methods contribute to the advancement of video-based anomaly detection techniques as well as enable the development of intelligent systems for identifying abnormal behavior or events in various domains.

D. Generative Adversarial Networks (GANs)

Generative Adversarial Networks (GANs) are a deep learning models class including two components: a discriminator and a generator [42, 43]. GANs are primarily known for their ability to generate realistic synthetic data that closely resembles the training data. However, GANs have also found applications in anomaly detection, including video-based anomaly detection [44]. By training GANs on normal video sequences, they can learn the underlying patterns and generate realistic frames [45]. Anomalies can be detected by measuring the deviation between the generated frames and the actual frames, thereby identifying abnormal events or behavior in videos.

Several existing GAN-based methods have been expanded for video-based anomaly detection, showcasing the effectiveness of GANs in this domain [46]. Notable examples include AnoGAN [47], Adversarial Variational Bayes (AVB) [48], and Video Anomaly GAN (VAD) [49].

AnoGAN is a GAN-based anomaly detection method that combines the power of GANs with an unsupervised learning framework. AnoGAN utilizes a generator network to generate synthetic data and a discriminator network to differentiate between generated and real data. The anomaly detection process involves finding the latent vector that generates the closest match to a given anomalous frame. By iteratively updating the latent vector, AnoGAN can generate frames that closely resemble the anomalies. AnoGAN has shown promising results in detecting anomalies in videos by effectively capturing the underlying patterns and generating synthetic anomalies for comparison.

Video Anomaly GAN (VAD) is a GAN-based method specifically designed for video-based anomaly detection. VAD employs a spatio-temporal GAN architecture to model the temporal dependencies and spatial patterns in video sequences. The generator network in VAD generates realistic video sequences, while the discriminator network distinguishes between real and generated videos. VAD utilizes the discrepancy between the generated and real videos to detect anomalies. By training on normal video sequences, VAD learns the normal patterns and can identify deviations that indicate anomalies in the video data. VAD has shown promising results in various applications, including surveillance and industrial monitoring, by effectively capturing the complex spatio-temporal dependencies in videos.

E. Graph Convolutional Networks (GCNs)

The GCNs are a neural networks class designed to process data structured as graphs[50] . GCNs extend the capabilities of traditional CNNs to handle data that exhibits complex relationships and dependencies, such as social networks, molecular structures, and video-based anomaly detection. In the field of video-based anomaly detection, GCNs can capture the spatio-temporal relationships between video frames and effectively model the interactions between different regions of interest. By leveraging the graph structure inherent in video data, GCNs enable the detection of anomalies by learning the normal behavior patterns and identifying deviations from them.

There are several existing GCN-based methods that have been utilized to video-based anomaly detection, showcasing the effectiveness of graph-based approaches in this domain. Some notable examples include Graph Convolutional Autoencoders (GCAEs), Temporal Graph Convolutional Networks (TGCNs), and Graph Convolutional Recurrent Networks (GCRNs).

Graph Convolutional Autoencoders (GCAEs) combine the power of autoencoders with graph convolutions to learn compact representations of video frames in a graph structure. GCAEs encode the video frames as nodes in a graph and leverage the connectivity information between the frames to capture their dependencies. By reconstructing the video frames from the learned latent representations, GCAEs is able to identify anomalies by measuring the deviation among the reconstructed frames as well as the actual frames. In tasks involving the detection of anomalous events or behavior in surveillance footage or traffic monitoring, GCAEs have demonstrated promising outcomes.

Temporal Graph Convolutional Networks (TGCNs) extend the capabilities of GCNs by incorporating the temporal dynamics of video data. TGCNs model the video frames as nodes in a temporal graph, where the edges capture the temporal dependencies between frames. By performing graph convolutions across the temporal dimension, TGCNs can effectively capture the spatio-temporal patterns and dependencies in videos. TGCNs have shown great potential in detecting anomalies in video sequences, such as identifying abnormal motion patterns or unusual temporal behaviors.

The GCRNs combine the strengths of both recurrent neural networks (RNNs) and GCNs to capture both spatial and temporal dependencies in video data. GCRNs model the video frames as nodes in a graph and utilize recurrent connections to capture the temporal dynamics. By performing graph convolutions and recurrent computations, GCRNs can effectively capture the complex spatio-temporal patterns and dependencies in videos. GCRNs have demonstrated promising results in video-based anomaly detection tasks, such as detecting anomalous events or behaviors in surveillance videos or monitoring industrial processes.

F. Algorithms Hyperparameter Setting

In this study, a CUHK Avenue dataset[1] is used the video-anomaly detection experiments. Moreover, the hyperparameter setting for the algorithms are as, for RNNs, the hyperparameter setting for RNNs is: hidden size = 256, learning rate = 0.001, batch size = 16, dropout rate = 0.2, number of epochs = 501. The hyperparameter setting for CNNs is: filter size = 3x3, number of filters = 64, learning rate = 0.0001, batch size = 32, dropout rate = 0.5, number of epochs = 100. For Autoencoders, the hyperparameter setting for Autoencoders is: latent dimension = 128, learning rate = 0.0005, batch size = 64, dropout rate = 0.1, number of epochs = 2003. For GCNs, the hyperparameter setting for GCNs is: number of layers = 3, hidden size = 64, learning rate = 0.01, batch size = 128, dropout rate = 0.2, number of epochs = 300. Finally, the hyperparameter setting for GANs is: latent dimension = 256, learning rate = 0.0001, batch size = 16, dropout rate = 0.3, number of epochs = 200.

IV. Performance Metrics

Performance measurements play an essential role in evaluating the effectiveness of deep learning-based anomaly detection models. When it comes to assessing the performance of such models, three commonly used metrics are F-score, recall, and precision. These metrics aid in quantifying the model's accuracy in detecting abnormalities and offer insights into many facets of model performance.

Precision is a measure of how many of the instances labeled as anomalies by the model are actually true anomalies. It represents the true positive predictions ratio (correctly detected anomalies) to the total number of predicted anomalies (both false positives and true positives). A high precision score means that the model is more accurate at correctly identifying abnormalities and has a lower rate of false alarms. Precision is calculated using the formula Recall, as well known as sensitivity or true positive rate, is a measure of how many true anomalies the model can successfully detect. It denotes the true positive predictions ratio to the total number of actual anomalies in the dataset. F-score, also called the F1 score, is a harmonic mean of precision and recall. It supplies a single metric that balances both recall and precision, taking into account false negatives and false positives. The F-score combines recall and precision into a single value and is useful when there is a trade-off among recall and precision. The F-score is calculated utilizing the formula:

$$F - score = 2 * ((Precision * Recall) / (Precision + Recall))$$

The F-score ranges from 0 to 1, with 1 being the ideal score that indicates perfect precision and recall.

V. Results and Discussion

A. Analysis of CNN-based Methods

The table shows the recall, F-score, and precision for various CNN-based methods used in anomaly detection. We selected most used CNN methods in literature. These methods include ConvLSTM, Temporal Convolutional Network (TCN), 3D Convolutional Networks, I3D (Inflated 3D Convolutional Networks), TSN (Temporal Segment Networks), and C3D (Convolutional 3D). Fig. 1 shows the result of CNN-based methods.

Examining the precision values, we observe a range from 0.86 to 0.92. Higher precision values indicate a lower rate of false positives, reflecting the ability of the models to accurately identify anomalies while minimizing incorrect detections. The method with the highest precision in the table is 3D Convolutional Networks, suggesting a stronger precision performance in anomaly detection.

In terms of recall, the values range from 0.82 to 0.92. Recall measures the ability of the models to capture the actual anomalies present in the data. A higher recall value indicates a higher proportion of correctly identified anomalies, reducing the risk of false negatives. The I3D stands out with the highest recall score, implying its effectiveness in capturing a larger number of true anomalies.

The F-scores in the table range from 0.84 to 0.92. The F-score combines recall and precision, supplying an overall assessment of model performance. A higher F-score shows a better balance among recall and precision. In this case, I3D (Inflated 3D Convolutional Networks) demonstrates the highest F-score, indicating its effectiveness in achieving a trade-off between accurately identifying anomalies and minimizing false alarms.

B. *Analysis of RNN-based Methods*

This section presents an overview of performance metrics for different RNN-based anomaly detection methods. These methods have been evaluated using precision, recall, and F-score, providing insights into their effectiveness in detecting anomalies. Among the evaluated RNN-based methods, notable approaches include the LSTM-Autoencoder, GRU-Autoencoder, Variational LSTM (VLSTM), Temporal Convolutional LSTM (TCLSTM), Stacked LSTM, and Gated Recurrent Unit (GRU).

The performance metrics in Fig. 2 provides valuable insight into the strengths and capabilities of these RNN-based methods. Precision values in the 0.80 to 0.95 range show the ability of the models to accurately identify anomalies while minimizing false positives. This is crucial for ensuring that detected anomalies are truly meaningful and actionable. Recall values, ranging from 0.86 to 0.92, reflect the models' ability to capture a significant proportion of actual anomalies present in the data. A higher recall value indicates a reduced risk of false negatives, ensuring that fewer anomalies go undetected.

C. *Analysis of Autoencoders Methods*

This section presents result of analysis for a collection of recent Autoencoders-based anomaly detection methods, along with their corresponding precision, recall, and F-score performance metrics. We selected most cited Autoencoders methods as methods include Variational Autoencoder (VAE), Adversarial Autoencoder (AAE), Deep Autoencoder, Denoising Autoencoder, Sparse Autoencoder, and Variational Graph Autoencoder (VGAE).

As shown in Fig. 3, in terms of recall, the Sparse Autoencoder demonstrates the highest value at 0.92. This implies that the Sparse Autoencoder has a superior capability to capture a larger proportion of actual anomalies present in the data. Considering the F-score, which combines both precision and recall, the Deep Autoencoder still emerges as the method with the highest score at 0.90. This indicates that the Deep Autoencoder achieves a better balance between accurately identifying anomalies and minimizing false alarms compared to the other methods.

The better performance of the Deep Autoencoder can be attributed to its ability to learn deep, hierarchical representations of the input data. The deeper architecture permits the model to capture more complex patterns and anomalies in the data, leading to ameliorated precision, recall, and overall F-score. The Dense Autoencoder's superior performance showcases the importance of utilizing deep architectures in Autoencoders-based anomaly detection methods.

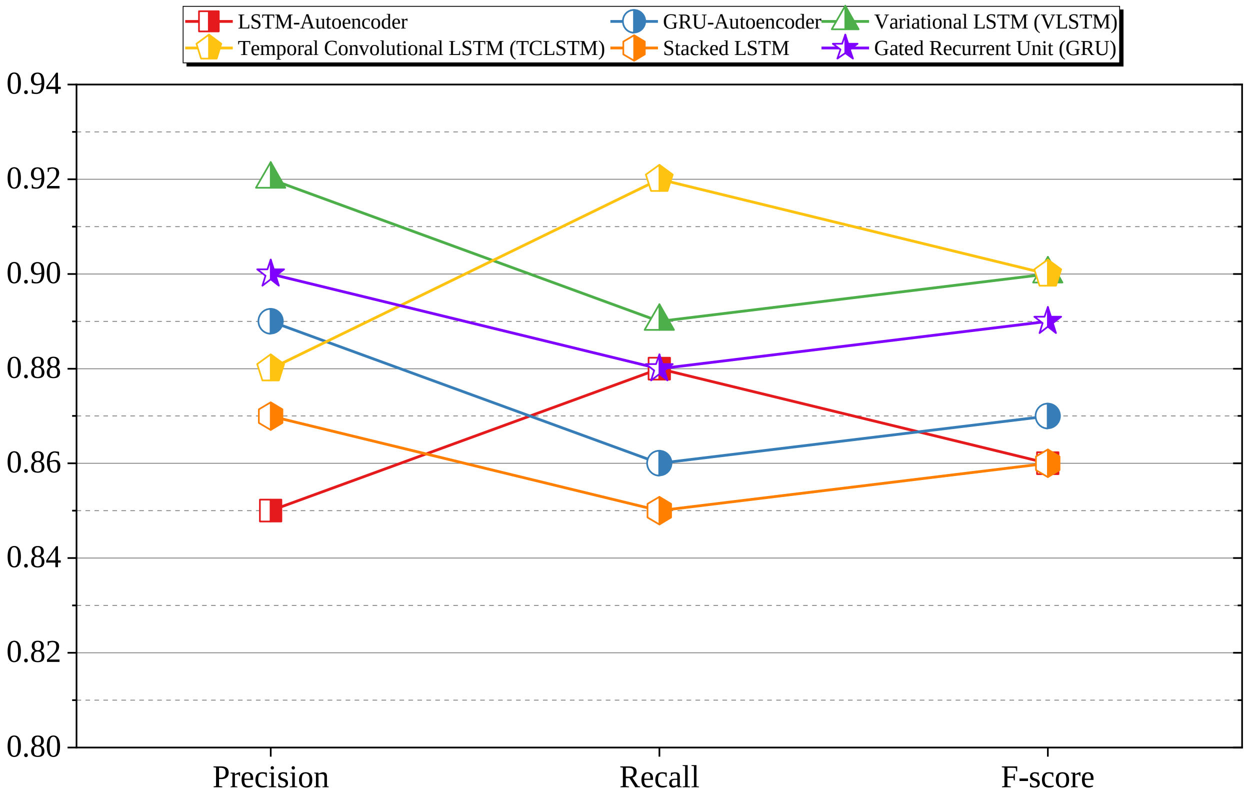

Fig. 2. Result of RNN-based methods.

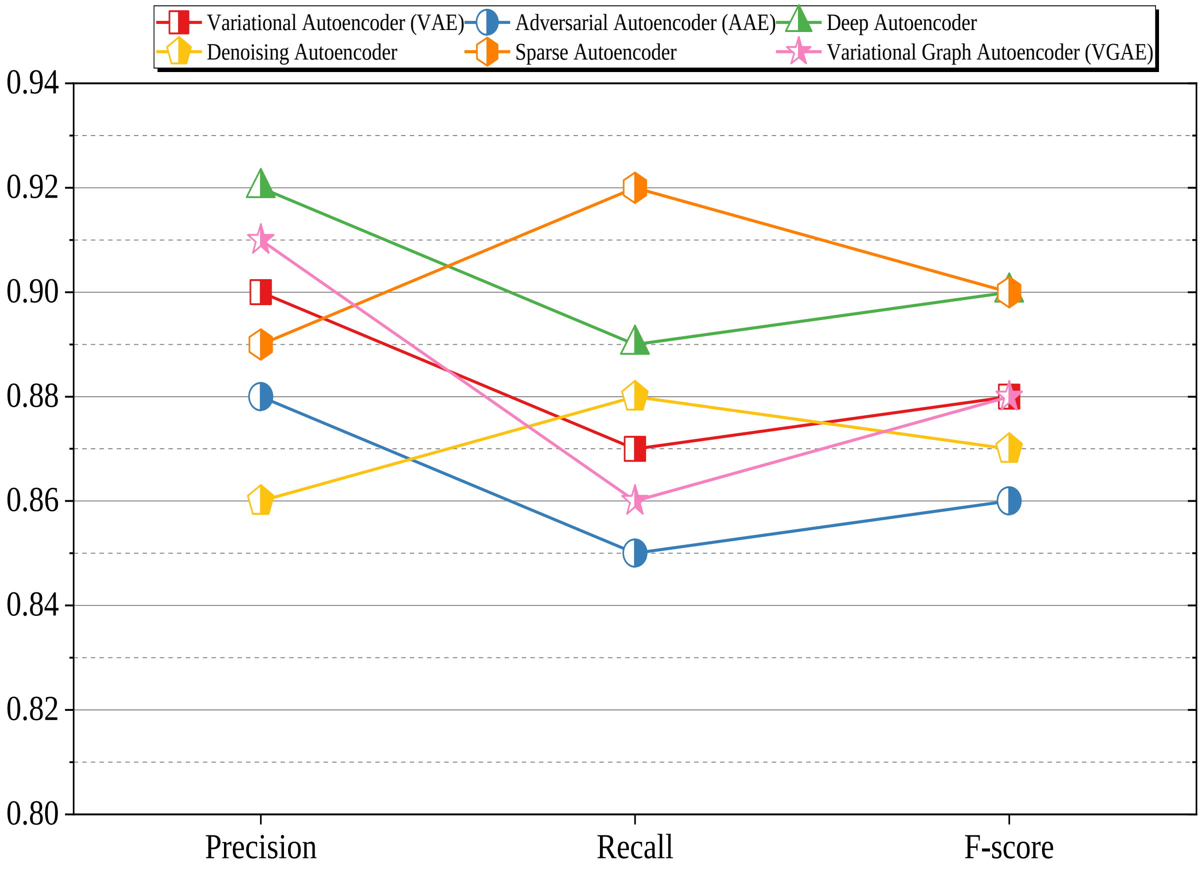

Fig. 3. Result of Autoencoders methods analysis.

D. Analysis of GANs-based Methods

This section presents a selection of GAN-based anomaly detection methods, along with their associated precision, recall, and F-score performance metrics. These methods include AnoGAN, Boundary-Seeking GAN (BGAN), Adversarial Variational Bayes (AVB), DualGAN, Energy-based GAN (EBGAN), and Generative Moment Matching Networks (GMMN).

As shown in Fig. 4, upon analyzing the table, it is clear that the performance of these GAN-based methods varies across different evaluation metrics. When considering precision, AVB stands out with a value of 0.90, indicating its ability to precisely identify anomalies while minimizing false positives compared to the other methods in the table. In terms of recall, DualGAN demonstrates the highest value at 0.89, suggesting its superior capability to capture a larger proportion of actual anomalies present in the data. Analyzing the F-scores, which provide a combined measure of precision and recall, AVB also outperforms other methods with an F-score of 0.88. This implies that AVB achieves a better balance between accurately identifying anomalies and minimizing false alarms compared to the other GAN-based methods. The better performance of AVB can be attributed to its ability to leverage the advantages of both adversarial learning and variational inference. By incorporating a variational autoencoder framework into the GAN architecture, AVB is able to model the underlying data distribution more effectively, resulting in improved precision, recall, and overall F-score.

E. Analysis of GCNs-based Methods

We select a collection of recent GCNs-based anomaly detection methods, along with their precision, recall, and F-score performance metrics. The selected methods include Graph Convolutional Autoencoder, GraphSAGE, Graph Attention Network (GAT), Deep Graph Convolutional Network (DGCN), Graph Convolutional LSTM (GC-LSTM), and Graph Isomorphism Network (GIN).

As shown in Fig. 5, upon analyzing the result data, it is evident that the GCNs-based methods exhibit varying performance across different evaluation metrics. Notably, GAT stands out in terms of precision, achieving an impressive value of 0.92. This indicates its exceptional ability to accurately identify anomalies while minimizing false positives compared to other methods listed in the table.

In the aspect of recall, GIN surpasses the rest with a score of 0.93, demonstrating its superior capability to capture a larger proportion of actual anomalies present in the data. Moreover, when considering the F-scores that provide a comprehensive measure of both precision and recall, GIN emerges as the top performer with an F-score of 0.91. This indicates that GIN strikes a better balance between accurately identifying anomalies and minimizing false alarms compared to other GCNs-based methods. The outstanding performance of GIN can be attributed to its innovative utilization of graph isomorphism as a fundamental concept within its design. By leveraging graph isomorphism, GIN effectively captures the underlying structural similarities and relationships in the data, leading to improved precision, recall, and overall F-score. This highlights the significance of incorporating domain-specific knowledge and leveraging graph-based representations to increase anomaly detection performance in GCNs-based approaches.

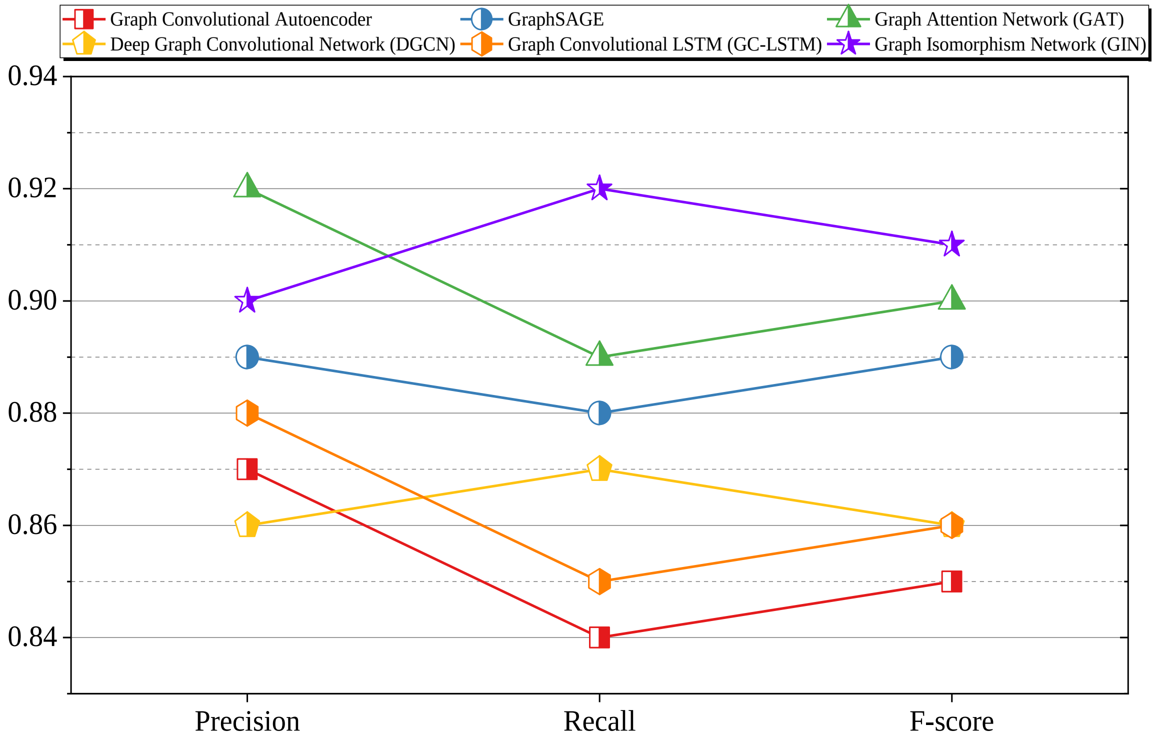

Fig. 5. Result of GCNs-based methods.

VI. Conclusion

In conclusion, this review paper sheds light on the significance of anomaly detection in IoT surveillance systems and the shift towards deep learning-based approaches to overwhelm the limitations of traditional methods. The justification for conducting a comprehensive review lies in the quest to identify the most accurate methods for anomaly detection. Through the collection of results and performance evaluations, this review paper provides a comprehensive analysis of existing deep learning techniques, bridging the research gaps in anomaly detection for IoT surveillance systems. By addressing these challenges and presenting a thorough examination of deep learning methods, this review paper paves the way for development of more efficient and effective anomaly detection solutions in the realm of IoT surveillance. For future work, one direction for further study is to concentrate on enhancing the interpretability of deep learning-based anomaly detection models for IoT surveillance systems. Developing techniques to explain the decisions and reasoning of these models can provide valuable insights into the detection process and build trust in their functionality. Exploring explainable AI methods, including attention mechanisms or feature visualization, can help in understanding the factors influencing anomaly detection and enable effective decision-making. Moreover, another important direction for future research is addressing the challenges posed by concept drift and dynamic environments in IoT surveillance systems. Anomaly detection models need to be adaptable and capable of continuously learning and updating their knowledge to accommodate changing patterns and emerging anomalies. Investigating techniques such as online learning, transfer learning, or adaptive models can facilitate the detection of evolving anomalies in real-time scenarios. Additionally, incorporating contextual information and temporal dependencies can enhance the models' ability to differentiate between normal variations and true anomalies in dynamic environments.

***Abstract*—Cervical cancer classification has witnessed numerous advancements through deep learning methods; however, existing approaches often rely on multiple models for segmentation and classification, leading to heightened computational demands and prolonged training times. In this research, a lightweight deep learning framework for cervical cancer classification is presented. The framework comprises three primary components: a Graph-Cut Guided Region of Interest (ROI) segmentation algorithm, a streamlined DenseNet architecture, and a Multi-Class Logistic Regression classifier. The Graph-Cut Guided ROI segmentation algorithm is used to accurately isolate nuclei regions within multicellular Pap smear images. This is a lightweight algorithm that is able to achieve high segmentation accuracy with minimal computational overhead. The streamlined DenseNet architecture is used to efficiently extract salient features from the segmented images. This architecture is specifically designed to reduce feature redundancy and eliminate incongruous feature maps. The Multi-Class Logistic Regression classifier is used to classify the segmented images into different cell types and stages of cervical cancer. Experimental results show the proposed method is able to achieve high classification accuracy with minimal training time. The framework was trained and evaluated on a dataset of 963 Pap smear images. The proposed framework achieved a 98% cell type classification accuracy in precision, recall, and F1-score for classifying multi-cell Pap smear images. The training loss was also very low. The average training time was 21 minutes for different sets of training images, and the average testing time was 0.50 seconds for different sizes of testing images, which is much lower than the existing methods.**

Keywords*—Cervical cancer classification; deep learning; lightweight deep learning framework; graph-cut guided ROI segmentation algorithm; nuclei region isolation

I. INTRODUCTION

Cervical cancer is the fourth most common cancer among women worldwide, with a substantial impact on public health [1]. The Pap smear, a widely used screening method, involves the microscopic examination of cervical cells to detect abnormalities and enable early intervention [2], [3]. Automated classification of these cells can significantly expedite the diagnosis process and facilitate timely medical intervention. In recent times, deep learning techniques have emerged as powerful tools for medical image analysis, with numerous methodologies proposed for cervical cancer classification While deep learning models have demonstrated impressive performance in various medical imaging tasks, they often require extensive computational resources, intricate model architectures, and prolonged training times [4], [5], [6], [7]. Many existing approaches to cervical cancer classification utilize separate models for segmentation and classification [8], [9], [16], [20]. The paradigm of utilizing separate models for segmentation and classification exacerbates the computational demands of the overall system. The need for multiple models not only increases resource requirements but also extends the time required for model training and inference. This can hinder the integration of automated cervical cancer classification systems into clinical practice, where prompt diagnosis is crucial for effective treatment planning. Additionally, some existing approaches employ feature fusion methods to combine the outputs of separate models [10], [11], [14], [18]. While these methods attempt to leverage the strengths of different models, they can introduce further complexity and potential sources of error. Integrating outputs from multiple models requires careful consideration of weightings and fusion strategies, and may not always result in optimal performance. Moreover, many existing methods for segmenting and classifying cervical cancer cells in pap smear images are only tested with single cell images [12], [13], [14]. However, in reality, Pap smear images often contain multiple cells, which can make it more difficult to accurately segment and classify the cells.

This research endeavors to address these limitations by introducing an innovative methodology that enhances computational efficiency while maintaining robust classification accuracy. To mitigate the computational burden and accelerate the time-consuming segmentation process, a lightweight Graph-Cut Guided ROI segmentation algorithm is introduced this research. This algorithm utilizes graph-cut techniques to effectively segment nuclei regions from multicell Pap smear images. By incorporating graph-cut guidance, this proposed approach significantly improves segmentation accuracy while maintaining computational efficiency. This innovation not only expedites the preprocessing step but also ensures that accurate nuclei regions are extracted for subsequent feature extraction. To extract the meaningful and relevant features from the segmented Pap smear images, this research employs a lightweight DenseNet architecture. DenseNet is renowned for its ability to alleviate the vanishing gradient problem and promote feature reuse across layers. The modified DenseNet architecture is tailored to the characteristics of cervical cell images, enabling efficient feature extraction while minimizing feature redundancy. The architecture's capacity to eliminate uncorrelated feature maps further enhances computational efficiency without compromising classification accuracy. After feature extraction, the next crucial step is accurate classification. A Multi-Class Logistic Regression model is adopted for this purpose. This model is well-suited for scenarios with multiple classes, such as different stages of cervical cancer. Logistic Regression is known for its simplicity and interpretability, while still delivering commendable classification performance. Integrating this classifier into the proposed architecture preserves computational efficiency without compromising the accuracy of the classification process. The collaboration between these key components results in an integrated methodology that offers several notable advantages:

1) *Computational efficiency:* By integrating lightweight Graph-Cut Guided ROI segmentation and an efficient DenseNet architecture significantly reduces computational demands.

2) *Streamlined pipeline:* The integration of segmentation, feature extraction, and classification into a cohesive pipeline eliminates the need for multiple models, simplifying the overall process and reducing model training time.

3) *Enhanced accuracy*: The precision of the segmentation process and the efficacy of the feature extraction mechanism contribute to improved classification accuracy. Accurate segmentation ensures that only relevant regions are considered for feature extraction, while the DenseNet architecture captures essential image characteristics.

Following section of the article reviews recently developed convolutional neural network (CNN) methods for cervical cancer detection. Section II outlines the literature review. Section III presents the proposed deep learning-based framework for cervical cancer classification. Section IV discusses the experimental analysis and results. Finally, Section V the paper concludes with a summary of the key findings and implications.

II. Literature Review

The literature review reveals a range of approaches aimed at improving cervical cancer classification using fusion and multi-model CNNs. These methods address the challenge of accurate and efficient classification while considering the complex nature of medical image analysis. However, each approach comes with its own strengths and limitations.

Md Mamunur Rahaman et al. [14]: This research proposes the DeepCervix approach, leveraging a hybrid deep feature fusion technique. By integrating XceptionNet, ResNet50, VGG19, and VG16 models, this method addresses cervical cell classification. The fusion process occurs after preprocessing, followed by fine-tuning specific layers. However, challenges might arise in effectively combining features from diverse models, potentially affecting performance and interpretability. Ponnusamy Sukumar et al. [15]: The study introduces an automated framework for cervical cancer classification in Pap smear images. Employing watershed segmentation for cell nucleus segmentation and a feature extraction strategy involving Local Binary Pattern, texture, GLCM, laws texture, and histogram features, the approach utilizes principal component analysis for classification. The reliance on watershed segmentation could lead to issues due to local minima and noise sensitivity. Zaid Alyafeai et al. [16]: A pipeline-based architecture is suggested, featuring two pre-trained deep models for cervix region identification and tumor classification. Through modules like ROI detection, pre-processing with data augmentation, and lightweight CNN-based feature extraction, the method strives to address segmentation and classification. However, this approach's complexity, dependence on specific pre-trained models, and potential challenges in integration. Yuexiang Li et al. [17]: This research presents a model with a key-frame feature encoding network and a feature fusion network. By encoding pre- and post-acetic acid test images using ResNet-101 and employing an interpretable graph convolution network (E-GCN) for classification, the method focuses on feature fusion. The interpretability of the graph convolution network might present difficulties in a clinical setting.

Long D. Nguyen et al. [18]: An ensemble method involving feature concatenation and deep CNNs is introduced for cervical cancer classification. Combining features from InceptionResNet-v2, Inception-v3, and ResNet152, the method seeks to enhance classification. However, the substantial ensemble of CNNs might lead to resource-intensive computations and complexity. Srishti Gautam et al. [19]: The proposed deep learning-based approach addresses detection, segmentation, and classification of nuclei in single cell Pap smear images. While the focus on feature-based segmentation and AlexNet classification through transfer learning is promising, the method's applicability to diverse nucleus types should be evaluated. Deepa. K et al. [20]: This deep learning architecture emphasizes the classification of cervical cancer using a combination of segmentation and feature extraction techniques. The use of Mask Region Based Convolutional Neural Network for segmentation and subsequent feature extraction from segmented images with GLCM, Contourlet, and Gabor filters contributes to classification using VGG networks. The intricacies of combining multiple feature extraction techniques merit investigation. Swati Shinde et al. – DeepyCyto [21]: DeepyCyto proposes a hybrid methodology utilizing two workflows for cervical cancer classification. Integrating feature fusion vectors from pre-trained models, this approach applies machine learning ensemble and artificial neural network methods. Challenges in computational cost and adaptability to overlapping images could limit its feasibility.

III. Proposed method

The proposed research is a deep learning-based framework for cervical cancer classification. The framework consists of five modules: dataset, contrast enhancement, graph-cut guided ROI segmentation, image augmentation, and feature extraction using lightweight DenseNet. The dataset consists of 963 pap smear images with four distinct classes: HSIL, LSIL, NIM, and

SCC. Contrast enhancement is applied to improve nuclei visibility and aid feature extraction.

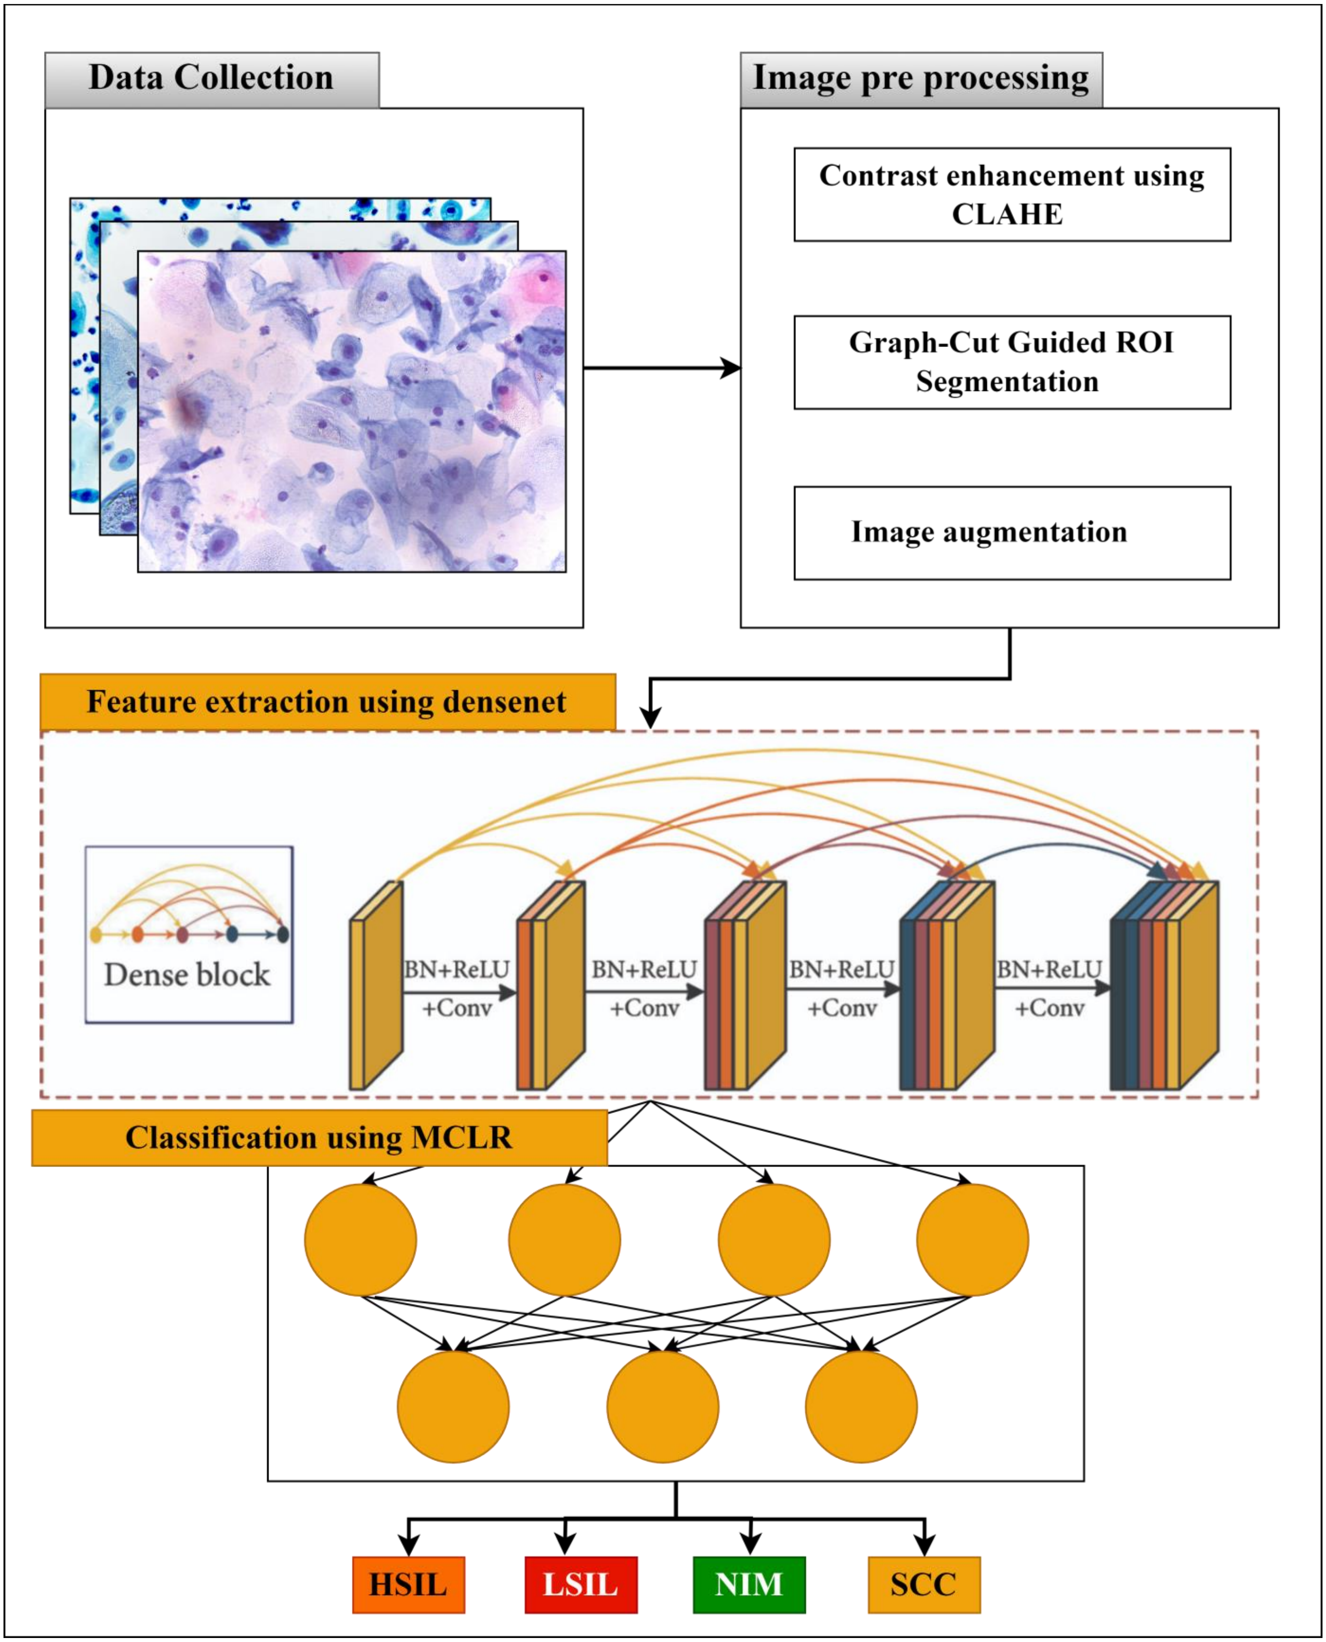

Fig. 1. Overall architecture of proposed cervical cancer classification system.

Graph-cut guided ROI segmentation is used to segment nuclei regions. Image augmentation is applied to enhance dataset diversity and generalize the deep learning model. Feature extraction using lightweight DenseNet is used to extract informative features from the segmented images. Finally, a Multi-Class Logistic Regression classifier is trained using the extracted features to classify the images into the four classes. Fig. 1 shows the overall architecture of proposed cervical cancer classification system.

A. Dataset Details

The dataset utilized in this research is named "Liquid based cytology pap smear images" [22].

This dataset was sourced from https://data.mendeley.com /datasets/zddtpgzv63/4, and it consists of a collection of 963 Pap smear images. These images were obtained using 40x magnification through the Leica ICC50 HD microscope. The dataset encompasses four distinct classes, each representing specific diagnostic categories. These classes are as follows: High Squamous Intraepithelial Lesion (HSIL), Low Squamous Intraepithelial Lesion (LSIL), Negative for Intraepithelial Malignancy (NIM), and Squamous Cell Carcinoma (SCC). These classes reflect different pathological conditions of cervical cells, enabling the classification of various stages of cervical cancer and cell types. Table I explains the different pap smear in the dataset.

TABLE I. DATASET OF PAP SMEAR IMAGES WITH CLASS NAMES AND NUMBER OF IMAGES

Image name	Image	Image details	Class name	Number of images
High Squamous Intraepithelial Lesion		HSIL refers to significant and advanced abnormal changes in the squamous epithelial cells of the cervix. These changes are considered more severe than low-grade lesions. HSIL is characterized by cells that appear markedly abnormal, with a higher likelihood of progressing to cervical cancer if left untreated [23].	HSIL	253
Low Squamous Intraepithelial Lesion		LSIL indicates milder abnormal cellular changes in the squamous epithelial cells of the cervix. These changes are not as severe as HSIL. While LSIL is generally considered less likely to progress to cancer than HSIL, it's still important to monitor and possibly treat these cases to prevent progression.	LSIL	198
Negative for Intraepithelial Malignancy.		This classification indicates that the cervical cell sample appears normal and lacks any signs of intraepithelial malignancy.	NIM	252
Squamous Cell Carcinoma.		Squamous cell carcinoma is a type of cervical cancer that originates from the squamous epithelial cells of the cervix. This classification indicates the presence of cancerous cells within the cervical sample. It's a more advanced stage of abnormality compared to HSIL, as it indicates the presence of actively dividing and invasive cancer cells.	SCC	260

B. Contrast Enhancement

Cervical cell images captured in Pap smears can have variations in intensity due to different acquisition conditions, staining procedures, and sample preparation techniques. These variations can make it challenging to differentiate between important structures like nuclei and background. Accurate nuclei detection relies on clear distinctions between nuclei and the surrounding background. Contrast enhancement enhances the visibility of nuclei, making them easier to detect. The streamlined DenseNet architecture relies on extracting meaningful features. Enhanced contrast helps the network identify subtle textures and structures, leading to more informative features. An accurate Multi-Class Logistic Regression classifier requires well-defined features. Enhanced contrast can make the differences between different cell types and stages of cervical cancer more pronounced, leading to improved classification accuracy. In this research, Contrast-Limited Adaptive Histogram Equalization (CLAHE) used to normalize the contrast of input pap smear image [24]. CLAHE enhances the contrast of an image while preventing excessive amplification of noise. It works by dividing the image intsmaller regions, applying histogram equalization to each region, and then limiting the contrast amplification. The process flow of contrast enhancement is explained in Algorithm 1.

Algorithm 1. CLAHE.

Step 1: Divide the Image into Tiles:

Divide the image into tiles of size (w, h).

Step 2: Compute Histograms:

For each tile, calculate the histogram for each colour channel (R, G, and B).

Step 3: Histogram Equalization:

Apply histogram equalization to each tile's histogram to redistribute pixel intensity values and enhance local contrast.

The equation for histogram equalization is:

$$\boldsymbol{f(x) = L - 1 - (L - 1) \times \frac{cdf(x)}{sum(cdf)}} \qquad [1]$$

where:

- **f(x) is the output intensity value for input intensity value x.**
- **L is the number of intensity levels in the image.**
- **cdf(x) is the cumulative distribution function of the input histogram.**
- **sum(cdf) is the sum of the values in the input histogram.**

Step 4: Clip Histograms:

To avoid over-amplification of noise, clip the histogram bins to a specified threshold.

The equation for clipping the histogram is:

$$if\ (x > threshold)\, \{\ x = threshold; \}$$

where:

- x is the current intensity value
- threshold is the clipping threshold

Step 5: Interpolation:

Smooth out intensity transitions between tiles by using interpolation techniques to maintain a coherent image appearance.

One common interpolation technique is bilinear interpolation, which is given by the following equation:

$$\boldsymbol{y = (x - x0) \times (y1 - y2) + (x1 - x) \times \frac{(y0 - y2)}{(x1 - x0)}} \qquad [2]$$

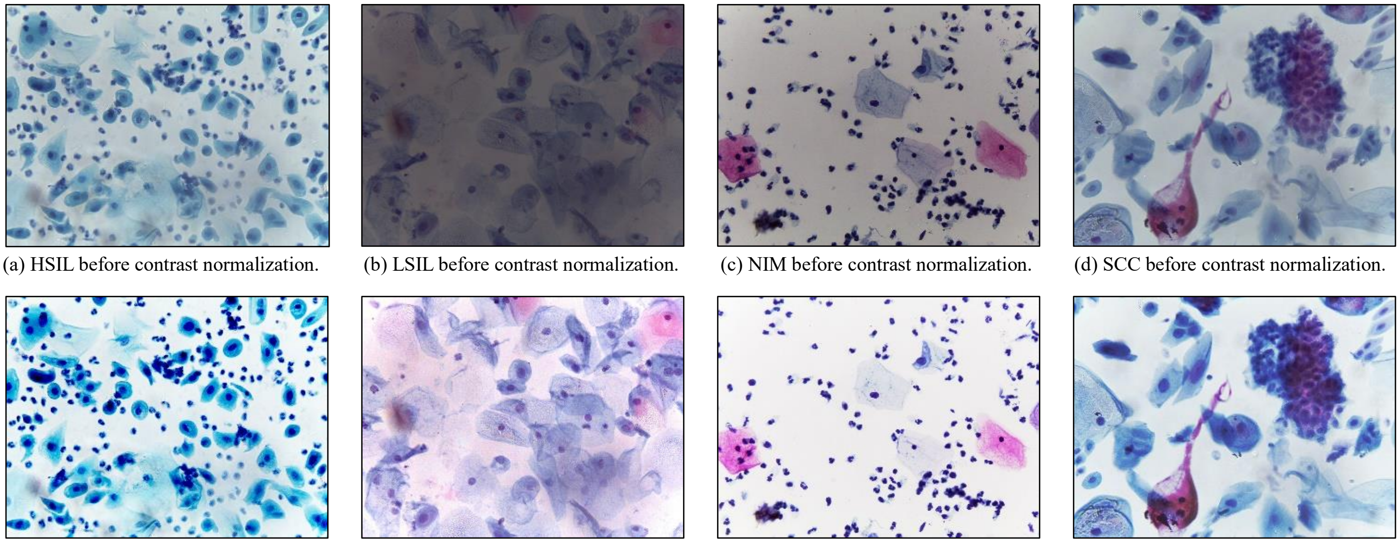
where:

- y is the output intensity value
- x is the input intensity value
- x0 and x1 are the x-coordinates of the two neighbouring pixels
- y0 and y1 are the y-coordinates of the two neighbouring pixels

Step 6: Reconstruct the Image:

Merge the enhanced tiles to reconstruct the full RGB image.

Fig. 2 illustrates the side-by-side comparison of Pap smear images before and after contrast normalization across different classes. The clear visual evidence showcases the remarkable impact of contrast enhancement using the CLAHE method. This enhancement process noticeably normalizes the contrast of the initial Pap smear images, resulting in enhanced image quality and improved visual clarity.



(a) HSIL before contrast normalization. (b) LSIL before contrast normalization. (c) NIM before contrast normalization. (d) SCC before contrast normalization.

(e) HSIL after contrast normalization. (f) LSIL after contrast normalization. (g) NIM after contrast normalization. (h) SCC after contrast normalization.

Fig. 2. Comparison of pap smear images before and after contrast normalization across different classes.

C. Proposed Graph-Cut Guided ROI Segmentation

The proposed graph-cut guided ROI segmentation algorithm is a way to divide an image into different regions of interest (ROIs). It works by using the principles of graph theory and energy minimization. By constructing a graph representation of the image, where pixels are nodes and their relationships are edges, the algorithm seeks to partition the image into foreground and background regions. Leveraging the concept of energy, the algorithm minimizes a cost function that encapsulates both local and global image characteristics. This approach yields detailed segmentation results, accurately defining nuclei regions from the complex background of multicell Pap smear images. The following steps outline the process of this segmentation method:

Algorithm. 2 graph-cut guided ROI segmentation

Step 1: Preprocessing

1.1 Input Image Preparation: The algorithm takes an input image I consisting of multicell Pap smear data. The image is represented as a grid of pixels, where each pixel is a node in the graph.

Step 2: Nuclei Detection and Seed Generation

2.1 Nuclei Detection: Nuclei are detected within the image I using method, S , that produces a binary mask M .

$$M = S(I) \quad [3]$$

2.2 Seed Point Generation: For each nucleus, a seed point $p\,i$ is generated. These seed points serve as initial markers for the graph-cut segmentation process.

$$p_i = (x_i, y_i), i = 1, 2, \dots, N \quad [4]$$

Step 3: Graph Construction

3.1 Construction of Graph: A graph $G = (V , E)$ is constructed, where V is the set of nodes (pixels) and E is the set of edges. Each pixel $v\,i\,j$ is a node in the graph.

$$V = \{v_{ij}\}, i = 1, 2, \dots, H; j = 1, 2, \dots, W \quad [5]$$

3.2 Edge Weights: Edge weights $w\,i\,j$, are assigned based on pixel intensities and spatial relationships.

$$wij, kl = exp\left(-\frac{(Iij - Ikl)^2}{2\sigma I^2}\right) \cdot exp\left(-dij, \frac{kl^2}{2\sigma d^2}\right) \quad [6]$$

Step 4: Graph-Cut Segmentation

4.1 Energy Minimization: The energy E is minimized to find the optimal cut that separates the foreground and background regions. The energy function involves unary and pairwise terms.

$$E = \sum_i D_i(s_i) + \sum_{i,j} V_{ij}(s_i, s_j) \quad [7]$$

Where $D\,i$ is the data cost, $V\,i\,j$ is the pairwise cost, and $s\,i$ is the label of node $v\,i\,j$.

4.2 Seed Propagation: The segmented regions S obtained from the graph-cut process are refined using a seed propagation mechanism.

$$S = SeedPropagate(M, S) \quad [8]$$

Step 5: ROI Extraction

5.1 Region of Interest Extraction: The segmented nuclei regions R are extracted from the input image I using the refined segmentation S .

$$R = I \odot S \quad [9]$$

Step 6: Postprocessing

6.1 Noise Reduction: Postprocessing techniques such as morphological operations and noise reduction filters are applied to R to remove small artifacts.

$$R = MorphologicalOperations(R) \quad [10]$$

Step 7: Output Generation

7.1 Segmentation Results: The final segmented nuclei regions R are obtained as output, representing accurate identification of nuclei within the multicell Pap smear image.

The Fig. 3 shows the results of nuclei segmentation for four different cervical cancer grades: HSIL, LSIL, NIM, and SCC using proposed Graph-Cut Guided ROI Segmentation algorithm. The algorithm's effectiveness in accurately isolating nuclei regions within multicellular Pap smear images is demonstrated through these segmentation results.

(l) SCC segmentation results

Fig. 3. Nuclei segmentation results for different cervical cancer grades using proposed Graph-Cut Guided ROI Segmentation algorithm.

D. Image Augmentation

Image augmentation is a crucial technique employed to enhance the diversity of the dataset and improve the generalization ability of the deep learning model [25]. This research, a set of image augmentation techniques is applied to the original pap smear images before being used for training. The augmentation techniques include rotation, horizontal and vertical flipping, random zooming, and brightness adjustments. These transformations introduce variations that reflect real-world conditions and different microscope orientations, thereby minimizing the risk of overfitting and improving the model's ability to generalize to unseen data. Fig. 4 shows the different image augmentation techniques used in this research for enhanced Pap smear analysis. Data augmentation expanded the dataset from 963 to 5,778 images.

(d) Flip horizontal (e) Flip vertical (f) brightness adjustments

Fig. 4. Image augmentation techniques for enhanced Pap smear analysis.

E. Feature Extraction using Proposed Lightweight DenseNet

DenseNet is particularly well-suited for feature extraction from medical images due to its dense connectivity pattern [26]. Traditional convolutional architectures lose information as they progress through layers. DenseNet mitigates this by connecting each layer to every subsequent layer, ensuring that all features are directly accessible by subsequent layers [27]. This not only enhances feature propagation but also reduces the risk of information loss, making it ideal for capturing intricate structures within segmented medical images. The DenseNet architecture consists of dense blocks, each composed of multiple convolutional layers, followed by a transition layer. The key components are:

1) Dense block: Multiple convolutional layers are stacked together, and each layer receives the feature maps from all preceding layers. This dense connectivity encourages feature reuse and fosters information flow.

2) Transition layer: It follows each dense block and comprises convolutional and pooling layers. Transition layers down-sample feature maps, reducing computational load and channel dimensions, which aids in compactly representing salient features.

To cater to the characteristics of segmented Pap smear images, a modification is introduced to the traditional DenseNet architecture. The modification's primary goals are to reduce feature redundancy and enhance feature correlation, leading to more efficient and meaningful feature extraction. In this modified DenseNet architecture, feature fusion and channel attention mechanisms are integrated within each dense block. Feature fusion combines the outputs of different convolutional layers, ensuring complementary information is considered. Channel attention recalibrates feature maps, emphasizing important channels and reducing redundancy. Table II explain the architecture details of proposed DenseNet. Fig. 5 shows the visual representation of the proposed DenseNet. The initial convolutional layer processes the input, followed by multiple dense blocks, which enhance feature extraction capabilities. Transition layers between dense blocks down-sample the feature maps, reducing computational load. The introduced modification for feature fusion and channel attention would be integrated within the dense blocks.

Specifically, the feature fusion mechanism combines features from different convolutional layers within each dense block. The channel attention mechanism recalibrates feature maps, improving feature correlation and reducing redundancy. This architecture effectively exploits the dense connectivity pattern of DenseNet, encouraging efficient feature reuse and hierarchical representation of image structures. The modification further enhances the model's ability to extract meaningful features from segmented Pap smear images, contributing to accurate cervical cancer classification.

F. Classification

The classification module of the research involves training a classifier to differentiate between different cervical cancer grades based on the features extracted from the segmented and enhanced pap smear images. A Multi-Class Logistic Regression (MCLR) classifier is employed for this purpose, leveraging the informative features obtained through the modified DenseNet architecture. The MCLR classifier assigns a probability distribution over the classes, allowing for the identification of the most likely class for each input image. Given an input feature vector **x**, the MCLR model computes the probabilities for each class $\mathbf{C}i$ using the softmax function. The probability ($\mathbf{C}i \mid \mathbf{x}$) represents the likelihood that the input **x** belongs to class $\mathbf{C}i$. The class with the highest probability is predicted as the final output. The equation for the softmax function is:

$$(Ci|x) = \frac{e^{zi}}{\sum_{j=1}^{K} e^{zj}} \qquad (11)$$

TABLE II. ARCHITECTURE DETAILS OF PROPOSED DENSENET

Layer	Type	Configuration
Input	Input	224x224x3 (RGB with segmentation mask channel)
Preprocessing	Normalization	Normalize pixel values
Initial Convolution	Convolution	7x7 filter, 64 filters, stride = 2, padding = 'same'
	Batch Normalization	
	ReLU Activation	
	Max Pooling	3x3 pool, stride = 2
Dense Block	Batch Normalization	
	ReLU Activation	
	Convolution (1x1)	k filters (bottleneck), padding = 'same'
	Batch Normalization	
	ReLU Activation	
	Convolution (3x3)	k filters, padding = 'same'
Transition Layer	Batch Normalization	
	ReLU Activation	
	Convolution (1x1)	k filters (reducing channels), padding = 'same'
	Average Pooling	2x2 pool, stride = 2
Global Average Pooling	Global Average Pooling	Across spatial dimensions
Fully Connected Layers	Flatten	Flatten pooled feature maps

(b)

Fig. 5. Proposed DenseNet architecture (a) overall architecture (b) layer details of the proposed DenseNet block.

where: zi is the logit for class $\mathbf{C}i$ calculated as a linear combination of the feature vector $\mathbf{x}$ and the class-specific weights. K is the total number of classes. The predicted class for an input image is the one corresponding to the highest probability among all classes. The MCLR classifier is trained using the cross-entropy loss function, it measures the dissimilarity between the predicted probabilities and the actual class labels in the training data. The formula for the Cross-Entropy Loss is as follows:

$$H(y,p) = -sum_i y_i log(p_i) \tag{12}$$

where: y is the ground truth label (a vector of 1s and 0s, where 1 indicates the correct class and 0 indicates the incorrect class). p is the predicted probability distribution (a vector of probabilities, where each element represents the probability of the input being in the corresponding classes: HSIL, LSIL, NIM, and SCC). i is the index of a class and log is the natural logarithm.

IV. Results and Discussion

In this section, a comprehensive analysis of the results obtained from the proposed cervical cancer detection method is presented. This section is divided into three significant parts, each contributing to a deeper understanding of the effectiveness and efficiency of the proposed approach. Firstly, the accuracy of the proposed method is evaluated in comparison to existing deep learning models and recently published cervical cancer detection systems discussed in the literature review. Specifically, a comparison is made regarding the accuracy achieved by the method against popular deep learning architectures such as AlexNet, GoogleNet, VGGNet, ResNet, and YOLO. Additionally, the method's performance is assessed against recently developed systems like the DeepCervix approach by Md Mamunur Rahaman et al. [14], utilizing a hybrid deep feature fusion technique. Furthermore, analysis is conducted on the pipeline-based architecture proposed by Alyafeai et al. [16], featuring two pre-trained deep models for cervix region identification and tumor classification. The model presented by Yuexiang Li et al. [17], which incorporates a key-frame feature encoding network and a feature fusion network, is also considered. Lastly, the deep learning architecture by Deepa. K et al. [20], emphasizing cervical cancer classification through a combination of segmentation and feature extraction techniques using two CNN models, is examined. Following this, the training efficiency of the proposed method is evaluated. Lastly, a comparison is made regarding the computational efficiency of the proposed method with existing deep learning models and recently published cervical cancer detection systems. Table III presents the parameter settings for both conventional techniques and existing deep learning models.

A. System Details

The research was conducted using a well-configured system that incorporated artificial intelligence software and hardware components. The software components included MATLAB 2018, operating on the Windows 11 operating system. Regarding the hardware details, the system featured an Intel Core i7 processor. The system was also equipped with an NVIDIA GPU. Additionally, the system was equipped with 16GB of RAM.

B. Accuracy Analysis

Accuracy, precession, recall, and F1-measure are used to evaluate the accuracy of the proposed cervical cancer classification system. These are based on true positive cervical cancer classification (TP), true negative cervical cancer classification (TN), false positive cervical cancer classification (FP), and false negative cervical cancer classification (FN). Accuracy metrics are calculated using the following formula. The proposed cervical cancer classification system's accuracy was tested using four different types of cervical cancer cells: HSIL, LSIL, NIM, and SCC (see Section III (A)). The samples were all multicell Pap smear images.

$$Accuracy = \frac{(TP+TN)}{Total\ samples} \tag{13}$$

$$Precision = \frac{TP}{(TP+FP)} \tag{14}$$

$$Recall = \frac{TP}{(TP+FN)} \tag{15}$$

$$F1 - measure = 2 \times \frac{(Precision \times Recall)}{(Precision + Recall)} \tag{16}$$

The proposed methodology's performance is evaluated against several existing deep learning models. The comparison is presented in Tables IV, V, VI, and VII.

TABLE III. Parameter Settings for Conventional Techniques and Existing Deep Learning Models

Parameter	Values
Learning Rate	0.001
Batch Size	64
Activation Function	ReLU
Dropout Rate	0.2
Data Augmentation	Yes
Optimizer	Adam
Weight Initialization	Random

TABLE IV. Classification Efficiency Comparison for HSIL Cells Classification with Deep Learning Models

Method	Accuracy	Precision	Recall	F1-Measure
AlexNet	91.25%	95.69%	91.9%	93.29%
GoogleNet	93.28%	96.70%	92.60%	94.60%
VGGNet	94.00%	97.20%	93.10%	95.10%
ResNet	94.60%	97.70%	95.60%	95.70%
YOLO	96.72%	97.80%	94.60%	95.70%
Proposed Method	98.15%	98.52%	97.33%	98.43%

TABLE V. CLASSIFICATION EFFICIENCY COMPARISON FOR LSIL CLASSIFICATION WITH DEEP LEARNING MODELS

Method	Accuracy	Precision	Recall	F1-Measure
AlexNet	91.72%	93.41%	94.91%	93.61%
GoogleNet	92.71%	94.91%	94.59%	94.78%
VGGNet	93.41%	95.40%	95.70%	95.20%
ResNet	94.99%	96.60%	95.51%	96.21%
YOLO	96.10%	95.58%	97.59%	97.70%
Proposed Method	98.28%	97.90%	98.49%	98.97%

TABLE VI. CLASSIFICATION EFFICIENCY COMPARISON FOR NIM CLASSIFICATION WITH DEEP LEARNING MODELS

Method	Accuracy	Precision	Recall	F1-Measure
AlexNet	92.30%	95.33%	92.38%	94.30%
GoogleNet	93.48%	94.91%	93.55%	95.10%
VGGNet	91.66%	93.43%	92.51%	93.91%
ResNet	95.76%	97.80%	95.41%	95.61%
YOLO	96.81%	98.51%	98.69%	91.90%
Proposed Method	98.90%	99.65%	99.41%	99.38%

TABLE VII. CLASSIFICATION EFFICIENCY COMPARISON FOR SCC CLASSIFICATION WITH DEEP LEARNING MODELS

Method	Accuracy	Precision	Recall	F1-Measure
AlexNet	90.41%	90.28%	91.70%	92.90%
GoogleNet	93.81%	91.83%	90.33%	91.80%
VGGNet	91.94%	91.48%	92.63%	93.18%
ResNet	90.18%	91.90%	92.40%	92.70%
YOLO	92.30%	93.63%	94.64%	94.65%
Proposed Method	97.15%	96.79%	97.24%	96.90%

Table IV showcases the performance comparison of the proposed method with popular deep learning models for HSIL classification using multicell pap smear images. The accuracy of the proposed method is demonstrated to be 98.15%, which outperforms other models such as AlexNet (91.25%), GoogleNet (93.28%), VGGNet (94.00%), ResNet (94.60%), and YOLO (96.72%). Table V presents the comparison results for LSIL classification using multicell pap smear images. The proposed method again demonstrates superior performance, achieving an accuracy of 98.28%. This accuracy surpasses the other models, including AlexNet (91.72%), GoogleNet (92.71%), VGGNet (93.41%), ResNet (94.99%), and YOLO (96.10%). Table VI illustrates the comparison of NIM classification efficiency using multicell pap smear images. Once more, the proposed method stands out with an accuracy of 98.90%, outperforming AlexNet (92.30%), GoogleNet (93.48%), VGGNet (91.66%), ResNet (95.76%), and YOLO (96.81%). The comparison for SCC classification using multicell Pap smear images is presented in Table VII. The proposed method exhibits an accuracy of 97.15%, surpassing AlexNet (90.41%), GoogleNet (93.81%), VGGNet (91.94%), ResNet (90.18%), and YOLO (92.30%). Similar to previous comparisons, the proposed method achieves higher values in Precision, Recall, and F1-Measure, underscoring its effectiveness in classifying SCC using multicell pap smear images. The analysis of the comparison tables demonstrates that the proposed methodology consistently outperforms existing deep learning models across all stages of cervical cancer classification, including HSIL, LSIL, NIM, and SCC.

C. Performance Comparison with Existing Methods

The proposed methodology addresses a critical challenge in cervical cancer classification by focusing specifically on multicell Pap smear images, where existing methods tend to show decreased accuracy. This section presents a comprehensive performance comparison between the proposed method and several existing techniques.

TABLE VIII. CLASSIFICATION EFFICIENCY COMPARISON FOR HSIL CLASSIFICATION WITH EXISTING METHODS

Method	Accuracy	Precision	Recall	F1-Measure
Md Mamunur Rahaman et al. [14]	86.25%	90.69%	86.9%	88.89%
Alyafeai et al. [16]	88.28%	91.70%	87.60%	89.60%
Yuexiang Li et al. [17]	89.00%	92.20%	90.10%	91.10%
Deepa. K et al. [20]	89.60%	93.70%	92.60%	92.70%
Proposed Method	98.15%	98.52%	97.33%	98.43%

TABLE IX. CLASSIFICATION EFFICIENCY COMPARISON FOR LSIL CLASSIFICATION WITH EXISTING METHODS

Method	Accuracy	Precision	Recall	F1-Measure
Md Mamunur Rahaman et al. [14]	87.13%	90.73%	91.36%	90.55%
Alyafeai et al. [16]	88.07%	91.77%	90.86%	90.81%
Yuexiang Li et al. [17]	88.73%	92.60%	92.90%	92.75%
Deepa. K et al. [20]	90.24%	93.70%	92.07%	92.94%
Proposed Method	98.28%	97.90%	98.49%	98.97%

TABLE X. CLASSIFICATION EFFICIENCY COMPARISON FOR NIM CLASSIFICATION WITH EXISTING METHODS

Method	Accuracy	Precision	Recall	F1-Measure
Md Mamunur Rahaman et al. [14]	87.30%	90.33%	87.38%	90.30%
Alyafeai et al. [16]	88.98%	91.91%	88.95%	91.10%
Yuexiang Li et al. [17]	86.16%	88.43%	87.51%	88.91%
Deepa. K et al. [20]	90.76%	92.80%	90.41%	91.61%
Proposed Method	98.90%	99.65%	99.41%	99.38%

TABLE XI. CLASSIFICATION EFFICIENCY COMPARISON FOR SCC CLASSIFICATION WITH EXISTING METHODS

Method	Accuracy	Precision	Recall	F1-Measure
Md Mamunur Rahaman et al. [14]	84.29%	84.10%	85.38%	84.78%
Alyafeai et al. [16]	88.23%	87.34%	87.02%	87.18%
Yuexiang Li et al. [17]	85.58%	85.74%	86.15%	85.94%
Deepa. K et al. [20]	84.46%	85.68%	85.88%	85.78%
Proposed Method	97.15%	96.79%	97.24%	96.90%

Table VIII highlights the comparison of the proposed method with existing techniques for HSIL classification. Notably, the proposed method achieves an accuracy of 98.15%, outperforming other methods such as Md Mamunur Rahaman et al. (86.25%), Alyafeai et al. (88.28%), Yuexiang Li et al. (89.00%), and Deepa K et al. (89.60%). In Table IX, the performance comparison for LSIL classification is presented. The proposed method once again achieving an accuracy of 98.28%. This accuracy significantly surpasses existing methods such as Md Mamunur Rahaman et al. (87.13%), Alyafeai et al. (88.07%), Yuexiang Li et al. (88.73%), and Deepa. K et al. (90.24%). Table X showcases the comparison results for NIM classification. The proposed method excels with an accuracy of 98.90%, surpassing Md Mamunur Rahaman et al. (87.30%), Alyafeai et al. (88.98%), Yuexiang Li et al. (86.16%), and Deepa K et al. (90.76%). The performance comparison for SCC classification is provided in Table XI. The proposed method achieves an accuracy of 97.15%, showcasing its superiority over Md Mamunur Rahaman et al. (84.29%), Alyafeai et al. (88.23%), Yuexiang Li et al. (85.58%), and Deepa K et al. (84.46%). The performance comparison clearly illustrates the proposed method's exceptional capability in addressing the limitations of existing methods, which struggle with decreased accuracy in multicell pap smear images.

The proposed method achieves remarkable accuracy, precision, recall, and F1-Measure values, indicating its robustness in accurately identifying different cell types and cancer stages using multicell Pap smear images. The existing methods were limited by their use of single pap smear images. This can be a problem because single pap smear images may not contain enough information to accurately classify the cell type or cancer stage. According to the results, the proposed method addresses this limitation by using multicell Pap smear images.

D. Training Efficiency Analysis

The training phase of deep learning models holds paramount importance in achieving accurate and robust results. To ensure optimal training, a combination of advanced training algorithms and techniques was employed. In this research, the Adam optimizer was selected as the primary algorithm for training the model. The Adam optimizer is known for its efficiency in parameter optimization and model tuning, making it well-suited for the complex and high-dimensional nature of deep learning models. To comprehensively evaluate the performance of the proposed model, a five-fold cross-validation strategy was adopted. This approach enhances the model's generalization ability by partitioning the dataset into five subsets, with four subsets utilized for training and one subset reserved for testing. The use of cross-validation mitigates the risk of overfitting and provides a robust estimate of the model's performance on unseen data. The average testing accuracy emerged as the pivotal metric to gauge the effectiveness of the proposed cervical cancer classification system. By aggregating the accuracy results from each fold, a more comprehensive and reliable measure of the model's classification performance was obtained. The training efficiency and effectiveness of the proposed method are visually depicted in Fig. 6 to Fig. 10 These figures show the model's performance across different folds, providing insights into its consistency and stability.

E. Computational Efficiency Analysis

This section has two sections: the first section analyses the training time analysis, and the second section analyses the testing time analysis.

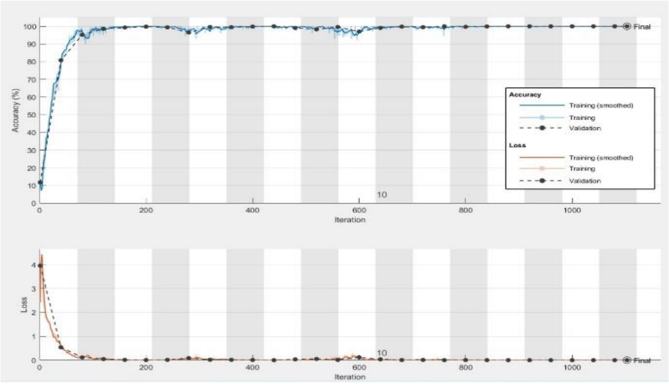

Fig. 6. Training details of cross fold 1.

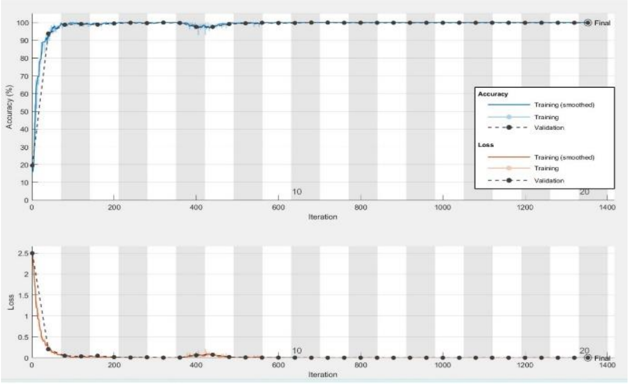

Fig. 7. Training details of cross fold 2.

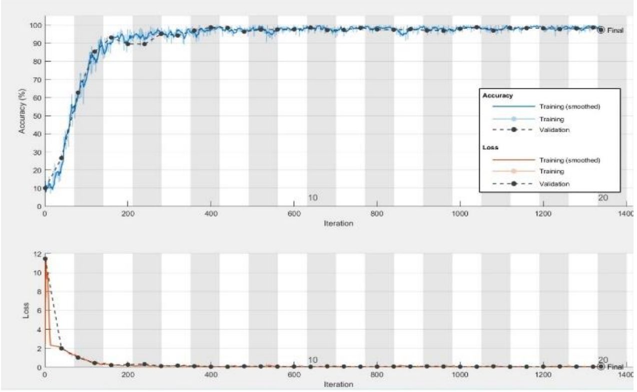

Fig. 8. Training details of cross fold 3.

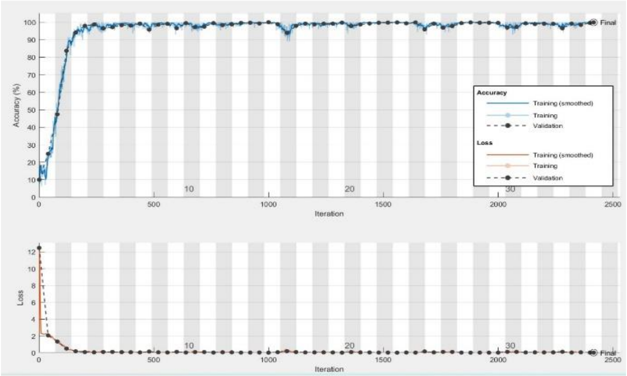

Fig. 9. Training details of cross fold 4.

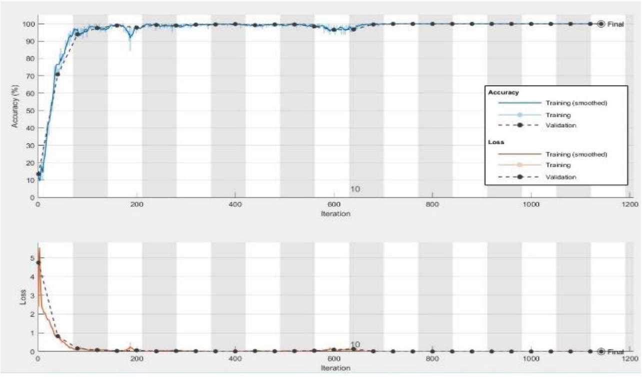

Fig. 10. Training details of cross fold 5.

The evaluation of computational efficiency plays a pivotal role in assessing the practical feasibility of deep learning models for medical image analysis. The efficiency of such models is influenced by a multitude of factors, including the effectiveness of the segmentation algorithm, the feature extraction model, the effectiveness of the training algorithm, the image type, and the image size. In order to conduct a thorough comparison of training time efficiency, three distinct sets of Pap smear images were utilized: the first set consisting of 200 images, the second containing 400 images, and the third encompassing 600 images. Each set was utilized for training the proposed deep learning model, thereby allowing for a comprehensive assessment of training time variations across different dataset sizes. The training process was carried out using the computational resources detailed in Section IV (B).

Table XII explains the training efficiency comparison results. This proposed method is much faster than existing methods. For example, it takes only 13.65 minutes to train on Dataset 1, while AlexNet, GoogleNet, VGGNet, and ResNet take 105-147 minutes. This trend continues for Dataset 2 and Dataset 3. Existing methods are effective, but they take too long to train, which is not practical for clinical applications. This proposed method is much faster without sacrificing accuracy. It uses Graph-Cut Guided ROI Segmentation and the enhanced DenseNet architecture to achieve this.

In addition to training time, the classification time of a cervical cancer classification methodology is a crucial performance metric, particularly for real-time clinical applications. This section presents an analysis of the classification time required by various methodologies, including the proposed approach, when processing images of different sizes. The assessment is carried out using three images of varying sizes: Image 1 (800 kb), Image 2 (1200 kb), and Image 3 (1800 kb). The following table presents the classification times for each methodology when applied to the three different images.

TABLE XII. TRAINING EFFICIENCY COMPARISON RESULTS

Methods	Dataset 1 (200 images)	Dataset 2 (400 images)	Dataset 3 (600 images)
AlexNet	147 minutes	241.5 minutes	329.25 minutes
GoogleNet	131.7 minutes	227.05 minutes	321.8 minutes
VGGNet	126 minutes	214.6 minutes	288 minutes
ResNet	105 minutes	171.7 minutes	213.8 minutes
YOLO	84 minutes	154.4 minutes	201.0 minutes
Md Mamunur Rahaman et al.	60.9 minutes	93.1 minutes	148.7 minutes
Alyafeai et al.	52.5 minutes	81.1 minutes	129.25 minutes
Yuexiang Li et al.	63 minutes	100.8 minutes	135.75 minutes
Deepa. K et al.	71.4 minutes	95.25 minutes	142.25 minutes
Proposed Method	13.65 minutes	17.85 minutes	32.55 minutes

This method is fast at classifying images of all sizes. For example, it takes 0.32 seconds to classify an image of 800 kb, 0.6475 seconds to classify an image of 1200 kb, and 1.04 seconds to classify an image of 1800 kb. This is important because it means that the proposed method can be used in real-time clinical applications. Other methods, such as GoogleNet, ResNet, and YOLO, are slower at classifying images of larger sizes. Alyafeai et al.'s method is fast for small images, but it becomes slower for larger images. The efficiency of proposed method is due to the Graph-Cut Guided ROI Segmentation Algorithm and the enhanced lightweight DenseNet architecture. These two techniques help to reduce the training and classification times while still ensuring accurate cervical cancer classification.

TABLE XIII. TESTING EFFICIENCY COMPARISON RESULTS

Methods	Image 1 (800 kb)	Image 2 (1200 kb)	Image 3 (1800 kb)
AlexNet	0.375 seconds	0.0975 seconds	0.4125 seconds
GoogleNet	0.90 seconds	1.80 seconds	2.70 seconds
VGGNet	0.36 seconds	0.5475 seconds	0.685 seconds
ResNet	0.80 seconds	1.60 seconds	2.40 seconds
YOLO	0.72 seconds	1.32 seconds	1.92 seconds
Md Mamunur Rahaman et al.	0.0925 seconds	0.6375 seconds	0.975 seconds
Alyafeai et al.	0.1425 seconds	0.3475 seconds	0.6825 seconds
Yuexiang Li et al.	0.61 seconds	1.07 seconds	1.53 seconds
Deepa. K et al.	0.67 seconds	1.12 seconds	1.68 seconds
Proposed Method	0.32 seconds	0.6475 seconds	1.04 seconds

F. Discussions

Cervical cancer is a major global health concern, and the accurate classification of cervical cells plays a critical role in its early detection and effective treatment. Many existing approaches to cervical cancer classification use separate models for segmentation and classification. This approach not only escalates computational demands but also prolongs training and inference times. The proposed method addresses this issue by integrating segmentation and classification into a single pipeline. The Graph-Cut Guided ROI Segmentation Algorithm and the enhanced lightweight DenseNet architecture enable simultaneous segmentation and feature extraction, reducing computational complexity and speeding up the overall process.

Existing approaches often rely on feature fusion to combine the outputs of separate models. However, this approach introduces complexities and potential sources of error. Proposed method avoids this pitfall by eliminating the need for feature fusion altogether. Instead, proposed unified architecture inherently incorporates both segmentation and feature extraction, mitigating the need for complicated fusion strategies. This simplification reduces the risk of errors introduced through fusion methods, leading to a more robust and accurate cervical cancer classification system.

Most existing methods for cervical cancer classification are tested with single cell images, which does not reflect the reality of pap smear images that often contain multiple cells. The proposed method directly addresses this limitation by utilizing multicell Pap smear images. The Graph-Cut Guided ROI Segmentation Algorithm effectively handles multiple cells within an image, overcoming the challenges of accurate segmentation and classification in such scenarios. This adaptability enhances the method's applicability to real-world situations, improving its reliability and clinical utility.

The results of this study demonstrate the exceptional performance of the proposed method in cervical cancer classification using multicell pap smear images. Proposed method consistently outperforms existing deep learning models and methodologies across all stages of cervical cancer classification. The accuracy, precision, recall, and F1-measure values attained underscore the method's efficacy in accurately identifying different cell types and cancer stages.

In addition, the proposed method is more efficient for training because it does not need to train multiple models or use complex feature fusion techniques. This means that it takes less time and uses fewer resources to train the model, while still being able to classify images accurately. Proposed method has been shown to be more effective than existing deep learning models for classifying cervical cancer at all stages. It is also faster and more accurate at classifying images of varying sizes. This is because proposed method uses a unified architecture that eliminates the need for complex fusion strategies.

While proposed method shows promising results, there are certain limitations that need to be acknowledged. Firstly, the performance of the method heavily relies on the quality of the input images. Variability in image quality, lighting conditions, and staining techniques can affect the accuracy of segmentation and classification. Secondly, although proposed method improves computational efficiency compared to existing methods, there is still room for optimization to further enhance speed and resource utilization. Lastly, the evaluation of the proposed method is based on specific datasets, and its generalization to diverse populations and different acquisition conditions should be thoroughly validated before widespread clinical adoption.

V. Conclusion

This study presents a novel and effective approach for automated cervical cancer classification using multicell pap smear images. The method is designed to address the limitations of existing approaches and enhance the accuracy, efficiency, and practicality of cervical cancer diagnosis. The implications of these findings are profound for the medical community. This research not only highlights the potential of deep learning in transforming cervical cancer diagnosis but also addresses the critical need for efficiency in real-world applications. The successful fusion of the Graph-Cut Guided ROI Segmentation Algorithm and the enhanced lightweight DenseNet architecture demonstrates the possibility of accurate and rapid classification, even in the context of multicell pap smear images. This has the potential to enhance clinical decision-making, treatment planning, and patient outcomes.

Department of ECE, Guru Nanak Institutions Technical Campus, Hyderabad -501506, Telangana, India[1]

***Abstract*—The inability to efficiently store distinguishing edges, local appearance-based textured descriptions generally have limited performance in detecting facial expression analysis. The existing technology has certain drawbacks, such as the potential for poor edge-related disturbance in face photos and the reliance on present sets of characteristics that might fail to adequately represent the subtleties of emotions and thoughts in a variety of contexts. In order to overcome the difficulties associated with identifying facial expressions identification and emotion categorization, this study presents an innovative structure that combines three different information sets: a new multimedia descriptors, prosodic functions, and Local Differential Pattern (LDP). The principal driving force is the existence of noise-induced warped and weak edges in face pictures, which result in inaccurate expressions characteristic assessment. By identifying and encoding only greater edge reactions, as opposed to standard local descriptors that the LDP approach improves the endurance of face feature extraction. Robinson Compass and Kirsch Compass Masks are used for recognising edges, and the LDP formulation encodes each pixel with seven bits of information to reduce code repetition. The last category comprises Long-Term Average Spectrum (LTAS) obtained from signals related to speech, Mel-Frequency Cepstral Coefficients (MFCC), and Forming agents. Fisher Criterion is used to reduce dimensionality, and unpredictable characteristics are used in picking features. Emotion prediction is achieved by classifying two distinct circumstances using Support Vector Machine (SVM) and Decision Tree (DT) algorithms, and combining the obtained data. The research also presents a unique Visual or audio Descriptors that gives priority to key structure selections and face positioning for Audio-visual input. A concise depiction of expression is offered by the suggested Self-Similarity Distance Matrix (SSDM), which uses facial highlight points to estimate both time and space correlations. Formant frequency range, energy sources, probabilistic properties, and spectroscopic aspects define the acoustic signal. The 98% accuracy rate is attained by the emotion recognition algorithm. Major improvements upon cutting-edge techniques are shown in validation studies on the SAVEE and RML information sets, highlighting the usefulness of the suggested model in identifying and categorising emotions and facial movements in a variety of contexts. The implementation of this research is done by using Python tool.**

Keywords*—Local Difference Pattern (LDP); Mel-Frequency Cepstral Coefficients (MFCC); Long-Term Average Spectrum (LTAS); Self-Similarity Distance Matrix (SSDM); Support Vector Machine (SVM)

I. Introduction

Emotion recognition is an intricate yet essential component of human communication, and computing and AI has placed a great deal of emphasis on it recently. The capacity to precisely recognise and comprehend human feelings has broad applications, from boosting behavioural care providers to advancing consumer-computer connection [1]. Facial expressions are an inherent means for people to communicate a wide range of emotions, and algorithmic systems may be developed to read similar nuanced signs [2]. Basic features including mouth expressions, blinking eyes and eyebrows twitches may be detected by facial identification applications, which can then be used to deduce moods like surprise, pleasure, sorrow, and rage. Apart from expressions on the face, speech assessment is an essential component in the identification of emotions [3][4]. Another approach used in mood detection systems is identification of gestures. Human behaviour, which includes posture and movements, may give important information about how one feels. Huge collections of movement of the body training may be used to train machine learning algorithms to recognise certain gestures as indicative of certain feelings [5]. This method is especially useful in situations when it may be difficult to read or understand facial emotions, including in crowded spaces or through video conferences. The creation of emotions detection mechanisms has great potential for a variety of uses as technology evolves. The capacity of computers to comprehend and react to human emotions offers up fresh prospects for developing empathic and flexible innovations, from interactions between humans and computers to mental wellness assessment and personalised experiences for consumers [6]. Still, the significance of appropriate research and implementation in such developing sector is underscored by ethical issues, privacy problems, and the possibility of bias in identifying feelings systems.

Numerous methodologies are now in use for recognising feelings, and they all use different forms and ways to gather and process emotional information. Among the techniques that have been studied and used frequently is facial expressions assessment. This method entails the detection and analysis of facial reactions and motions employing machine learning tools. Convolutional Neural Networks (CNNs) are a popular neural network method used by investigators and programmers to recognise similarities linked to different feelings from enormous datasets of labelled facial movements

[7]. By examining the meaning included in words written or spoken, machine learning techniques improve this technique even further and make it possible to identify the feelings communicated via language. Voice-enabled devices, digital assistants, and contact centres are among the places where identifying emotions in conversation is frequently used [8]. The field of gesture identification is centred on the interpretation of nonverbal cues such as posture, movements of the hands, and various other physiological motions. This technique is especially useful in situations when facial emotions might not be apparent or may lack sufficient data. Machine learning techniques may be developed on databases that link particular movements to associated sentiments [9]. Such algorithms frequently depend on neural networks with recurrence or related sequence-based designs. Applications such as augmented realities, surveillance footage, and interactions between humans and computers can benefit from this strategy. The use of multiple methods techniques work especially well in everyday life when there are a variety of influenced by context signs of emotion [10]. Even though these techniques have shown promise in a number of applications, problems still exist. Important factors to take into account are the possibility of biased results, confidentiality difficulties, and ethical issues.

A significant barrier to attaining global application is the subtleties and cultural differences in expressing one's feelings [11]. Dependent on environment is a further important restriction. Because feelings are so dependent on the setting, current frameworks may find it difficult to account for the subtle differences in how emotions seem in various contexts. The subjective nature and variability among individuals present further difficulties for emotion detection methods trying to be generalised [12]. Individualised variations in personality, socioeconomic situation, or mental state can provide unpredictability that is challenging for systems to compensate for, and humans may exhibit moods in various manners. The use of such devices in vulnerable or public areas may violate people's fundamental right to safety, hence rules and moral requirements must be carefully considered in order guarantee proper usage [13].

Recent years have seen tremendous progress in the field of emotion recognition, especially with the incorporation of multimedia descriptors, speech characteristics, and facial patterns. Despite these advancements, there are still significant obstacles in the way of the practical uses of current techniques. A significant problem is the restricted capacity to represent the subtleties of affective responses in many media. The process of feature extraction, which is essential for distinguishing minute differences in speech intonations, facial expressions, and multimedia information, is frequently difficult for traditional approaches. The suggested strategy addresses the drawbacks of current techniques by introducing a number of novel algorithms in response to these difficulties. We highlight how important it is to extract features using the Local Directional Pattern (LDP) method, which improves facial pattern representation and guarantees a deeper examination of emotional indicators. But the problem goes beyond feature extraction, which is a precisely sophisticated method like feature selection and dimensionality reduction are needed. In order to ensure a more effective and efficient emotion detection procedure, these stages are essential for simplifying the data and conserving just the most discriminative aspects.

The limitations of traditional classification techniques are addressed by our approach's use of Decision Tree Classifier and Support Vector Machines (SVM). These classifiers improve the system's capacity to identify intricate patterns in multimedia information, speech tones, and facial expressions, enabling a more complicated comprehension of emotions. Moreover, the incorporation of the Self-Similarity Distance Matrix (SSDM) enhances the analysis and facilitates a thorough assessment of similarity patterns among modalities. A fundamental problem with current emotion identification systems is the absence of a cohesive methodology that effectively integrates data from many sources. Seeing this gap, the foundation of our strategy is our suggested Emotion Recognition Fusion mechanism. This fusion technique offers a comprehensive and more accurate representation of the subject's emotional state by cleverly merging information from multimedia descriptors, voice features, and facial patterns. The key contributions of the proposed framework for Facial Expression Recognition and emotion classification can be summarized as follows:

1) The system offers a complete method to capture subtle emotions by integrating three different feature sets: prosodic characteristics, a unique Audio-Visual Descriptor, and Weighted Edge Local Directional Pattern (WELDP). This lessens the reliance on present feature sets.

2) WELDP optimises the encoding process by using seven bits to represent each pixel, hence minimising code repetition.

3) This helps to portray face characteristics more effectively and efficiently, especially when there are weak or warped edges present.

4) The suggested system leverages both individual models by combining the Support Vector Machine and Decision Tree methods for categorization.

5) Combining the output from various models improves the prediction of emotions and yields a categorization result that is more trustworthy.

6) A novel method is provided by the introduction of the Audio-Visual Descriptor based on the Self-Similarity Distance Matrix (SSDM).

7) SSDM computes spatial and temporal distances using facial landmark points, giving priority to face alignment and key frame selection for Audio-Visual input.

8) This results in a succinct yet powerful depiction of emotion in a variety of settings.

The format for the enduring paragraphs is as follows: The relevant work based on various methodologies for diabetes prediction is examined in Section II, and the research gap is identified in Section III. The feature selection and classification process for the proposed method is explained in the Section IV. The outcomes and considerations are covered in Section V; the prospective applications for the future are covered in Section VI.

II. Related Works

The techniques for identifying emotions using multiple interfaces EEG data and multipurpose physiological indicators are the main topic of this extensive literature analysis [14]. The research employs a conventional emotional identification pipeline, looking at different approaches to extracting features like wavelet transformed and nonlinear behaviour, and also decreasing features and machine learning (ML) classification system design methodologies like k-nearest neighbour (KNN), naive Bayesian (NB), support vector machine (SVM), and random forest (RF). The work delves deeper into the complex relationship between various brain regions and mental conditions by analysing EEG patterns that are significantly connected with sentiments. The paper also compares and contrasts machine learning and deep learning methods for emotion identification, highlighting the advantages and disadvantages of each. The study finds that the scope of the collection of features and the data set used for training have a major impact on how well DL models can recognise emotions.

Communication between humans and computers has greatly increased availability of educational resources, data, and the sharing of significant skills on a worldwide scale. The model in [15] offered suggests fusing speech qualities and face emotions to overcome these drawbacks. The technique particularly employs the Speech (Mel Frequency Cepstral Coefficients) and Facial (Maximally Stable Extremal Regions) aspects, which add to an organised and methodical investigation. This methodology presents a more resilient and adaptable emotion identification system, highlighting the possibility of using multifaceted characteristics for enhanced accuracy in a variety of situations in life. Although the bi-modal approach which combines voice and face features has shown to improve accuracy and resilience in the sense of emotion identification network when compared with unimodal. This method, one significant drawback is the requirement for additional expansion.

Two neural network methods in [16] for recognising and categorising objects are included in the suggested flexible design. These approaches are taught separately to facilitate use in real time. AdaBoost cascading models are used for face identification, and then neighbourhood difference features (NDF) are extracted to get localised attractiveness knowledge. This allows for the development of various structures depending on the interactions between surrounding areas. The adaptable structure of the system, which focuses on seven primary facial gestures, enables it to be extended to categorise a wide variety of emotions. In order to manage mis-/false detection, a classifier using random forests with a deep mood indicator has been developed, providing self-determination through sexual orientation and face complexion. The investigation of shape characteristics and face modification brings complexities that can necessitate advanced mathematical methods, which could have an impact on the computing effectiveness of immediate video analysis.

This study in [17] offers a thorough overview of micro-expression evaluation using videos, highlighting the distinctions among broad and tiny movements and using them as a foundation for assessment. The research presents a fresh collection of data, the micro-and-macro emotion warehouse (MMEW), with a greater quantity of video frames and tagged groups of emotions in recognition of the shortcomings of the current micro-expression databases. The writers compare typical techniques uniformly on CAS(ME)2 for finding and on MMEW and SAMM for classification. In the latter section of this investigation, several avenues for further study are discussed, emphasising the dynamic environment and continuous difficulties in the field of video-based micro-expression evaluation. Quick breakthroughs or changes might arise from the multifaceted nature of micro-expression research and the ever-changing nature of technological devices, requiring regular updates exceeding the scope of this paper. To get latest findings in this quickly increasing field of research, investigators should be aware of how the environment is changing and take into account further sources.

By creating an in-depth structure [18] that combines three different classifiers a deep neural network (DNN), a convolutional neural network (CNN), and a recurrent neural network (RNN), this study tackles the difficult job of audio emotion detection. The approach uses segment-level mel-spectrograms (MS), frame-level modest descriptions (LLDs), and utterance-level outcomes of the highest-level statistical algorithms (HSFs) on LLDs to concentrate on categorising detection of four different feelings. Adopting a multifaceted learning approach, the separate versions of LLD-RNN, MS-CNN, and HSF-DNN that are produced are merged to conduct extraction on continual emotion characteristics and categorise defined types of emotions all at once. It is important to take into account the computing requirements of these optimisation techniques, especially if working with huge data sets or apps that operate in real time. This highlights the necessity for efficient and flexible systems in further research.

The promise of blended learning for automated identification of emotions is discussed in this work, with a focus on the relationships and dependencies between sight and aural domains that are still poorly understood. This approach [19] to Multimodal Emotion Recognition Metric Learning (MERML) seeks to simultaneously learn an adequate representational in a space known as latent and a selective score for both techniques, appreciating the distinctive features of each. A Support Vector Machine (SVM) kernel founded on the Radial Basis Function (RBF) effectively applies the learnt metric. The work acknowledges that developing an efficient measure in multi-modal settings is an important aim for a variety of use cases involving machine learning. There are worries over adaptability across different datasets with different channels and emotions as the evaluation's statistics' unique qualities and complexity may have an impact on MERML's efficacy. For assessing MERML's realistic practicality in cases outside of the assessed datasets, more research is necessary to test its effectiveness and versatility in applications that utilise real-time or huge data sets. Even if this research shows better performance, there is still work to be done on the accessibility of the learnt measure and its applicability to other multimodal recognition of emotions activities.

The literature addresses traditional emotional identification pipelines, like subject-independent behavioural characteristics and machine learning classification algorithms, but also acknowledges the field's developing problems. A possible solution is the suggested bi-modal strategy that combines speech and facial clues; nonetheless, the study rightly highlights the need for further research, especially when dealing with a variety of human faces and environments. Moreover, the study of face expression recognition in autonomous vehicles and human-computer interactions highlights the necessity for thorough assessment, particularly with the influence of temporal and geographical factors. The study on micro-expression evaluation emphasizes the dynamic nature of technology in the sector and emphasizes the significance of dataset limits. While highlighting the need for more research and highlighting the difficulties of complicated models, the work on audio emotion recognition presents intriguing multimodal learning approaches. In a similar vein, while Multimodal Emotion Recognition Metric Learning (MERML) research shows good results, more investigation is necessary to ensure that the model is flexible enough to work with different datasets and in real-world circumstances. In summary, these assessments of the literature successfully highlight the deficiencies and intricacies in the field of emotion recognition, offering significant perspectives for further studies.

III. Problem Statement

This comprehensive overview of the literature aims to address the central problem of identifying mental states using different interfaces, with particular focus on EEG results and numerous physiological markers. The research explores conventional emotional identification pipelines, which include smaller feature sizes and classification algorithms such as KNN, NB, SVM, and RF, in addition to methods like wavelet modification and nonlinear behaviour extraction. Through examining EEG patterns linked to affect, the study investigates the complex relationship between mental states and particular brain regions [14]. It also clarifies the benefits and limitations of using machine learning for emotion recognition as opposed to deep learning methods. The study also addresses the difficulties that arise when applying deep learning techniques in practical settings and emphasizes how important feature selection and data accessibility are in deciding how effective deep learning models are. In order to improve accuracy and overcome the shortcomings of current emotion identification methods, the study suggests a bi-modal approach that combines facial and voice signals [15]. It also explores the rapidly developing field of computational learning for emotion recognition and uses neural network techniques for real-time applications, namely facial expression recognition in HCI, autonomous driving, and micro-expression analysis in movies. Moreover, the paper addresses the complexities of auditory emotion recognition and provides an extensive framework with three different categorization techniques for real-time learning and improved accuracy [18].These difficulties are all related to the larger objective of creating more reliable and effective emotion detection techniques, which emphasizes the critical need for additional study to get beyond present barriers and progress the area.

IV. Proposed SVM and Decision Tree for Emotion Recognition

Datasets from reliable sources, like the Surrey Audio-Visual Expressed Emotion (SAVEE), Ryerson Audio-Visual Database of Emotional Speech and Song (RAVDESS), and Ryerson Multimedia Laboratory (RML), are first acquired for the suggested application. The later steps in the process are built upon these datasets. To ensure consistent feature scaling across various datasets, the data goes through a preprocessing step wherein Min-Max normalization is done. Finding pertinent features in the pre-processed data, the feature extraction procedure applies the Local Directional Pattern (LDP) approach. After that, the Fisher criteria—a technique that finds distinguishing features—are applied to feature selection and dimensionality reduction, maximizing the dataset for further examination. Support vector machines (SVMs) and decision trees are used as classifiers to improve classification accuracy. These classifiers use the chosen features to classify the dataset's emotional content. Furthermore, the Self-Similarity Distance Matrix (SSDM) is utilized as a metric to evaluate the degree of similarity across emotional patterns included in the data. The process of integrating the outputs from various classifiers and matrices is called emotion recognition fusion, and it is the culmination of the suggested technique. By utilizing each component's unique capabilities, this fusion method seeks to increase the overall accuracy and dependability of emotion recognition across the datasets. The all-encompassing strategy, which combines preprocessing, feature extraction, classification, and fusion, highlights how reliable and successful the suggested method, is in identifying emotions in audio-visual data. Fig. 1 explains the conceptual Diagram.

A. Dataset Collection

The data collections utilised in the present investigation are from the Ryerson Multimedia Laboratory (RML), Surrey Audio-Visual Expressed Emotion (SAVEE), and Ryerson Audio-Visual Database of Emotional Speech and Song (RAVDESS). The 1440 audio recordings in the RAVDESS data set are spoken in English by 12 male and 12 female participants. It is composed of eight distinct emotions: fear, fearlessness, rage, calmness, happiness, surprise, disgust, sadness, and neutrality. The 480 videos in the SAVEE data set are narrated in English by four male participants. It is composed of seven distinct emotions: fear, fearless, pleased, astonished, angry, dissatisfied and sad. The 720 videos in the RML data set are voiced in Persian, English, Italian, Urdu, Chinese, and Punjabi [20].

B. *Data Pre-Processing*

The method of identifying speech and visual disorders is thought to begin with pre-processing. It is used for both pattern extraction and data recognition. Pre-processing techniques are used to modify or amend the speech or visual data, *X(k)*, in order to prepare it for further processing. There is sometimes too much unnecessary and disruptive noise in the transmission of voice or visual data. Traditionally, sound-absorbing cotton or directional microphones were employed to cover up background noise produced by unwanted signals, such as noise from winds and object movement. It is a process for verifying the voice/vision message, *x(k).*If the voice/vision transmission is affected by the surroundings or ambient noise, like *a(k),*this is known as additive disruption. This can be removed using Eq. (1).

$$x(k) = s(k) + a(k) \tag{1}$$

The previous equation yields *s(k),*an exact voice/vision communication. Numerous noise reduction methods can be applied to a noisy speech stream to complete the procedure. The windowing technique: At this stage, the speech or vision information has been split into segments. The windowing functionality, or *w(k),*whose total length is represented by the character l, where l is the audio message's frame length, is used to amplify the signal's frames. Windowing is a type of analysis method where a speech/vision message section in a waveform is multiplied by a time window for a specific form to highlight the signal's intended distinctiveness is shown in Eq. (2).

$$w(k) = 0.54 - 0.46\cos\left(\frac{6.28k}{p-1}\right), \quad 0 \le k \le p-1 \tag{2}$$

Preprocessing must be normalized in order to be categorized. To expedite the learning procedure, the given information has to be normalized. Also, some kind of data normalization might be required to prevent numerical issues like accuracy loss from arithmetic mistakes. Attributes with large starting ranges are likely to dominate an upward descent after first outweighing characteristics with lesser beginning ranges. Since feature space normalization is not applied to the input vectors outwardly, it may be better understood as a kernel perception of preparation than as a specific kind of preprocessing. For instance, in some elements of detection of intrusions statistics, the highest and lowest points in typical and assault are varied by between nine and ten times. Put another way, normalization is a unique kernel mapping method that makes computations easier by converting the data onto a useful plane. The complicated normalization procedure would require an extended period to process because of the massive volume of data points. The chosen Min-Max normalization method is efficient and rapid.

The real information m is transformed linear into the necessary interval max_n, min_n by applying Min-Max Normalization in Eq. (3).

$$m = min_n + (max_n - min_n) * \left(\frac{m - min_u}{max_u - min_u}\right) \tag{3}$$

One benefit of the approach is that it accurately preserves the relationships between the locations in the information. There is no possibility that it could in any way skew the statistics.

C. *Feature Extraction using LDP Method*

When taking into account variations in age, different orientations, and sizes, illuminating effects, and pose variations, regional characteristics outperform global features. Consequently, for AIFR, we have suggested a texture local description. The highly prejudiced local characteristic from the facial components is found by using the suggested descriptor. The variation in the pattern generates a histogram by computing the particular region's pixel differential from the triplet's layout and the relationship among the dual-directional designs. The suggested extracting features method uses the suggested descriptors' local differential pattern [21].

1) Local difference pattern: The appearance and shape of a face evolve with age, making facial recognition harder. To identify a similarity feature that is robust against intra-class variation, research have, consequently, calculated the disparity among pixels of a local region of dimension $a \times a$in an image of dimension $X \times Y$. The suggested feature descriptor covers every local region of a face image.

The set of all the local region variance sequences is represented by Eq. (4),

$$LDP = \left[LDP^{1}_{R^{1}_{u,v}}, LDP^{2}_{R^{2}_{u,v}}, LDP^{3}_{R^{3}_{u,v}}, \ldots..LDP^{Y_i \times Y_j}_{R^{1}_{u,v}}\right] \quad (4)$$

where, u = 1, 2, 3., X − a +1 and v = 1, 2, 3., Y− a + 1.

For a single local region of $LDP^{1}_{uv}, LDP^{1}_{R^{1}_{u,v}}$is calculated. The pixels $A_{u,v}$ in the local region *LR1 i, j* have intensity values$U_{u,v}$, where *∀u,v = 1, 2, 3, …p.*

$$LR^{1d}_{1,v} = \left[A^{1}_{1,v}, A^{2}_{1,v}, \ldots.A^{1}_{1,v}, ..A^{1*a}_{1,v}, A^{p+1}_{1,v}, A^{p+1}_{2,v}, \ldots..A^{a*a}_{a,v}\right] \quad (5)$$

All of the local region pixel intensity values have been organised in three different formatsrow-wise, column-wise, and orderedto compute the local difference pattern of a face image. The calculation of the difference structure is then performed by transposing the resulting data. The pixels in Eq. (5) have been arranged row-wise and assigned to the 1-dimensional array$A^{1*a}_{1,v}$. The intensities of the correlating pixels are numbered as I and organised in the identical order, with an increasing order of magnitude as the superscript as mentioned in Eq. (6).

$$LR^{1^{1d}}_{u,v} = [U^{1}_{u.v}, U^{2}_{u.v}, U^{3}_{u.v} \ldots.U^{a*a}_{u.v}] \quad (6)$$

where, *u,v = 1,2,…a*. The subsequent Eq. (7) is used to compute the row-wise, column-wise, and ordered pattern variance of the intensity of the pixels of local area$k = a \times a$.

$$\gamma^{k}_{u,v+1} = \left[\gamma^{k-1}_{u,v+1} - \gamma^{k-1}_{u,v}\right] \qquad \forall u = 1, \forall v = k - 1 \quad (7)$$

Ultimately, the aforementioned formulas are used for calculating the k^{th}difference pattern. Finding the sum of the directed difference pattern, row-wise difference pattern, and column-wise difference pattern represented as $\gamma^{k}_{u,v}$ will yield the final absolute value of a local region.

The distinction arrangement in a single local region is calculated using the above equation; similarly, all variance patterns are obtained to form the final LDP feature vector, which is used to find the histogram. Eq. (8) displays the difference pattern's final feature vector:

$$LDP = \left[LDP^{1}_{LR^{1}_{u,v}}, LDP^{2}_{LR^{2}_{u,v}}, LDP^{3}_{LR^{3}_{u,v}}, \ldots..LDP^{v}_{LR^{1}_{u,v}}\right] \quad (8)$$

A feature vector Local Difference Pattern (LDP) of a face image contains all of the computed values. To generate a unique code for every neighbourhood, the process entails thresholding the intensity differences and assigning binary values. The resulting patterns draw attention to differences in intensity by highlighting textural details such as corners or edges. For tasks like texture analysis, object detection, and facial recognition, LDP is especially helpful because it efficiently encodes local information that can be useful for differentiating between various regions in an image. All things considered; Local Difference Pattern is a reliable technique for obtaining discriminative features that can improve the efficiency of a range of computer vision applications.

2) Spectral features: The present investigation incorporates MFCC, LTAS, and three spectral characteristics formants. Formants are an illustration of the resonant that occurs in the vocal cords at the peak of high intensity. Since formants change with emotion, they are often used in speech emotion recognition. Then measure the MFCC from a quadratic Me-scale to investigate the significance of low-frequency variables in comparison to high-frequency elements. Since they are highly responsive to variations in sounds at lower ranges, they are often used in voice and recognition of speech mechanisms as they mimic the way people's hearing systems adjust for tone and the exponential signal power ratio of vocal parts of speech signals. Furthermore, Long-Term Average Spectrum (LTAS) has less computational demand than MFCC. The final three formants, the overall mean of the LTAS, the average of the 12 MFCCs, and the ranges, greatest, and lowest constitute the characteristics of segments [22]. Fig. 2 shows the workflow of Mel-frequency cepstral coefficients (MFCC).

The feature-extracting method known as MFCC collects both non-linear as well as linear features, which are necessary for speaker identification. The frequency spectrum employed by the MFCC adjusts the frequency exponentially for frequencies above and below 1 kHz. With MFCC, the crucial component that constitutes sound transmissions may be recorded. The acronym for complex cepstral coefficients is MFCC. Since the MFCC provides both time and frequency information about the signal, it is more beneficial for feature extraction. MFCCs have found widespread application in voice recognition due to their ability to effectively handle dynamic features of the audio data while capturing all non-linear and linearity qualities. Since the sounds have both non-linear as well as linear properties, MFCC is a useful technique for feature extraction. MFCC is a particularly often employed feature in contemporary speech verification/identification methods, according to a number of studies. These factors make MFCC a popular choice for speech recognition systems:

- The discrete cosine transformation (DCT) effectively makes the cepstral features orthogonal.
- Noise from stationary channels is eliminated by subtracting the cepstral average.
- MFCC is less vulnerable to additive noise than other feature extraction techniques like linear prediction of cepstral coefficients.

The following are the methods that MFCC employs to extract features: Initially signal pre-processing is applied to a voice message. It applies pre-emphasis filtering to equalize the exact dimensions. A Hamming is the Window that has been attached to each block to mitigate the edge impacts caused by the window cutting. A discrete cosine transformation is applied to the processed signal, and it is then softened using a series of triangle filters separated along a Me1 Scale.

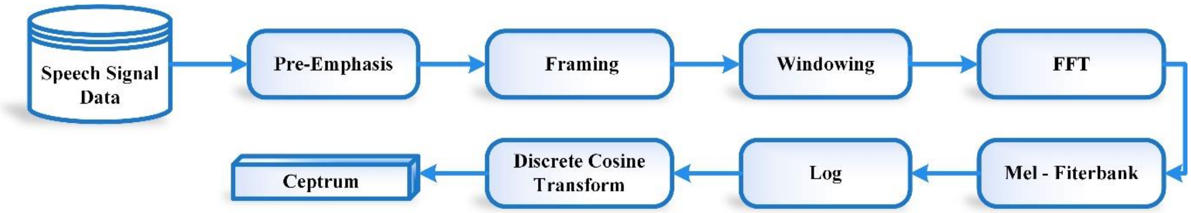

Fig. 2. MFCC workflow.

In audio and voice audio processing, MFCCs are a frequently used feature extraction method. The Fast Fourier Transform (FFT) is used to transform the data into the domain of frequencies, and filter bank processing is then applied to replicate human aural perception. After applying logarithmic compression to the filter bank energies, the MFCCs which capture crucial spectral properties for tasks like sound classification and speech recognition are obtained by the discrete cosine transform (DCT).

D. Feature Selection and Dimensionality Reduction

The purpose of selecting features is to ascertain the characteristics' relative relevance. Following the process of extraction aspects of the input voice signal, only significant characteristics are selected, with the other features eliminated. The characteristics' relevance is calculated at this stage. In this paper, they implement the feature selection procedure using correlational evaluation. In addition, they employ a linear discriminatory analysis approach for feature reducing dimensionality called the Fisher criteria. Initially, Euclidean distance investigation, partial correlation estimation, and vicariate correlation assessment are used to choose the features. The final features with decreased dimensions are then obtained by applying the Fisher criteria to the consequent aspects that were acquired [22].

1) Correlation analysis: The Euclidean distance analysis is completed at this point, and all of the characteristics are grouped together. The correlation between the attributes in each category is then determined by using a modified study of correlation on each group. The final feature set is then determined by evaluating the resulting features for Spearman rank correlation (SRC) assessment. Following the start of the correlation investigation, the resulting emotional traits become increasingly apparent.

2) Euclidean distance analysis: An individual's emotions may be described by a variety of qualities, but it might be difficult to apply them concurrently when conducting emotion recognition. As such, it is crucial to determine which traits are fundamental and have a significant impact on management and emotions. Each characteristic is first examined to see how it relates to other characteristics; those characteristics are then categorised according to the results of this analysis. In this case, the features are grouped using distance analysis. The Euclidean distance shows the true distance between two points in an aspect set of n dimensions. Eq. (9) expresses the Euclidean distance between two points, (X_1,Y_1) and (X_2,Y_2).

$$E = \sqrt{(X_2 - X_1)^2 + (Y_2 - Y_1)^2} \tag{9}$$

where, characteristics that have lower *E*scores are clustered into a single group. E indicates the Euclidean distance. X=X_1,X_2, ...,X_n *and* Y=Y_1,Y_2, ..., $Y_n$are locations in a space with n dimensions. Equivalent characteristics are chosen from the closest proximity characteristics.

3) Partial correlation analysis: Since many emotional components share characteristics with a state of feeling, it may be difficult to ascertain how features influence the emotional state. Before examining the link between characteristics and associated feelings, it is necessary to exclude or regulate the features that negatively impact the other aspects. One may refer to this type of study as net correlational analysis or partial correlation assessment. This type of research uses the linear relationship across two features to identify how one affects the other. X= $\{X_1,X_2, ...,X_n\}$ is the set of independent factors; the partial correlation between these variables is calculated using Eq. (10)

$$r = (\rho^{ij})_{n\times n} = \begin{bmatrix} \rho^{11} & \cdots & \rho^{1n} \\ \vdots & \ddots & \vdots \\ \rho^{n1} & \cdots & \rho^{nn} \end{bmatrix} \tag{10}$$

Eq. (11) is used to obtain the inversion for the Matrix mentioned above.

$$r^{-1} = (\lambda^{ij})_{n\times n} = \begin{bmatrix} \lambda^{11} & \cdots & \lambda^{1n} \\ \vdots & \ddots & \vdots \\ \lambda^{n1} & \cdots & \lambda^{nn} \end{bmatrix} \tag{11}$$

Eq. (12) is used to determine the partial relationship among the two variables.

$$Y^{ij} = \frac{-\lambda^{ij}}{\sqrt{\lambda^{ii}}\sqrt{\lambda^{jj}}} \tag{12}$$

The relation between the two separate variables is defined by the coefficient. It subtly illustrates their dependence and the need for selecting or elimination.

4) Nonlinear correlation analysis: There are multiple techniques available when calculating the correlation coefficient between both variables which are a Spearman Rank Correlation (SRC), a Kendall Coefficient of Concordance (KCC), and a Pearson Product Moment Linear Correlation Coefficient (PLCC). However, the characteristics that were taken from all frames inside every time frame are distinct, completely sorted variables, and we used the SRC approach to determine their rank. One kind of index that examines the statistically significant relationship between two variables under a linear function is the SRC Coefficient. The SRC Coefficient is either +1 or - 1 for variables that are strictly monotonic to one another; these variables are referred to be full spearman correlations. Let *X*= $\{X_1, X_2, ..., X_n\}$, and *Y*=$\{Y_1, Y_2, ..., \ Y_n\}$be two variables. Using Eq. (13), the SRC coefficient for each is determined.

$$\rho^s = \frac{\sum_{i=1}^{n}(X_i-\bar{X})(Y_i-\bar{Y})}{\sqrt{\sum_{i=1}^{n}(X_i-\bar{X})^2}\sqrt{\sum_{i=1}^{n}(Y_i-\bar{Y})^2}} \quad (13)$$

In the *X* variable, *Xi*represents i-th characteristic, this is whereas *Yi* represents*i-th* feature in the *Y* variable. The Mean of *X* and *Y* are denoted by $\bar{X}$ and $\bar{Y}$, respectively. A not-parametric correlation value is typically used to calculate the SRC coefficient. When knowing the combined probability distribution of *X* and *Y* samples, the SRC Coefficient calculates precisely the distribution of the two observations. Between *X* and *Y*, the SRC Coefficient is present up through the monotonic connection. The SRC is not the same as the PLCC, which is only dependent on linearity characteristics.

5) Fisher criterion: The multidimensionality of the feature set presents a number of challenges in the development of statistical algorithms for recognised patterns purposes. Low dimensionality methods can provide optimal performance with minimal computing burden. More relevant characteristics are acquired at the feature identification stage, and they undergo a transformation into lower-dimensional space with very little data loss. The loss of data is the main problem of reduction in dimensionality. Therefore, we use the Fisher Criterion, which establishes the concept of linear relation-based reduction in dimensions, to provide an ideal set of attributes with low dimensionality space. Another well-liked technique for reducing complexity is PCA, yet it is unable to separate differentiates between low from very high multidimensional emotional traits. Eq. (14) is used to compute the Fisher Criterion analytically.

$$\lambda^F = \frac{\sigma^B}{\sigma^W} \quad (14)$$

where, σ^W denotes the variation inside the class, σ^B denotes the variance among classes, and λ^F stands for Fisher's rate for characteristics. Eq. (15) definesσ^B.

$$\sigma^B = \sum_{c=1}^{N}(E^c - \bar{E})(E^c - \bar{E})^T \quad (15)$$

where, as specified in Eq. (16),$\bar{E}$ is the average of the whole set of data.

$$\bar{E} = \frac{1}{m}\sum_{i=1}^{m} X_i \quad (16)$$

Moreover,E^c which is specified in Eq. (17), is the sample's average for *ith* Emotions classes.

$$E^c = \frac{1}{N_p}\sum_{X \epsilon E^c} X_i \quad (17)$$

The whole quantity of feelings is denoted by the value *M* in Eq. (16) and the total amount of instances in the speech's emotional signals is denoted by the expression in Eq. (17). Likewise, it has a mathematical definition found in Eq. (18).

$$\sigma^w = \sum_{c=1}^{N}\sum_{i=1}^{N_p}(X_i - E^c)(X_i - E^c)^T \quad (18)$$

They next used decrease in dimensionality to the shape of the distribution vector, σ^w in order to eliminate extraneous features while keeping the crucial data intact.

E. SVM, Decision Tree Classifier

The total amount of characteristics defines *N*, which is utilized to find the hyperplane in the space with *N* dimensions using SVM. The hyperplane facilitates the information point classification procedure. The greatest distance on the plane among the different categories should be used. Non-linear (RBF) kernels are employed in this study to classify support vectors. Using Eq. (4), the kernel aids in obtaining the hyperplane for identifying various classes in Eq. (19):

$$K(X^i, X^j) = e^{-\gamma\|X^i - X^j\|^2} \quad (19)$$

where, the squared Euclidean spacing among the two input information vectors, X^i and $X^j$is represented as $\left\|X^i - X^j\right\|^2$. The incorrect classification rate, C, for the study described in this article, has been fixed at 2. The percentage of inaccurate classifications made by the model that was trained is known as the misperception rate. In order to get the most significant margins between the classes and to signal a smaller erroneous bound, a minimum amount was used [23]. Fig. 3 shows the structure of SVM.

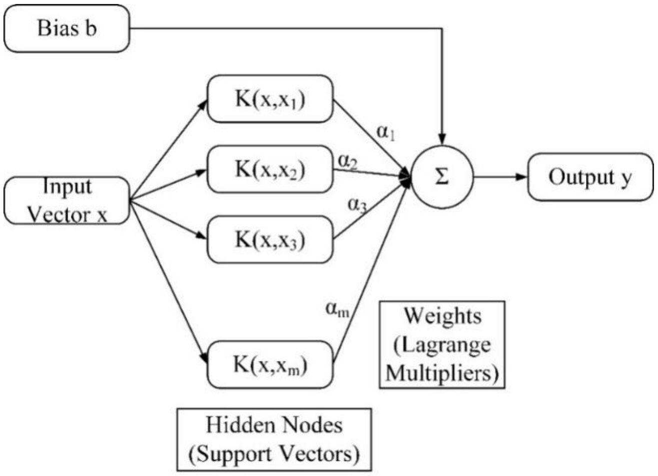

Fig. 3. Structure of SVM.

An optimal splitting of the input characteristics is generated to choose the nodes of a tree that makes up the DT classifier. The greatest information gain (IG) is produced by the separation of the data itself and the tree roots. The tree pruning had been configured with a maximum cutting depth of 8 in order to prevent overfitting of the simulation. Obtaining the parental node's *IG* (20) was applied.

$$IG(D^p) = ID^p - \frac{N_{left}}{N^p} ID_{left} - \frac{N_{right}}{N^p} ID_{right} \quad (20)$$

where, an array comprising the parent, left, and right datasets is represented by D^p, D_{left} , and D_{right}. In this investigation, *I*, the value of entropy, was employed to determine the separated entropy criterion's efficiency. Eq. (21) was used to compute the entropy.

$$I = -\sum_i p^i . log_2 p^i \quad (21)$$

The value that is targeted i'sprobability is represented byp^i. Eq. (22) was utilized in addition to determining the categorization error.

$$DTmodel^{error} = 1 - \max(p^i) \tag{22}$$

F. Self-Similarity Distance Matrix (SSDM)

They represent every movie as a collection filled with regional SSM descriptors H and use recently effective bags-of-features techniques to identify emotion events. Next, they train and categorize examples that represent action classes using SVM.

They create visual text histograms and utilize them as a source of inputs for training using SVM and classifications. Using 10,000 local SSM descriptors (h) divided into k = 1000 clustered from the training collection, a visual language is created. The graphical representation of visual phrases is then calculated for every image in the sequence, and every characteristic is then paired with the vocabulary word that is the closest to it (although they utilize the Euclidean distances). They use the χ 2 kernels for training, not linear SVMs, and use a one-versus-all strategy for the classification of multiple classes [24].

They give n-fold cross-validation findings for each of the recognition investigations in the following section and ensure that a single person's behaviours are not seen in both the training and test sets at the same time.

G. Emotion Recognition Fusion

The methods mentioned above deal with single-frame and 400 ms sound segment prediction. The frame-based forecast was converted to a video-based projection so that the outcomes could be compared with human users. Similarly, to how the audio recordings are divided into manageable chunks, the outcomes were combined to provide one recorded prediction. The following procedure was followed in order to make a single prediction: Each of the six scores for audio and video predictions relates to the expected accuracy for a certain class. Since all probabilities add up to one, the label that is predicted is represented by the value with the greatest sum [25]. To obtain the final forecasting, the individual probabilities are added together and normalized. To get a single forecast for an instance file (audio + video) in a similar fashion, the earlier indicated technique is required. Since the six probabilities form the basis of the audio- and video-predicted labels, these can be easily compared, a process known as decision-level fusion.

V. Result and Discussion

The proposed method's performance evaluation shows notable improvements in the accuracy of emotion recognition. Based on thorough experimental validation using the SAVEE, RAVDESS and RML datasets, the combined strategy shows significant gains over current techniques. A comprehensive feature set that enhances classification is demonstrated by the combination of speech attributes and Weighted Edge Local Directional Patterns for facial pattern extraction.

Metrics for emotion recognition accuracy are displayed in the Table I for a range of emotional categories in three different datasets: SAVEE, RAVDESS, and RML. The reliability for the method of classification is further highlighted by the use of Decision Tree and Support Vector Machine algorithms. The approach gains a valuable dimension with the addition of the novel's Audio-Visual Descriptor, which focuses upon facial alignment as well as selection. This leads to an improvement in emotion recognition performance. The cohesive integration of speech characteristics, multimedia descriptors, and facial patterns enhances the method's adaptability and resilience in identifying feelings within a variety of methods. Based on the percentage accuracy of detecting seven different emotions angry, calm, disgusted, fearful, happy, sad, and surprised each dataset is evaluated. In addition, the SAVEE dataset scored 75% accuracy within the angry category, the RAVDESS dataset obtained 90% accuracy, and the RML dataset showed a high accuracy of 93% accuracy. To identify the remaining emotions within every dataset, the table also gives accuracy percentages. These metrics are useful for comparing how well emotion detection models trained regarding the different datasets perform, showing the different levels of success in correctly classifying different emotional states.

Fig. 4 shows the performance of emotion recognition using accuracy measures for different emotions across three different datasets: SAVEE, RAVDESS, and RML. Particularly, the RML dataset performs well in the angry category with an accuracy of 93%, outperforming both SAVEE (75%) and RAVDESS (90%). The SAVEE dataset is better at identifying Fearful emotions (71%) than the RAVDESS dataset is at identifying Calm emotions (95%). Accuracy in the happy category is comparatively similar, using RAVDESS and RML receiving scores of 86% and 88%, correspondingly. The RML dataset consistently scores well within the disgusted and surprised categories, achieving accuracies of 87% and 88%. The significance of choosing relevant datasets over training models customized to particular emotional states is highlighted by these results, which highlight the dataset-specific details in emotion recognition.

TABLE I. PERFORMANCE OF THE DATASET

Dataset	SAVEE	RAVDESS	RML
Metrics			
Angry	75	90	93
Calm	73	95	90
Disgusted	70	88	87
Fearful	71	88	84
Happy	69	86	88
Sad	70	83	85
Surprised	68	87	88

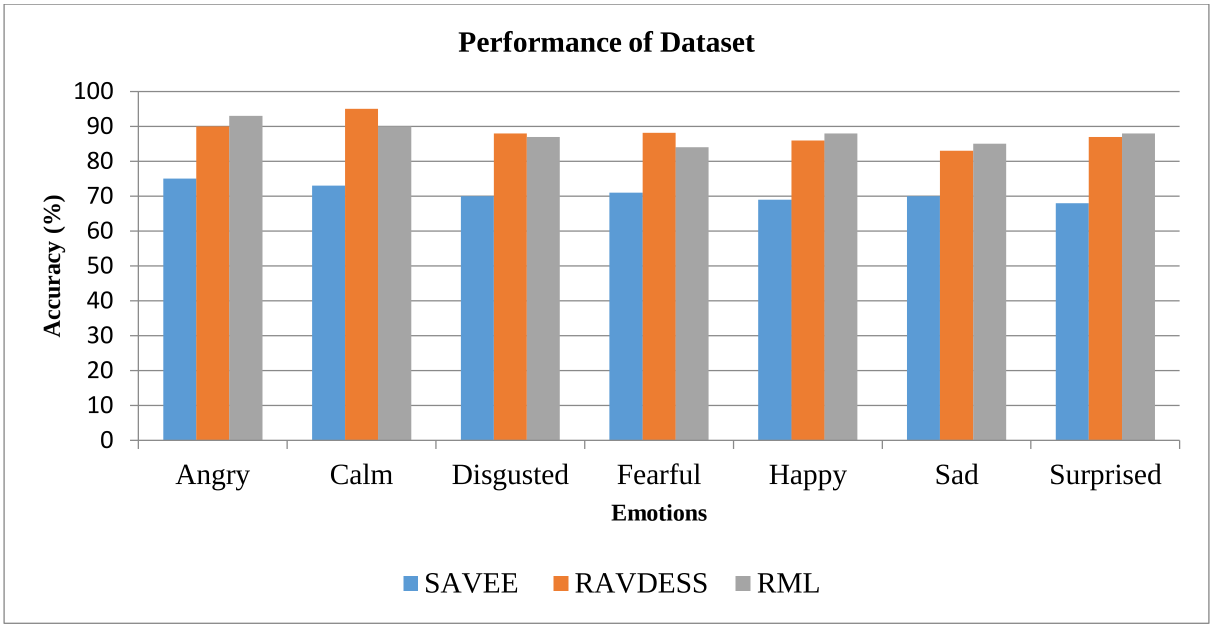

Fig. 4. Graphical representation for performance of the dataset

CNN-LSTM, CNN with Class Activation Mapping, Transformer with Self-attention, the suggested SVM and Decision Tree approach, and other classification techniques are all thoroughly compared in Table II that is presented. With an astounding accuracy of 98.2%, the suggested SVM and Decision Tree technique notably beats its competitors, demonstrating its efficacy in correctly classifying data. The robustness and reliability of the suggested strategy are shown by the precision, recall, and F1-Measure scores of 98.6%, 97.9%, and 98.3%, respectively. With improvements in classification accuracy over the most advanced techniques, this higher performance establishes the suggested SVM plus Decision Tree approach as a highly competitive solution and makes it a viable option for applications needing accurate and dependable classification.

TABLE II. PERFORMANCE COMPARISON WITH EXISTING AND PROPOSED METHOD

Classification method	Accuracy of Classification Method	Precision	Recall	F1-Measure
CNN-LSTM [26]	80%	83.2%	72%	85%
CNN and Class Activation Mapping [27]	90%	93%	90.5%	88%
Transformer and Self-attention [28]	97%	97.8%	98.1%	98%
Proposed SVM and Decision Tree	98.2%	98.6%	97.9%	98.3%

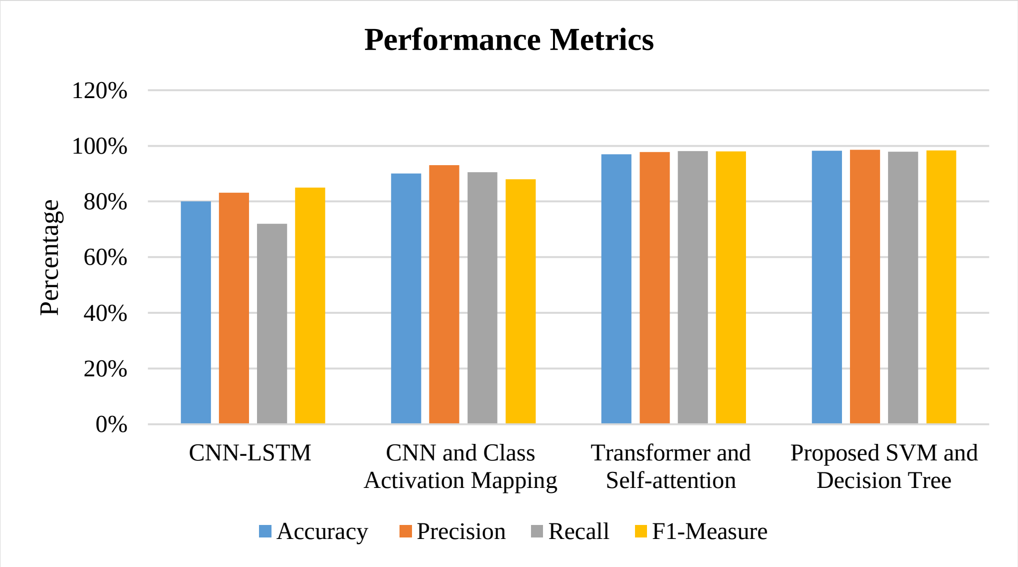

Fig. 5. Graphical representation of performance comparison with existing and proposed method.

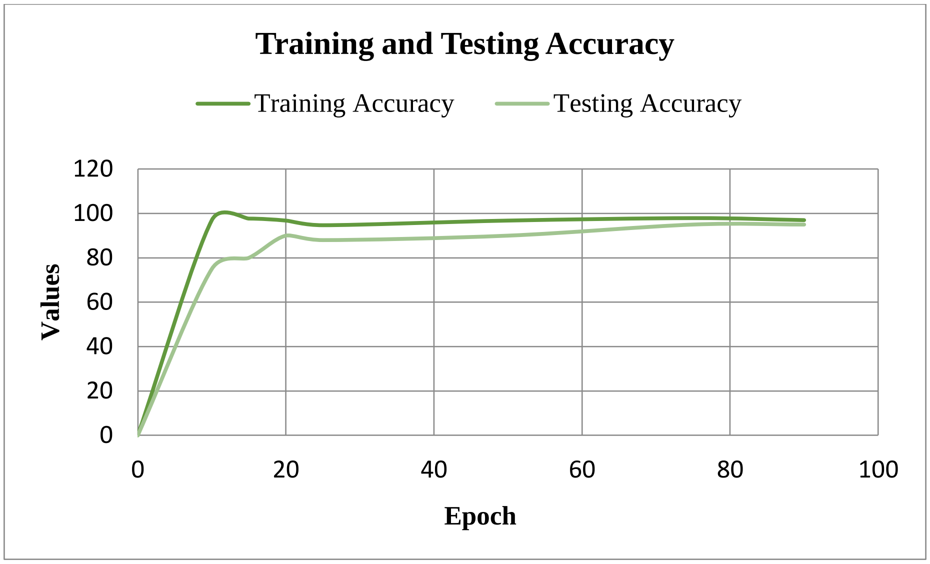

Fig. 6. Graphical depiction for training and testing accuracy of proposed SVM and proposed model.

The performance measures of several classification techniques are shown in the Fig. 5 in terms regarding percentage accuracy. With an accuracy of 80%, the CNN-LSTM model demonstrated its ability to combine long short-term memory (LSTM) networks and convolutional neural networks (CNNs) for classification tasks. A higher accuracy of 90% was shown by the CNN and Class Activation Mapping approach, demonstrating the efficiency of convolutional neural networks enhanced about class activation mapping over localization. With an astounding accuracy of 97%, the Transformer and Self-attention framework demonstrated the effectiveness of self-attention mechanisms in identifying complex patterns. Support vector machines (SVMs) and decision trees work well together to provide accurate classification in the given context. This is demonstrated by the proposed SVM and Decision Tree ensemble, which performed better than other approaches and achieved an impressive accuracy of 98.2%.

Fig. 6 shows the training accuracy graph, within the framework of the proposed SVM and decision tree model, shows how well the model classifies emotions using the training dataset throughout its training iterations, or epochs. This graph shows how the model is learning and if it is becoming more accurate or if the training data may be overfitting. However, the effectiveness of the model on a separate, untested dataset that was not used for training is depicted on the testing accuracy graph. This graph sheds light on how well the model can use its knowledge of emotion recognition to situations outside of the training set. A high testing accuracy shows the model's competence in consistently identifying emotions in a variety of real-world scenarios, and those is essential for improving emotion recognition. A substantial training accuracy suggests that the framework successfully acquired from the training data.

The suggestedSVM and decision tree model demonstrates how the model's loss function changes over the training and evaluation stages in a graphical representation for training and testing loss is shown in Fig. 7. The training loss graph illustrates where the loss, a measure of the discrepancy between expected and actual values, varies throughout the course of the model's training epochs or iterations. The framework learns from and adjusting to the training data when there is a decreasing training loss.The model repeatedly adjusts its variables during training epochs, and the evolution of the loss values which quantify the difference among the predictions made by the model and the actual target values is shown in the training loss curve. The training loss shows that the model is becoming better at fitting the training data. On the other hand, the testing loss curve shows how well the model performs on a test dataset that has not yet been seen, providing information about how well it can generalize and generate correct predictions in practical situations. When faced with new, untested data, the model's capacity to generalize well and provide a lower error rate is demonstrated by the testing loss value that decreases.

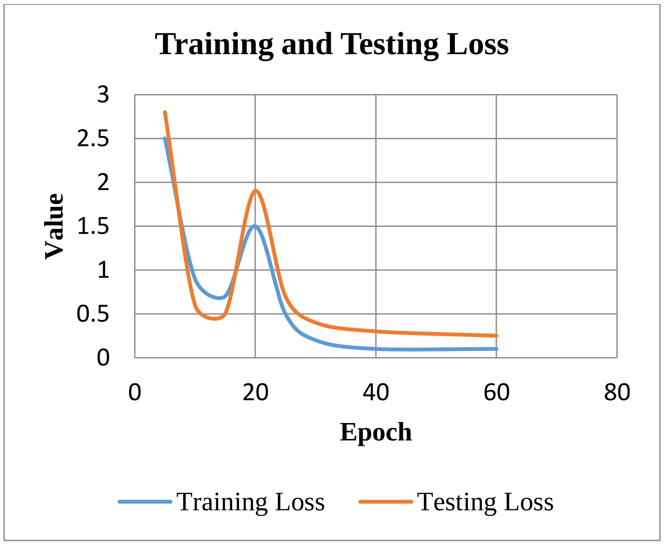

Fig. 7. Graphical depiction for training and testing loss of proposed SVM and decision tree model.

A. Discussion

The outcomes demonstrate the significant progress made by the suggested emotion recognition approach, particularly in contrast to other methods now in use. Using three different datasets, including SAVEE, RAVDESS, and RML, the method's performance is methodically assessed over a range of emotional categories. The increased accuracy of the method's emotion recognition can be attributed to the addition of the Audio-Visual Descriptor, which highlights face alignment and selection. The thorough measurements offer a thorough grasp of how well the approach recognizes seven distinct emotions throughout the datasets. the performance across datasets and emotions, highlighting the subtleties unique to each dataset in the identification of emotions. The suggested SVM and Decision Tree method's exceptional accuracy of 98.2% can be seen when compared to advanced techniques[26] [27] [28]. Its robustness and reliability are further highlighted by the precision, recall, and F1-Measure scores. The suggested approach performs better than CNN-LSTM, CNN with Class Activation Mapping, and Transformer with Self-attention, as demonstrated by the graphical representations. In addition to performing better than existing techniques, the suggested strategy attains a greater accuracy of 98.2%.

The accuracy graphs for training and testing provide information on how the model learns and how well it generalizes to new data. A high testing accuracy shows that the model is useful outside of the training set and demonstrates its competency in real-world circumstances. In addition, the model's learning dynamics are demonstrated by the training and testing loss curves, where lowering loss values denote better generalization and data fitting. The suggested technique for identifying emotions uses a combination of speech characteristics and Weighted Edge Local Directional Patterns, and it shows excellent accuracy and resilience in a range of datasets and emotional classifications. Because of its increased versatility, the Audio-Visual Descriptor presents a viable option for applications that demand accurate and dependable emotion recognition.

This study has certain limitations, despite the notable advancements and gains shown in facial expression analysis and emotion recognition. The suggested model's dependence on edge detection might provide difficulties in situations with different illumination conditions, which could affect the expression assessment's correctness. The model's efficacy can vary depending on the context, and more research may be necessary before applying it to a wider range of real-world settings. The study may have limited cross-platform compatibility and interoperability with other programming languages or frameworks due to its exclusive usage of Python tools for implementation. Further research and development may be needed in the model's ability to handle complex or delicate emotional expressions.

VI. Conclusion and Future Work

In order to overcome difficulties with emotion classification and facial expression identification, this research offers a fresh and practical paradigm. A thorough method for capturing minor emotional cues is demonstrated by the integration of three different feature sets: prosodic characteristics, a new audio-visual descriptor, and Local Differential Pattern (LDP). Specifically designed to improve face feature extraction, the LDP approach is useful for reducing distortion and unreliability associated with edges in facial images. The proposed Audio-Visual Descriptor uses a Self-Similarity Distance Matrix (SSDM) to give a concise description of emotion while giving priority to key frame selection and facial alignment. Experimentation validation using SAVEE, RAVDESS, and RML datasets demonstrates notable advances over existing approaches, highlighting the usefulness of the suggested framework in correctly categorizing emotions and facial expressions in a range of contexts. There are numerous directions for more research and development. More advancement in classification accuracy may be possible by enhancing the suggested framework by adding deep learning architectures, evaluating alternative machine learning algorithms, and examining sophisticated feature extraction methods. Increasing the size and diversity of datasets included in the experimental validation process would improve our comprehension of the generalizability of the model. For practical applications, addressing real-world issues like varied lighting and dynamic face expressions may be essential. It would also be beneficial to investigate how the framework is implemented in real-time settings and evaluate how well it works in erratic environments. In conclusion, the proposed framework raises the bar for the field of emotion identification technology and provides a strong basis for future research projects. Regarding theoretical ramifications, this study makes a substantial contribution to the field by presenting a novel framework that integrates a variety of feature sets, giving emotion categorization a more sophisticated and reliable method. The limitations of current approaches are addressed by the integration of prosodic features, audio-visual descriptors, and LDP, creating opportunities for the exploration of richer emotional cues. From a practical standpoint, the suggested framework has a benefit in that it can reliably categorize emotions and facial expressions in a range of situations. The model has been shown to outperform existing approaches in a number of real-world applications, including affective computing, mental health assessment, and human-computer interaction. These advantages are especially evident in datasets like SAVEE, RAVDESS, and RML. It is essential to recognize the constraints of this research. The accuracy of expression assessment may be affected by the dependence on edge detection algorithms in situations when illumination conditions are changeable. More research and validation are needed to fully understand how the model works in different real-world contexts and how context-specific it is.The suggested framework's potential can be increased for further studies by incorporating deep learning architectures and investigating different methods. A more thorough grasp of the model's capabilities and constraints will also result from extending experimental validation to bigger datasets and tackling real-world issues. Important objectives for future research include investigating real-time implementation and assessing performance in dynamic situations.The foundation for developing emotion recognition technology is laid by this research; however, further investigation and improvement are necessary to ensure the technology's advancement and usefulness.

Research on Efficient CNN Acceleration Through Mixed Precision Quantization: A Comprehensive Methodology

Yizhi He[1], Wenlong Liu[2], Muhammad Tahir[3], Zhao Li[4*], Shaoshuang Zhang[5], Hussain Bux Amur[6]
School of Computer Science and Technology, Shandong University of Technology, Zibo 255049 China[1, 2, 4, 5]
Department of Computer Science, Mohammad Ali Jinnah University, Block 6, P.E.C.H.S, Karachi, 75400, Pakistan[3, 6]

Abstract—**To overcome challenges associated with deploying Convolutional Neural Networks (CNNs) on edge computing devices with limited memory and computing resources, we propose a mixed-precision CNN calculation method on a Field Programmable Gate Array (FPGA). This approach involves a collaborative design encompassing both software and hardware aspects. Initially, we devised a CNN quantization method tailored for the fixed-point operation characteristics of FPGA, addressing the computational challenges posed by floating-point parameters. We introduce a bit-width strategy search algorithm that assigns bit-widths to each layer based on CNN loss variation induced by quantization. Through retraining, this strategy mitigates the degradation in CNN inference accuracy. For FPGA acceleration design, we employ a flow processing architecture with multiple Processing Elements (PEs) to support mixed-precision CNNs. Our approach incorporates a folding design method to implement shared PEs between layers, significantly reducing FPGA resource usage. Furthermore, we designed a data reading method, incorporating a register set buffer between memory and processing elements to alleviate issues related to mismatched data reading and computing speeds. Our implementation of the mixed-precision ResNet20 model on the Kintex-7 Eco R2 development board achieves an inference accuracy of 91.68% and a computing speed 4.27 times faster than the Central Processing Unit (CPU) on the CIFAR-10 dataset, with an accuracy drop of only 1.21%. Compared to a unified 16-bit FPGA accelerator design method, our proposed approach demonstrates an 89-fold increase in computing speed while maintaining similar accuracy.**

I. INTRODUCTION

Nowadays, deep learning has brought new development opportunities for Internet of Things (IoT). Among them, CNNs are widely used in many areas such as face recognition, autonomous driving, and unmanned air vehicles for their outstanding performance [1]. CNN consists of two stages, which are training and inference. Usually, training is a one-time off-line process, which is based on computing platform with large computing resources and high power consumption. Inference can be deployed on edge computing devices, in order to obtain shorter processing delay and avoid the impact of communication situation [2].

However, with the development of deep learning, the size of CNNs continues to increase to obtain stronger learning ability, resulting in larger network computations, more parameters, and more complex network structures. At the same time, many edge computing platforms have limited storage and computing resources, restriction on power consumption and latency. Therefore, the use of CNN inference on edge computing devices has become an important challenge in the field of Artificial Intelligence (AI) research.

Currently, many FPGA acceleration methods [3] for CNNs have been proposed. With FPGA's parallelism and flexible configuration, it can be deeply customized for the CNN structure through parallel computing methods [7] to provide accelerated services for deep learning, achieving higher performance and power efficiency.

Chen et al. [10] proposed the DianNao CNN accelerator, which adopted a three-level pipeline architecture consisting of multiplication, addition, and sigmoid functions. By reusing the weights stored in the on-chip memory, it reduced the need for accessing off-chip data, thereby lowering memory access power consumption. The CNN accelerator Eyeriss [11] was proposed, which employed a row stationary dataflow to maximize data reuse in the computation array and minimize memory access. The authors of this article reference [12] proposed the energy-efficient and reconfigurable hybrid neural network processor Thinker. Each computing unit in Thinker supports adaptive computation for different data bit-widths required by neural networks. The maximum operating frequency is 200MHz, and the supported data bit-widths are 8-bit and 16-bit.

Additionally, quantization [13] can be used to reduce model sizes and hardware resource consumption, such as replacing original 32-bit floating-point operations with lower precision fixed-point numbers like 8-bit or 16-bit. Jacob et al. [15] proposed an integer quantization method, which uniformly quantizes both weight and activation to 8-bit. Furthermore, there are ultra low-bit quantization methods, such as ternary quantization [16] which quantifies weights into {-*w*, 0, +*w*}, and even binary quantization neural networks [17], which quantize weights and activation values to 1 or -1.

However, using a unified quantization bit-width in ultra low-bit-width situations would significantly affect CNN performance. A highly effective solution to this problem is through mixed precision quantization [20]. It allows each layer of the CNN model to have different quantization bit-widths. which can greatly preserve the performance. Lin et al. [21] proposed an analytical solution to address the fixed-point quantization problem. It seeks an optimal bit-width allocation strategy across network layers by optimizing the Signal-to-Quantization-Noise Ratio (SQNR). Wang et al. [22] designed a Hardware Aware Quantization (HAQ) algorithm that incorporates inference speed information evaluated by a hardware simulator into the training process, which utilized reinforcement learning to automatically determine quantization strategies. It reduces latency by 1.4-1.95 times and energy consumption by 1.9 times. However, the current methods face challenges in their applicability to FPGA platforms or in terms of high time and space complexity when searching for mixed precision strategies.

In conclusion, if we have an efficient mixed precision search algorithm and can apply the strategies obtained by this algorithm to FPGA platforms; it will be greatly significant for the application of deep learning on AIoT devices. Therefore, we propose a method for implementing a mixed precision CNN model on FPGA, co-designing from software and hardware aspects. The main innovation points are as follow:

1) A quantization method is proposed that is more suitable for FPGA's fixed-point operation characteristics. Combined with a mixed precision strategy search algorithm with the optimization objective of the lowest bit-width for each layer and the constraint of the accuracy of the CNNs achieve mixed precision calculation of CNNs.

2) In terms of FPGA accelerator design, an inter-layer storage and multi-PEs reuse mechanism is proposed based on the streaming processing architecture. And performing folding design between different CNN layers not only retains the flexibility of the streaming processing architecture but also saves hardware resources and improves the computing efficiency of each PE.

3) A new data reading method is designed using a high bit-width data transmission mode to read multiple data in a single cycle, efficiently utilizing bandwidth to transfer data. In addition, a register set is added as a buffer between the Block Random Access Memory (BRAM) and the PE to solve the problem of mismatch between reading and computing speed.

Based on the above, the purpose of this paper is to explore an efficient method for searching mixed precision quantization strategies and implementing mixed precision computation of CNN on the FPGA platform. The goal is to achieve high performance CNN computations within limited computational and storage resources.

This paper is structured as follows: Section II elucidates the mixed precision quantization method and outlines the strategy for bit-width exploration in the context of CNNs. In Section III, the FPGA platform accelerator is detailed, encompassing the overall architecture, parallel processing elements (PE), and an efficient data transfer mechanism. Section IV delves into the experimental results of quantization and assesses the performance of the mixed precision accelerator. Finally, Section V provides a comprehensive conclusion and future work for the paper.

II. Mixed Precision Quantization for CNNs

A. *Design of Quantization Method*

Although many existing quantization methods can reduce the parameter storage of CNNs through encoding and decoding, the quantized parameters are still computed using floating-point numbers [23]. When implemented to the FPGA platform, the fixed-point number used differs in precision from the original floating-point number, which leads to calculation error and causes drop of inference accuracy. Therefore, a quantization method suitable for FPGA has been designed to convert the parameters in the CNN model into fixed-point numbers, and retrain the quantized model to reduce the degradation of its accuracy. The quantization process consists of two steps: first, the floating-point number is transformed into a fixed-point number, which is left shifting, amplified, rounded, and truncated to a *n*-bit fixed-point integer. Then, the fixed-point decimal value is restored to an approximately original value through right shifting.

The process of converting a 32-bit floating-point number *X* to a *n*-bit integer X_{int} is shown as follows:

$$X_{int} = clamp(round(2^{n-l-1} \cdot X), Q_{min}, Q_{max}) \tag{1}$$

Where *l* is the number of bits in the integer part of *X*, Q_{min}=-2^{n-1}， Q_{max}=2^{n-1}-1， *round*() is the rounding function, and *clamp*() is defined as follows:

$$clamp(x,a,b) = \begin{cases} a, & x < a \\ x, & a \le x \le b \\ b, & x > b \end{cases} \tag{2}$$

For example, the process of quantizing a decimal with a floating-point number of 1.253 to an 8-bit fixed-point number (assuming 1 sign bit, 3 bits of integer width, and 4 bits of decimal width) can be shown in Fig. 1.

The floating-point number 1.253 is shifted left by 4 bits (multiplied by 2^4) and then amplified to obtain 20.048. Then, it is rounded and clamped to obtain an integer value of 20. Finally, the quantized integer value is shifted right by 4 bits (divided by 2^4) to obtain the fixed-point value of 1.25. Hence, it is possible to replace 32-bit floating-point numbers with 8-bit fixed-point numbers in order to make them more easily deployable in FPGA.

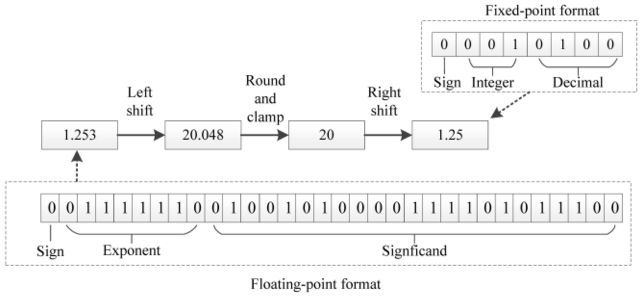

Fig. 1. Quantization Process Diagram.

Suppose the activation value A and weight parameter W in the CNNs are quantized to A_{int} and W_{int} respectively, then the convolutional process can be transformed into,

$$Y = A*W + b = A_{int} * W_{int} \cdot 2^{l_A + l_W + 1 - 2n} + b \tag{3}$$

where b represents bia, l_A and l_W represent the integer bit width of activation value A and weight parameter W, respectively.

Through (3), the floating-point number in the convolution process can be quantized into n-bit integer. After completing the convolution calculation, right shifting can restore the approximate value to the original result. Using shifting and integer operations instead of floating-point arithmetic can reduce the computational resource requirements for floating-point operations, which is easy to implement in FPGA. Moreover, the quantized fixed-point CNN can be retrained, greatly reducing the accuracy drop caused by directly implementing the CNN model to the FPGA platform.

B. Quantization Bit-Width Strategy Search Algorithm

Allocating appropriate quantization bit-widths for each layer in a CNN model is an important challenge in implementing mixed precision operations. Assuming there are 20 convolutional layers in a CNN model, each convolutional layer can be assigned a bit-width value ranging from 1 to 32. There are 32^{20} quantization schemes, and several schemes produce different inference accuracy and occupy different hardware resources. Therefore, selecting a suitable quantization scheme that has high accuracy and is also easy to deploy on FPGA requires an efficient strategy search algorithm. A novel CNN mixed precision quantization method is proposed by using quantization loss variation [25] to adjust the bit-widths of each layer, which can avoid this exponential search space.

1) Calculation of quantization loss variation: The quantization loss variation is an important indicator of bit-width allocation. We found that the loss variation is related to both the first and second derivatives (Hessian matrix) information of each quantization layer and the quantization error. It can be expressed by as shown as follows using Taylor expansion:

$$\Delta L = L(W_Q) - L(W) \approx g(W)^T \Delta W + \frac{1}{2} \Delta W^T H(W) \Delta W \tag{4}$$

g() represents the first derivative of the weight parameter W in the full-precision CNNs, H() represents the second derivative, L() represents the cross-entropy loss function commonly used in CNNs, and W_Q represents the weight parameter of the quantized CNNs. When studying the loss variation brought by second-order information, it is very difficult to directly calculate the relevant values of the Hessian matrix due to the large amount of weight parameters in CNNs. Therefore, the power iteration method can be used to approximate the maximum eigenvalue of the Hessian matrix. For each quantization layer, perturbations can be added in the direction of the corresponding eigenvector of the Hessian matrix as the quantization error [25], and then calculates the corresponding loss variation. Thus, we add perturbations in both gradient direction and Hessian matrix eigenvector direction separately in each quantization layer as the quantization error ΔW, as shown in (5).

$$\Delta W = \begin{cases} \lambda \times g(W) \\ \lambda \times H_i(W) \cdot V_i \end{cases} \tag{5}$$

The λ can be used to adjust the size of perturbation. $H_i(W) \cdot V_i$ represents the eigenvector corresponding to the maximum eigenvalue of the Hessian matrix for the *i-th* quantization layer, which can be calculated by (6) and the power iteration method.

$$\frac{\partial (g_i^T V_i)}{\partial W_i} = \frac{\partial g_i^T}{\partial W_i} V_i + g_i^T \frac{\partial V_i}{\partial W_i} = \frac{\partial g_i^T}{\partial W_i} V_i = H_i V_i \tag{6}$$

V_i is a random vector with the same dimension as the *i-th* quantization layer. The quantization error ΔW in the gradient direction is applied to the selected quantization layer and calculate the perturbed CNN loss variation ΔL_1. Then, the quantization error in the eigenvector direction of the Hessian matrix is applied to this quantization layer and the new loss variation is recalculated as ΔL_2. Finally, the maximum value between ΔL_1 and ΔL_2 is taken as the loss variation caused by this quantization layer.

2) Search method design: To reduce the search space, adjacent quantization layers in the CNNs with the same structural characteristics (such as kernel size, number of channels, and padding method) are merged into quantization blocks. The method described in last section is used to calculate the loss variation of different quantization blocks. High bit-widths are assigned to the quantization blocks that cause large loss variations, while low bit-widths are used for those that cause small loss variations. Then, the model is retrained according to the bit-width allocation strategy. The feedback results from the training are fed back to the policy search module, and the output policy is adjusted based on the feedback until the best bit-width allocation method is found. The specific process is shown in below Algorithm 1.

Algorithm 1: Quantization Bit-Width Policy Search

```
Input：Pre_Model, Dataset, Loss, Blocks, Acc_Set
Output：Bit-Width Policy
Blocks = Sort (Blocks, Loss)
Bit_Width = [16, 15, 14, … 4, 3, 2]
Index = 0
While (Index < length (Bit_width)) do
    New_policy = upgrade_policy (Bit_width [Index], Blocks)
    Model = Quantize (Pre_Model, New_policy)
    for i in range(epoch) do
        Acc = Train (Model, Dataset)
    if (Acc ≥ Acc_Set) then:
        Index = Index + 1
    else:
        Restore (Blocks)
        Choice_next_block (Blocks)
return New_policy
```

In this algorithm, a full precision pretrained model is used as the Pre_Model, and the corresponding Loss variation is used as input. The layer in pretrained model is merged into Blocks. Dataset is used as model training. Then, based on step 1, the quantization blocks are sorted in descending order according to the Loss values they produce. For the quantization block with a larger Loss value, it is quantized first, and the assigned bit-width is not less than that of the quantization block with a smaller Loss value. The quantization bit-width is set from 2 to 16 bits according to step 2, and the Index set by step 3 is used to select the bit-width value. Initially, every quantization block selects 16 bits, as shown in step 5. Next, a new CNN model is quantized based on the strategy generated by step 5, and the model is iteratively trained for epoch times. The highest training result is recorded as Acc, as shown in steps 7 and 8. Then, the highest training result is compared with the required accuracy Acc_Set in step 9 to make a decision. If the requirement is met, the Index value is increased according to step 10, and an attempt is made to reduce the bit-width of the quantization block. If the requirement is not met, the current qutization is restored the last policy, then the next quantization block is selected to adjust the bit-width value according to steps 12, 13. By following the above steps, the appropriate bit-width is selected for each quantization block in sequence.

III. Mixed Precision Accelerator Design

The mixed precision quantization of CNN achieves a balance between accuracy and compression rate by selecting appropriate bit-widths for the weight and activation parameters in each layer [26]. Therefore, in the accelerator, a design method is adopted that uses multiple types of Conv modules to support different bit-width precision operations. This can avoid inefficiency of high-bit-width arithmetic units used by low-bit-width operations. The structure is shown in Fig. 2.

In advance, the calculation method of each layer in CNN model is written into the finite state machine (FSM) in the form of instruction according to the sequence. The input image can be stored in an off-chip memory, and during computation, burst transmission via the AXI4 bus can be used to read the input image from the off-chip memory to the Conv module [27]. The entire computing process only needs to read the input image from off-chip memory once to reduce the high latency and energy consumption caused by off-chip reading and writing operations.

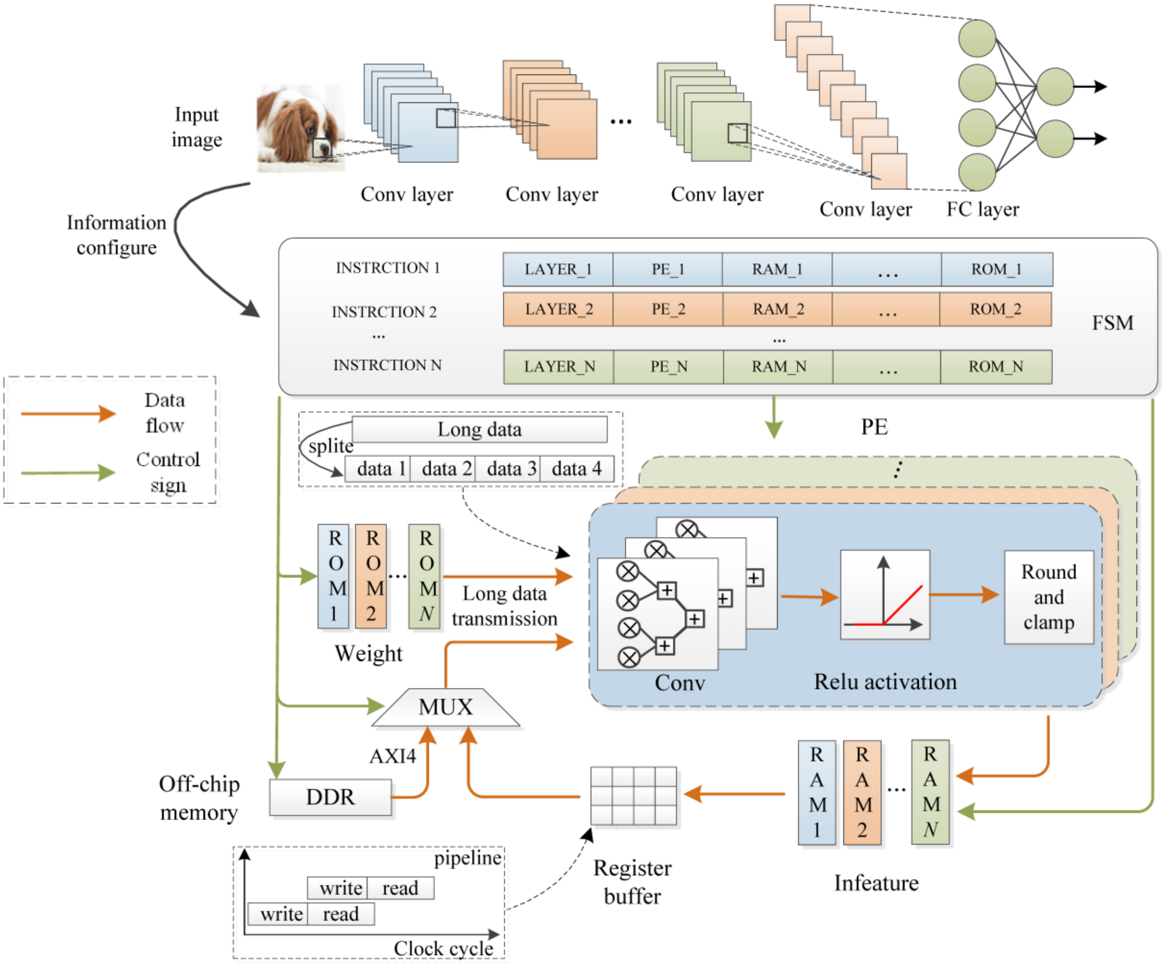

Fig. 2. The mixed precision accelerator design structure.

Then, the FSM sends instruction to control the reading of weight parameters from the Weight Read-Only Memory (ROM) and sends them to the designated PE for convolution, activation, quantization (Round and Clamp). Then the calculation results are cached in the RAM specified by the instruction, and execute subsequent processing according to the next instruction provided by FSM.

For the intermediate buffer data reading and writing operations, their throughput can easily become a bottleneck for the entire accelerator performance due to the limitations of the BRAM reading and writing interfaces. This can cause a problem of mismatch between data calculation speed and reading speed. Therefore, a register set is introduced as a data buffer. The true dual-port RAM and pipeline are simultaneously used, which greatly increase the speed of reading data into PE.

In term of weight parameter storage, the quantized weight parameters of each layer in the CNN are stored in the ROM array (Weight ROM) built of on-chip RAM resources according to the address order. During circuit initialization, the parameters are stored in the on-chip memory in a ROM initialization method. The read width is set to the sum of all weight parameter bit-widths in a single convolution kernel. Data slicing allows for extracting specific bits from a signal by using indices. So the entire long bit-width data can be split and sent sequentially to the Conv module after reading the data. In ROM IP core provided by Xilinx, the maximum read width can reach 4608 bits, which is sufficient to read the weight parameters in a convolutional kernel within one cycle.

The overall processing adopts a streaming processing architecture, and the CNN is folded according to the mixed precision quantization results in order to share PEs and memory resources among different layers. This not only alleviates the problem of large resource consumption of the streaming processing architecture, but also allows the saved resources to be used in each Conv module to improve computation parallelism. Meanwhile, the entire network can still be designed with pipeline processing. Each computing module can serve as a stage pipeline, forming a large-scale pipeline design to reduce computation latency under the condition of multiple input data.

A. PE Design

The PE structure is shown in Fig. 3. It is composed of the Conv module, Relu activation, Round and Clamp module. In the same PE, all multipliers are the same type. For example, the multipliers in Fig. 3 are all $M\times N$ type, where M corresponds to the weight bit-width and N corresponds to the feature data bit-width. The number of multipliers in each group is set according to the convolution kernel size. Assuming the convolution kernel size is $K\times K$, then K^2 multipliers are set as one group. The number of groups S is set to the least common multiple of input channels of all quantization layers using this PE. This can fully utilize all multipliers and improve computation efficiency when calling this PE.

In each convolution module, there are multiple layers of adder trees and a multiplexer. The number of adder operations can be controlled based on the input channel number of the current layer to adapt to different computation modes with different input channel numbers. For example, if the convolution channel S is set to 64 in the PE and the current network layer has 32 input channels, then two output pixels can be obtained through a binary adder tree of depth 5. When computing a network layer with 64 input channels, one output pixel needs to be obtained through a binary adder tree of depth 6. Therefore, we can reuse the PE for different layers by setting a multiplexer to output results at different layers of the adder tree.

In CNN models, to accelerate the convergence speed, prevent problems such as gradient explosion, gradient vanishing, and overfitting, many networks have Batch Normalization (BN) layers [28]. The process of calculating the BN layer with convolutional result Y through (7), can be represented as:

$$Y_{bn}=\gamma\cdot(\frac{Y-\mu}{\sqrt{\sigma^2+\varepsilon}})+\beta=\gamma\cdot(\frac{W*A+b-\mu}{\sqrt{\sigma^2+\varepsilon}})+\beta \tag{7}$$

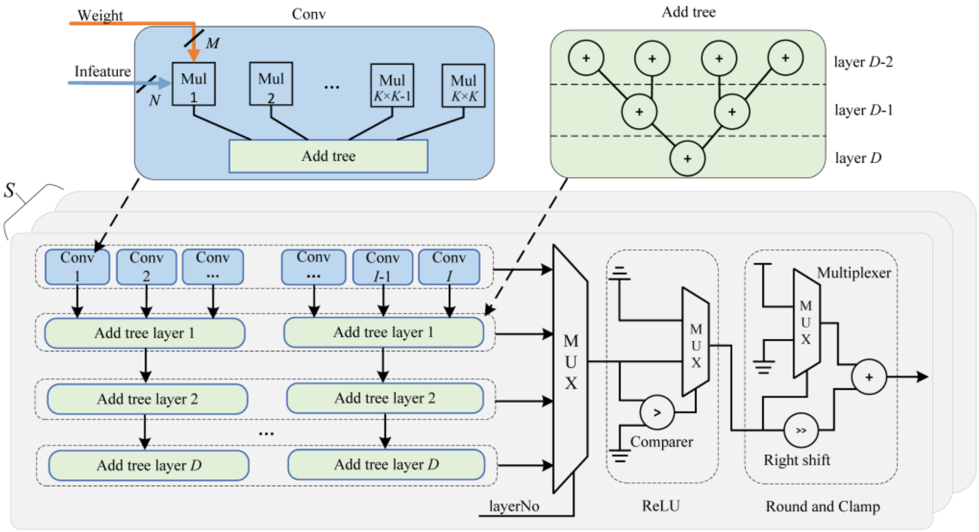

Fig. 3. Structure diagram of the PE unit.

Where *μ* and *σ* represent the mean and standard deviation within a batch, *γ* represents the scaling parameter, *β* represents the offset parameter, and *ε* is a very small constant set to 0.001. However, the additional computation brought by this layer makes it more difficult to implement the CNNs on FPGA platforms. Thus, the convolution, batch normalization and quantization operation are integrated together to solve this problem. Firstly, the process of integrating convolution and BN can be represented as follows:

$$Y = W' * A + b' \tag{8}$$

ωηερε $W' = \dfrac{\gamma W}{\sqrt{\sigma^2 + \varepsilon}}$, $b' = \dfrac{\gamma(b - \mu)}{\sqrt{\sigma^2 + \varepsilon}} + \beta$

Furthermore, the quantization operation (3) can be merged into (8) as follows:

$$Y = W'_{int} * A_{int} \cdot 2^{l_A + l_W - 2n+1} + b' \tag{9}$$

The low bit-width fixed-point weight W_{int} can be obtained directly by using the optimal parameters for the weight *W'* and quantization bit-width *n* and scale factor l_A. All of them can be obtained from algorithm 1. By integrating the three operations, many complex calculations can be completed during quantization training, the trained parameters W'_{int} can be stored directly in the on-chip ROM of FPGA during circuit initialization. So, this significantly reduces lots of calculations on the FPGA.

In addition, an activation layer is often used after the convolution operation to increase the non-linear ability of the CNN. To simplify the design, we also integer the activation layer into PE. The logic structure of the commonly used ReLU activation function is shown in the Fig. 3, which uses a comparer and multiplexer. The comparer compares the input value with zero, and the result controls the multiplexer to output either the input value or 0 as the activation value.

The convolution operation with *M* bits weights and *N* bits input feature values will result in *M+N* bits of convolution results. However, in the next layer of the network, the bit-width for the computation has already been specified by the quantization strategy, and the convolution result needs to be quantized to the specified bit-width for the next layer. Therefore, we perform Round and Clamp operations on the activated convolution result to truncate the length of the data to the specified bit-width as the input feature value for the next layer. In this way, the intermediate calculation results can also be stored in low bit-width BRAM, which saves the storage resources. The Round and Clamp operations consist of a multiplexer and an adder, which determine whether the first bit after the reserved bits of the data is equal to 1. If it is 1, the rounding operation will add 1 to the reserved data result. Otherwise, it will keep the original value.

With the above design, calculating one pixel in the output feature map requires multiplication unit, adder tree, activation, and quantization process. Considering the delay caused by these processes, it is difficult to output one result value in each cycle. Therefore, we perform pipeline to improve computing efficiency, and the specific process is shown in Fig. 4.

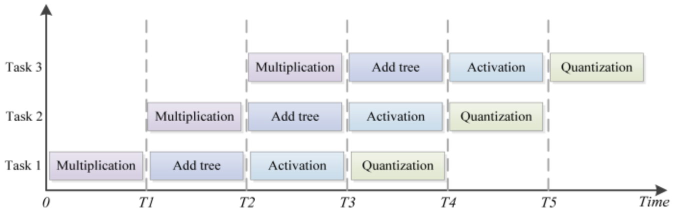

Fig. 4. The PE pipeline.

We assume that each process requires one clock cycle *Δt*, and calculating one output pixel requires *m* processes. According to the above settings, if no pipeline is applied, the number of cycles required to calculate all the pixels in the output feature map can be expressed as:

$$T_i = mH_{out}W_{out}\Delta t \tag{10}$$

W_{out}, H_{out} represent the width and height of the output feature map, which can be calculated based on the convolution process.

$$\begin{cases} H_{out} = \dfrac{H_i - K + 1}{S} \\ W_{out} = \dfrac{W_i - K + 1}{S} \end{cases} \tag{11}$$

H_i, and W_i are the height and width of the input feature map, *K* is the size of the convolution kernel, and *S* represents the convolution stride. With the pipeline, every clock cycle can generate one output pixel value except for the first output pixel point calculation process. The total number of calculation cycles can be reduced to the result expressed in (12). By comparing (10) and (12) , the computing efficiency has got improved significantly.

$$T_i = (H_{out} \cdot W_{out} - 1)\Delta t + m\Delta t \tag{12}$$

B. Folding Design

In one layer of the CNNs, there are many identical structures of channels, and even in many CNNs, there are many layers with the same structure and convolution method. When there are many channels in each layer, full parallel design according to the layer order in FPGA will inevitably use a large amount of calculation and storage resources, which may even exceed the existing resources of the FPGA [29]. Moreover, in CNNs, data needs to be passed in layer order, and it is difficult to parallelize between layers. Therefore, based on the above two calculation characteristics, we fold the original data flow to reduce the number of PE, and map it to hardware using the method of PE reuse. So different network layers can share PE while still keep the original computing efficiency. The process is shown in Fig. 5.

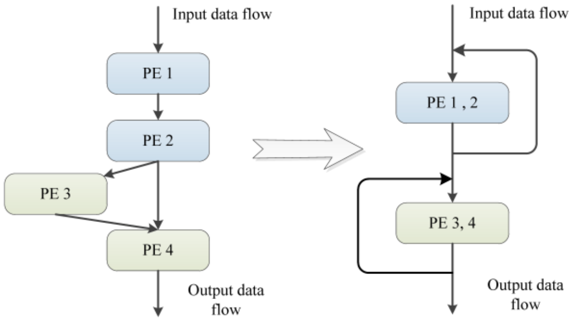

Fig. 5. Streaming folding diagram.

When different layers share the same PE, a control module needs to be introduced because there are differences in weight parameters, convolution strides, and other information between each layer of the CNN. The control module can dynamically switch the computing mode according to the requirements of different layers, such as adjusting the address for loading pre-trained weights, the source of input feature, and the address for storing intermediate calculation results. So, we need to pre-analyze the structural parameters of the selected CNN, compile the layer number, the storage address of the pre-trained weight, the convolution stride, the BRAM position where the intermediate cached result is stored, and other information of each layer into one instruction data and write it into FSM. After FSM outputs instructions, they are divided into segments. The calculation and data flow in FPGA can be uniformly allocated through various instruction segments. The length L of each segment can be macro-defined according according to (13).

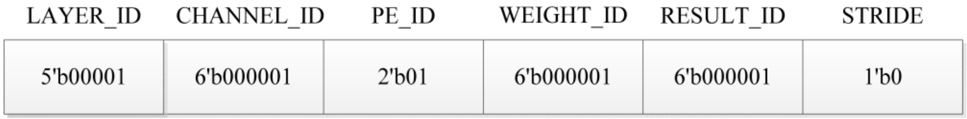
$$L_i = \lceil log_2 N_i \rceil \quad (13)$$

N_i represents the number of species included in the *i-th* segment. If it is assumed to perform calculations on the first channel (64 channels in total) of the first layer (20 layers in total) of the network, the format of this instruction provided by FSM is shown in Fig. 6.

C. Optimization of Data Reading Methods

In the design of mainstream accelerators [31], to avoid high latency caused by accessing off-chip memory, weight parameters and intermediate calculation results are usually stored into on-chip BRAM memory in sequential order directly. However, when reading data, only one or two data can be read per clock according to the corresponding address. After quantization to low-bit-width fixed-point numbers, if the data is still transmitted according to the previous method, it will result in underutilization of bandwidth resources and a mismatch between data reading speed and computation speed. Therefore, a new data reading method is proposed to reorganize low-bit-width data by concatenating multiple low-bit-width data into one long word. At the same time, true dual-port RAM and register set are used in combination with data reuse to improve reading speed.

This method for reading data through 3×3 convolution is explained as follows: When reading the data, it is necessary to first set up a two-dimensional register set as a buffer between RAM and Conv module, as shown in Fig. 7.



LAYER_ID	CHANNEL_ID	PE_ID	WEIGHT_ID	RESULT_ID	STRIDE
5'b00001	6'b000001	2'b01	6'b000001	6'b000001	1'b0

Fig. 6. The instruction format.

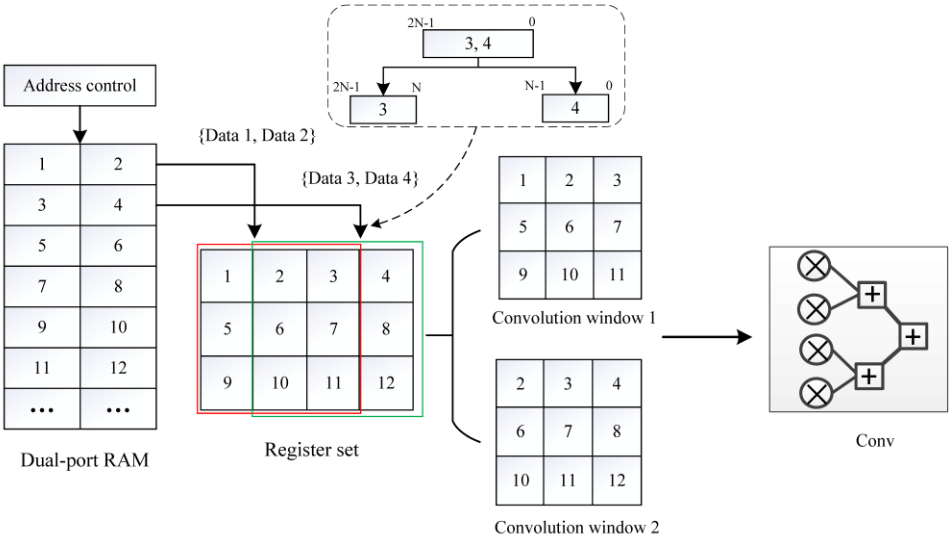


Fig. 7. Buffer structure diagram

Double-port RAM is a type of memory component that has two independent data ports. The write data width of a double-port RAM is set to twice the read data width, *2N* bits. When reading the data, two addresses are set as adjacent numbers, so that four adjacent data can be read and stored into the first row of the two-dimensional register set within one clock cycle. Then, in the next clock cycle, four adjacent data are read according to the address and stored into the second row of the register set. After the register set is full, the data from columns 1 to 3 can be directly read to achieve 3×3 full parallel convolutional calculation. Then, the data from columns 2 to 4 can be read to complete the second convolution, while reusing the second and third columns of data, thus reducing the overall data access. Additionally, when FPGA resources are sufficient, a larger register set and higher reading data width can be set, which not only can realize a higher data reuse ratio, but also can achieve a faster pipeline operation.

IV. Experiments and Result

To verify the effectiveness of the proposed method in this paper, the Resnet20 model was selected for validation on the CIFAR-10 dataset. The deep learning framework PyTorch was used to complete the quantization training experiment and mixed precision strategy search process on a server equipped with an NVIDIA Tesla T4 GPU. The quantized Resnet20 model was designed using the Verilog language on a Kintex 7 Eco R2 development board, and data reports were generated through synthesis and implementation with Vivado 2019.2 to analyze resource utilization and power consumption.

A. Resnet20 Quantization Experiment

The full precision Resnet20 model is iteratively trained on the CIFAR-10 dataset for 300 times. The accuracy of the training result is 92.89%, which was used as the pretrained model for quantization. We set the inference accuracy of the quantized model to not be less than 91.5%. The main network structure of Resnet20 is shown in Fig. 8, which has three types of residual blocks, with the convolution kernel size, channel number, and padding mode being the same in each type. According to this structural feature, we divided the network into five major structural blocks. The first layer is the first structural block, layers 2-7 are the second structural block, layers 8-14 form the third structural blocks, layers 15-21 form the fourth structural block, and the last fully connected layer is the fifth structural block.

Based on the above settings, we search for the quantization strategy in Algorithm 1, the final quantization bit-width results of the Resnet20 are shown in Fig. 9.

The activation and weight bit-widths of the first and fifth structural blocks are both quantized to 8 bits, the weight bit-widths of the second and third structural blocks (layers 2-14) are quantized to 7 bits, and the weight bit-widths in the fourth structural block (layers 15-21) are quantized to 8 bits, with the activation bit-width being 7 bits.

After mixed precision quantization and retraining of Resnet20, the inference accuracy is 91.68%, with only a 1.21% loss compared to the full precision Resnet20.

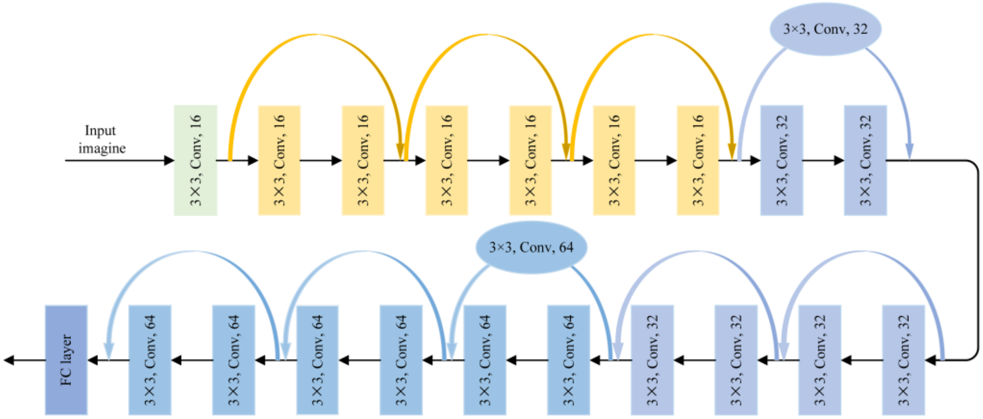

Fig. 8. Partial structure diagram of Resnet20.

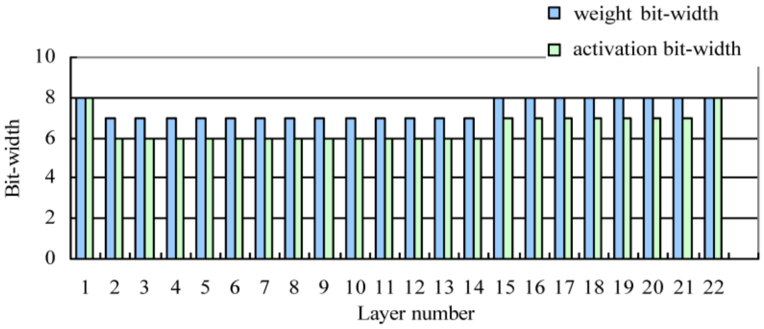

Fig. 9. Quantization bit width strategy for Resnet20.

Table I shows the comparative results of related work. In [33], the method of uniformly quantizing to 8 bits was used, and the accuracy was 90.7%. But in our paper, by reasonably allocating different bit-widths for each quantization layer, the accuracy is still 0.98% higher than their method even with lower bit-widths. In [34], after quantizing the full precision model to 8 bits and directly transplanting it to the FPGA platform, the calculation error caused by replacing the original floating-point numbers with fixed-point numbers resulted in an accuracy loss of 6.92%. By comparing this method, it can be seen that our paper greatly reduces the loss of CNN accuracy by performing quantization training and selecting a more suitable quantization method for the FPGA, making the quantized CNN closer to the full precision one.

B. Accelerator Design Experiment

1) Analysis of FPGA resource usage: Firstly, we tested the resource requirements for different bit-width multipliers in this experiment by using the synthesis tool in Vivado 2019.2, as shown in Table II. It can be seen that it takes 2 Digital Signal Processors (DSPs), 128 Look UpTables (LUTs) and 299 Flip Flops (FFs) to complete 32-bit floating-point multiplication. If DSP is not used, it would require 606 LUTs and 805 FFs to construct a 32-bit floating-point multiplier. By quantizing the multiplication operation to no higher than 8 bits, the resource usage can be reduced significantly. For example, the 7bits×bits multiplier only needs 45 LUTs and 13 FFs. The main chip xc7k325tffg676-2 in the development board used in this experiment has only 840 DSPs, but it has 203800 LUTs. Despite the limited number of DSPs available, additional multipliers are still required to achieve high parallel computations. So both DSPs and LUTs are needed to be used in combination to perform convolution operations in this paper.

Table III displays the Multiply-Accumulate operations (MACs) and resource usage and for each PE. According to the quantization results of Section IV.A in the first block, calculations are performed using 8bits8bits multipliers, therefore, PE 1 is equipped with 432 DSPs of the 8bits×8bits type, allowing for concurrent processing of 48 sets of 3×3 convolutions. The 7bits×6bits multipliers can be used for the calculations in both the 2nd and 3rd structure blocks according to the quantization results. So, these two structure blocks (the 2nd to 14th quantization layers) are designed to be folded and share a single PE (PE 2) with 1152 multipliers, which can compute up to 128 parallel convolutions of 3×3. The PE 3 used in the fourth structure block can use 8bits×7bits multipliers, so the 15th to 21th quantization layers are folded and also designed with 1152 multipliers. In PE 2 and PE 3, all the multipliers are implemented using LUTs to compensate for the limited on-chip DSP resources. In the 22nd layer, which is a fully connected layer, the computation process is carried out in PE 4. With its structure consisting of 64 inputs and 10 outputs, it is designed with 10 DSPs capable of simultaneously performing 10 parallel Multiply-Accumulate operations.

TABLE I. QUANTIZATION EXPERIMENT RESULTS OF RESNET20.

Quantization Method	Weight Bit-Widths	Weight Integer Bit-Widths	Activation Bit-Widths	Activation Integer Bit-Widths	Accuracy (%)
Baseline	32	/	32	/	92.89
[33]	8	/	8	/	90.7
[34]	8	/	8	/	84.81 (91.73)
Ours	7/8	2	6/7/8	4	91.68

TABLE II. COMPARISON OF RESOURCE USAGE FOR DIFFERENT MULTIPLIERS

Multiplier Type (*m*-bit × *n*-bit)	LUTs	FFs	DSPs	Power (W)
32×32 (float)	128	299	2	0.184
32×32 (float)	606	805	0	0.191
16×16 (fixed)	280	32	0	0.192
8×8 (fixed)	71	16	0	0.173
8×8 (fixed)	0	0	1	0.173
8×7 (fixed)	63	15	0	0.172
7×6 (fixed)	45	13	0	0.17

TABLE III. RESOURCE USAGE FOR PE UNITS

Quantized layer number	Convolution kernel size	MACs	PE number	Multiplier type (*m* bits×*n* bits)	LUTs	DSPs	FFs	BRAMs
1	16×3×3×3	884736	1	8×8	7040	432	11008	8
2-7	16×16×3×3	28311552	2	7×6	67768	0	40392	48
8-14	32×16×3×3/32×32×3×3	28311552	2	7×6	67768	0	40392	48
15-21	32×64×3×3/64×64×3×3	28311552	3	8×7	89528	0	49144	96
22	64×10(fully connected layer)	1280	4	8×8	325	10	166	0

TABLE IV. RESOURCE CONSUMPTION FOR RESNET20

Resnet20	Resource usage	Available	Utilization (%)
LUT	186257	203800	91.39
FF	148385	407600	36.4%
DSP	442	445	52.6
BRAM(36Kb)	152	840	34.2

The resource requirements for the entire Resnet20 are shown in Table IV, where the DSP resource utilization rate is 52.6% and LUT resource utilization rate is 91.39%. DSP resources are used for the first quantized layer and the last fully connected layer, while both shared accelerators are constructed entirely using LUTs with low bit-width multipliers to minimize resource usage. Storage areas can be recycled, thereby saving a large amount of BRAM resources.

2) Analysis of the buffer reading and writing: In the Resnet20, all convolution kernel sizes are 3×3, so only one data reading and writing method needs to be designed. This paper sets the register set size to 6×8, and each set can hold 48 data to provide the data required for 24 convolutions. Using the method described in Section 3.3 to read and write data, four data can be written into the register set per cycle, so it will take 12 cycles to fill the entire register set.

To achieve efficient computation, pipeline is added to the writing and reading operations. The specific process is shown in Fig. 10. When reading data from rows 4-6, new data is written into rows 1-3, and the data in rows 4-6 can be used to complete reading and calculation in 6 cycles. During these 6 cycles, the data in rows 1-3 can be updated by writing new data into them. Similarly, when reading data from rows 1-3, new data is written into rows 4-6. This can achieve the ability to read 9 data required for a 3×3 convolution every cycle.

3) FPGA accelerator performance analysis: In order to validate the advantage of FPGA accelerator, we evaluated the computational efficiency of three different platforms: CPU (Intel Core i5-12400), GPU (NVIDIA RTX 2070 SUPER), and FPGA. Table V shows the results of Resnet20 model inference time and energy consumption on CIFAR-10 dataset using three different platforms. Since the CPU and GPU platforms perform better with large batch sizes, we set the batch size to multiple values to obtain their highest performance. The inference time per image was obtained by dividing the total time by the batch size.

The experimental results show that, the computing speed is 4.27 times faster than that of the CPU after quantization, layer fusion, and parallel computation using FPGA, and the required power only needs 5% of the CPU's power consumption. Moreover, because we design a large number of parallel PEs while also deeply customizing the CNN structure, our work achieves similar computational speed under a power consumption of only 6.2% of the GPU platform. Since our design retains the characteristics of the streaming processing architecture, it can still adopt pipeline design when applied to the computation of multiple sets of input images, and each PE can serve as a stage pipeline, which can further improve the overall computational performance.

TABLE V. COMPARISON WITH OTHER EXPERIMENTAL PLATFORMS

Platform	Frequency (MHz)	Latency (ms)	Power consumption (W)	Speedup ratio
CPU	2500	2.01	65	1
GPU	1605	0.54	215	3.72
FPGA	100	0.47	13.31	4.27
