This dataset contains the latest and most realistic DDoS attacks. It was developed at the Canadian Institute of Cybersecurity to cover normal traffic. DDoS attacks are the most common and resemble real traffic, network, and properties. It consists of a set of servers and software such as computers, switches, and traffic generators. The dataset provides a knowledge file of the attacks that were performed and models about the applications, networks, and protocols. The dataset has been studied so that it can simulate the types of attacks, consisting of 47 traffic characteristics from the original information traffic consisting of UDPSYN. The prediction and evaluation tests and performance measures are used as evidence for the results and comparisons to analyze the models [17]. To detect DDoS, a group of data was proposed, but none of them were able to detect it. The CICDDoS2019 dataset deals with these problems to achieve optimal performance. This group consists of benign and malicious DDoS attacks. The dataset specifications are listed, and the dataset files use binary classification. The dataset includes missing and duplicate data records processed by applying feature engineering or by disposing of missing records. Feature selection is done using chi-square features. It calculates chi scores to rank features. Feature selection techniques can obtain the optimal feature for target DDoS variables using machine learning algorithms [18].

D. Machine Learning Models

After obtaining the optimal feature sets, KNN, DT, NB, SVM, RF, and LR models are used as models for intrusion detection and attack classification. Using the set and features obtained, the performance of ML techniques is compared in terms of accuracy, Recall, F1, and Precision. The main objective of the research was to resolve the effect of feature selection techniques on detection accuracy, Recall, F1, and Precision. Here is a quick rundown of these methods:

1) Logistic Regression (LR): This adapted linear regression approach is commonly employed in addressing classification challenges, as it has the capability to predict the assignment of an observation to a particular class. Its practical applications include tasks like spam filtering and intrusion detection. In instances where the anticipated likelihood surpasses a predefined threshold, it is anticipated that the occurrence aligns with an attack, given its position above the threshold. Conversely, if the anticipated likelihood falls below the threshold, the occurrence is categorized as normal. This is determined by the following equation:

$$h_{(\theta(x))} = \sigma(\theta^T X) \tag{1}$$

where, $\theta(x)$ is the hypothesis, x is the input feature vector, θ is the LR parameters, and σ (r is a sigmoid function that is used for the threshold definition. The sigmoid is defined as:

where, r is the term $(\theta T x)$ in the previous equation, the output is between (0:1) [19].

$$\sigma(r) = \frac{1}{1 + e^{-r}} \tag{2}$$

2) Naive Bayes (NB): A simple but effective probabilistic algorithm with real-world applications ranging from product recommendations to controlling self-driving vehicles. Using Bayes' theorem for classification, NB is superior to other alternative techniques. NB assumes normally distributed data and defines the conditional probability of the class. Bayes' theorem provides a systematic method for calculating probability based on the advantage of independence assumptions.

$$P(L|X) = \frac{P(X|L)P(L)}{P(X)} \tag{3}$$

where, $P(L|X)$ the posterior probability of class L is, P(L) is the prior probability, $P(X|L)$ is the likelihood function, and P(X) is the probability. The training set is used to estimate these parameters [20].

3) k-Nearest Neighbor (KNN): A method used to classify objects. Based on the learning data closest to the object, the comparison is based on previous and current data. It is a basic strategy that uses new instances from a test set to the closest instance in the training set. The number of neighbors and the distance are the two basic parameters of the KNN technique. The algorithm calculates the distance to the nearest neighbor by applying the Euclidean distance formula and is known as:

$$d(x, y) = \sqrt{\sum_{i=1}^{n}(x_i - y_i)^2} \tag{4}$$

where, $d(x, y)$ is a Euclidean distance function between the two samples, x_i is the initial observation, y_i is the second sampling of the information, and n represents the observations [21].

4) Decision Tree (DT): DT classifiers are one of the most popular ways to represent classifiers for data classification. It is one of the widely used techniques in data mining and can handle a vast amount of information. It is likened to a tree with its branches and leaves, where the inner node refers to the rules of classification, the leaves refer to the chapter label, and the branch refers to the results. The greatest degree of information acquisition is used as a measure for choosing the optimal traits and is used to construct the decision node, by creating a new sub-tree under the decision tree. The cycle continues until all the results of the subsets have the same value, at which point the process stops, and the final value is calculated as an output value. Gini inclusions were used as division criteria, as shown:

$$G(D) = \sum_{i=1}^{C}(P(i) * (1 - P(i)) \tag{5}$$

where, D is the training dataset, C is a collection of class labels, and $p(i)$ is the proportion of samples having the class label i in C. When there is just one class in C, the Gini impurity is zero [22], [23].

5) Random Forest (RF): ML technology is a supervised technique and gives excellent results. It consists of several trees planted randomly, and each leaf node is named for each tree. Each internal node contains a test that divides the data space to be classified by sending images to the bottom of the tree and collecting the leaf distributions obtained. The best way to determine the number of trees necessary is to compare forest predictions with subset predictions from the forest to produce a model that predicts the dataset more accurately and consistently. Its advantage lies in the fact that it is highly adaptable and enables it to solve classification and regression issues [23]. The general equation for a random forest model can be written as:

$$y = f(x) = \sum(i = 1\ to\ n)\ Ti\ (x)/n \tag{6}$$

where, y is the predicted outcome, x is the input feature vector, n is the number of DTs in the forest ,and $Ti(x)$ is the prediction made by the RF.

6) Support Vector Machine (SVM): Supervised learning models with machine learning analyze the data used in classification and regression analysis and can handle linear datasets. The main goal of SVM is when the problem is not linearly separable, then it will be with a nonlinear kernel such as RBF for nonlinear mapping to transform the unique form of training data into a higher dimension through the equation.

$$K(x, y) = e^{\frac{||x-y||^2}{z\sigma^2}} \tag{7}$$

where, σ is the variance and the SVM hyper-parameter, $||x - y||$ is the Euclidean distance between two points [24].

E. Executing DDoS Attacks

A subclass of DoS attacks disrupts normal traffic for a particular target. DoS attacks from multiple sources are performed simultaneously. On the IoVs, malicious vehicles can launch DDoS attacks, so it is important to detect attacks in real-time. Intended to flood threats to undermine the availability of vehicular Internet operations to perform DDoS attacks through an SSH-based master agent. The types of attacks described in the dataset are as follows: UDP-Lag attack is an attack that disrupts the communication file between the server and the client, and a SYNflood attack that controls the transmission to drain the victim's resources and affects them by not responding [25]. ML is one of the most popular methods, as it is considered a powerful model that predicts modern forms of DDoS attacks, as it analyzes them in real-time and classifies them into normal behavior or abnormal behavior. It also predicts attacks before they occur based on DDoS modeling and many algorithms such as KNN and SVM [21]. DDos attack in IoV is drawn in Fig. 4.

F. Confusion Matrix

The confusion matrix as in Fig. 5 is a measure of self-learning rating performance. It is a table of type $n * n$ where n is the number of possible labels for the data. The confusion matrix plays an important role in determining performance. In our model, we have three types of values: Benign , UDPLag, and SYN.

Most of the measures mentioned above can be calculated from the confusion matrix illustrated in Fig. 5, which is a typical tool used to record model performance. The rows in the matrix are the actual class, and the columns are the expected class. In the confusion matrix, TN, FN, FP, and TP represent true positives (the number of negative samples correctly classified, similar definition for the rest), false negatives, false positives, false negatives, and true positives, respectively. This is especially important under imbalanced learning conditions [26].

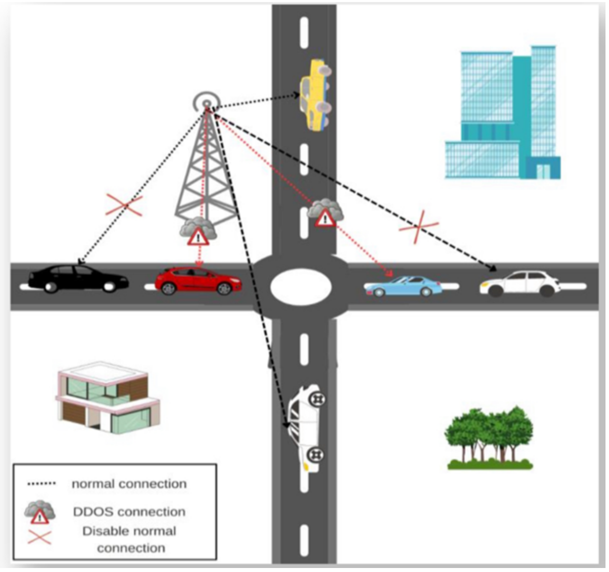

Fig. 4. DDoS Attack in IoV.

		Actual Values	
		Positive (1)	Negative (0)
Predicted Values	Positive (1)	TP	FP
	Negative (0)	FN	TN

Fig. 5. Confusion matrix [24].

G. Data Oversampling

Sampling is the most used method to solve the problem of class imbalance. The process of data sampling involves creating a data set by adjusting the number of samples of the majority class in the unbalanced data set and it occupies the largest part while the minority class occupies the smallest part. The sampling method is classified as a reduction or oversampling method, depending on which of the two categories is the number of samples [27].

• Random oversampling Random oversampling is done by increasing the samples of the minority group randomly, which means increasing the cases corresponding to the minority group by repeating them at a certain rate. It is considered an additional advantage as it does not cause the loss of any information. (a) Oversampling increases the number of instances of the training set, and random oversampling increases the training time of the model [28], [29]. Algorithm 1 shows the random sampling for the initialization of the backing sample.

H. MinMax Scaler

MinMax Scaler is one of the most popular scaling algorithms. The main idea of the linear data conversion algorithm where the algorithm assigns the value of V from the variable to the value of V using the formula:

$$X_{scaled} = \frac{x - x_{min}}{x_{max} - x_{min}} \tag{8}$$

The goal is to measure the variable MinMax in the interval [0,1] using linear assignment, meaning that the minimum and maximum value of a feature/variable is going to be 0 and 1, respectively [30].

I. Feature Extraction

The feature plays a big and important role in the performance of the model. Excluding or including features leads to the deterioration or improvement of the model. Accordingly, the features are the only ones relevant to the improvement of the model. The main objective of the classification is to know the benign and malicious traffic. The model is trained using the selected features before the training ends. The K1Fold is validated to divide the model into training and testing and also serves to help evaluate the model. The model is divided into five groups of equal size, four groups are trained, and one group is tested. The process is repeated ten times. The performance measures used in the model are feature selection. Reducing the number of features contributes to reducing the processing time that machine learning algorithms take. We can calculate the Chi-square between each element and the target, then select the ideal number of features with the best Chi square scores [31], [32].

$$FE = REM + RMD + DER \tag{9}$$

Were,

- FE Feature Extraction as shown in Algorithm 3,
- REM: Review Existing model,
- RMD: Remove missing data, and
- DER: Domain expert review

The argmax function returns the index of the element in the list that has the maximum value. You can use any appropriate performance metric to evaluate the models, such as accuracy, precision, recall, F1-score.

V. Experiments

In this section, we will learn how to measure the effectiveness of the security model, as the study was based on the efficiency of the proposed model in detecting security attacks. We analyzed the results of the attacks through a typical ML machine learning model where the features are extracted from the raw data and tested by the ML model. The CICDDoS2019 dataset is then tested and predicted, and the working efficiency of the ML model is evaluated.

Algorithm 1 Feature Extraction to optimize features
Input: A large Number of Features
Output: Optimized Features

```
1) Start
2) Extract Datasets
3) Delete missing data, Feature selection using domain expert
4) Data pre-processing
5) Use 10-fold cross-validation.
6) While all data sets are trained and test
  a. Split data into k-5 and 10-fold cross-validation.
  b. Model fitting
  c. Model Evaluation
7) End while
8) End
```

A. Models Implementation

ML models and configurations are evaluated based on evaluation scales: TP represents the true positives; TN represents the true negatives through the criteria.

1) Data preprocessing: Processing the dataset is the main stage before entering the data into the ML to achieve high performance. There are many challenges in the dataset such as missing values, categorical features, and class imbalance. Also, useless features may affect the performance of the selected ML.

2) Feature selection: Feature selection is necessary to detect intrusions, get the best score for the prospective feature, and choose the best. Where the different features should be checked gives a positive and negative category for each of them and thus get rid of the useless ones to improve the performance. The feature is selected using Chi2 technology, as it achieves better performance for many classification problems. A selection strategy is used to exclude the features using the null hypothesis. A higher Chi2 value means that the feature is more significant [33].

$$x^2 = \sum_{i=1}^{m} \sum_{j=1}^{n} (\frac{O_i - E_i}{E_i})^2 \tag{10}$$

Where: m represents the number of features, and n represents the number of classes and O_i is any observed frequency and E_i expected frequency [34].

3) Data normalization: The numerical values in the dataset pose a challenge to the classifier during training. Maximum values must be set for each property within the range of (0, 1). Values outside the range can lead to incorrect results, as the technique may skew to the higher advantage. Data normalization plays a vital role in outperforming features with higher values over features with lower values. The data is oversampled to balance the class distribution, as presented in Eq [35], [36]

$$Z = \frac{x - x_{min}}{x_{max} - x_{min}} \tag{11}$$

where x is the feature value, Z is the value after normalization, and x_max and x_min are the maximum and minimum values of the feature.

4) Data cleaning: The CICDDoS2019 dataset contains missing values and infinite values. The values are processed in two ways: In the second dataset, the infinite values are replaced by extreme values, and the missing values are replaced by averages. Only attack information packets were used to evaluate the proposed approach. Data packets representing normal network traffic are discarded in both groups, which improves accuracy and reduces computing time.

B. Proposed Models

In the dataset, the selected methods were used for training and tested by different parameters in feature engineering for intrusion detection. We selected different workbooks using: Accuracy, Recall, Precision, and F1 point. The methods used have shown strong performance in creating IDS. We explore the following strategies: K- Nearest Neighbor (KNN), DT, NB, SVM, RF, and LR.

C. Experiments

The CICDDoS2019 dataset and ML machine learning models were used to detect DDoS attacks. The implementation was done using Python 3.10 with many libraries such as Pandas, NumPy, Seaborn, and Matplotlib.pyplot.

VI. Results and Discussions

In this section, we review all the features for analyzing system performance, detecting events that are not compatible with normal behavior, confirming auditing and examining this data, and quality measures for the fully utilized ML model to be able to take a proactive step to avoid potential damage to vehicular Internet networks. Outstanding results appear in the field of discovering anomalies in time series data due to its ability to learn patterns and complex behavior. Therefore, it is the appropriate solution to distinguish deviant behavior from normal behavior.

A. Results Measurement Formulas

- Accuracy: It is responsible for evaluating classification models by depicting the proportion of correct predictions in the dataset, and is based on:
$$Accuricy = \frac{TP + TN}{TP + TN + FP + FN} \tag{12}$$
- Recall: measures the ratio of correctly identified labels to the total number of instances and is based on the following:
$$Recall = \frac{TP}{TP + FN} \tag{13}$$
- Precision: measures the ratio of correctly selected labels to the total number of positive ratings:
$$Precision = \frac{TP}{TP + FP} \tag{14}$$
- F1: points measure the harmonic mean of precision and recall [37].

$$F1 = 2 * \frac{Precision * Recall}{Precision + Recall} \tag{15}$$

B. Results Analysis

Exploit-based attacks are attacks in which the attacker's identity is kept hidden by a third party. Packets are sent by the attacker to mirroring servers with the source IP address changed to the target victim's IP to confuse it. These attacks are carried out through transport layer protocols such as TCP and UDP. These include exploits based on SYN floods and flooding attacks such as UDP floods. The dataset includes CICDDoS2019 token 25 which consists of UDP, and SYN traffic. It is used to analyze system performance and discover events that are not consistent with the normal behavior of the network. Through mathematical models of ML algorithms: LR, KNN, DT, NB, RF, and SVM. we trained the models and performed validation to calculate the evaluation metrics.

C. Description of Network Attacks

- UDP Lag: UDP Lag attack is an attack that disrupts file communication between a client and a server. The attack can be carried out in two ways: through hardware switching, known as delay switching, or through software running on the network and consuming the bandwidth of others. It involves a special UDP stream that consumes more bandwidth while decreasing the number of packets.
- SYN Flood: In addition, SYN Flood is a type of TCP flood that targets the initial handshake of the TCP connection. The SYN flood sends a large volume of packets to the target server.

D. Dataset Scenarios

The files contain all the packets, and the CSV files provide a simpler way to load the data. These files consist of features extracted from the original pcap and are fixed- size files. The files are converted from pcap to CSV by capturing all sides of the network traffic data. Along with the innocuous packets, the traffic is then broken down into smaller data through parallel conversion using TCP Dump. The features are then extracted using chi2 and stored in separate CSV files. The extracted features are used to aggregate the captured values to reduce discrepancies in data size.

E. Results Discussion

In this section, we present the evaluation of the performance of classification algorithms, namely LR, KNN, DT, NNB, RF, and SVM models.

We trained the models and performed validation to calculate the evaluation metrics. The evaluation scheme is a performance evaluation, as it determines the efficiency and robustness of the proposed scheme. A dataset with identical characteristics is needed for real traffic and DDoS traffic flows, so we evaluated the performance of classification algorithms using the CICDDoS2019 dataset. The performance of the six-model considering UDP-Lag attack is shown in Fig. 6.

We trained the models and performed validation to calculate the evaluation metrics. Fig. 6. Performance for proposed ML models for UDP-Lag attack.

We adopted six ML models for binary classification (benign or malicious). The results showed high accuracy in Random Forest, k Nearest Neighbor algorithm, and Decision Tree. These results demonstrate how ML models can be used to classify attacks against IoV. These models may face challenges in classifying other attacks as benign or malicious, and despite the similarity in patterns, the classification is successful. The accurate results are shown in Table I.

TABLE I. Proposed ML Models Results for UDP-Lag Attack

Model + chi2 FE	Accuracy	Precision	Recall	F1score
LR	0.9950	0.992	0.9856	0.9875
LR+chi2	0.9954	0.996	0.9949	0.9971
KNN	0.9976	0.9974	0.9967	0.989
KNN+chi2	0.9986	0.9984	0.9987	0.999
DT	0.9971	0.9954	0.9949	0.9925
DT+chi2	0.9991	0.9994	0.9989	0.9995
NB	0.9722	0.9792	0.9661	0.9817
NB+chi2	0.9782	0.9892	0.9681	0.9857
KNN	0.9980	0.9924	0.9957	0.991
KNN+chi2	0.9986	0.9984	0.9987	0.999
RF	0.9976	0.9962	0.9943	0.9972
RF+chi2	0.9996	0.9996	0.9995	0.9997
SVM	0.9962	0.9943	0.991	0.9916
SVM+chi2	0.9982	0.9973	0.999	0.9988

The best ML models tested in the UDP Lag attack outperformed. The DT model, and RF model had the best results with a precision, recall, and F1 score of 99.9%. For the SYN flood, the performance of the six models is presented in Fig. 7.

In the SYN flood attack, the best tested ML models appeared superior, with KNN, DT, and RF models having the best results with 99.9% precision, recall, and F1-score. The details results are shown in Table II.

The confusion matrix plays an important role in determining performance. The Confusion matrix for UDP-Lag and SYN Flood are shown in Fig. 8 and 9 .

VII. Conclusions and Future Work

We presented a new and large-scale IoV data set for the training and evaluation of threat detection systems. The results reveal high response rates for the models with the selected features. A system based on ML models has been developed

SVM	0.9969	0.9970	0.9963	0.9970
SVM+chi2	0.9989	0.9990	0.9975	0.9982

to prevent communication errors that could cause traffic disruptions or accidents between networks and interconnected vehicles. Development of IoV protection technologies and increased security investment. Ensuring security for vehicle exchange data storage and infrastructure. For the UDP Lag, DT, and RF models had the best results with a precision, recall, and F1 score of 99.9%. In the SYN flood attack, the best tested ML models appeared superior, with KNN, DT, and RF having the best results with 99.9% precision, recall, and F1score. This work opens the door to the development of many future endeavors. For example, optimizing ML models, analyzing features and their impact on different ML models, interpreting ratings, and assessing portability based on comparisons to other datasets.

ACKNOWLEDGMENT

The authors are thankful to the Deanship of Graduate Studies and Scientific Research at University of Bisha for supporting this work through the Fast-Track Research Support Program.

A Review on DDoS Attacks Classifying and Detection by ML/DL Models

Haya Malooh Alqahtani*, Monir Abdullah
College of Computing and Information Technology, University of Bisha, Saudi Arabia

***Abstract*—Internet security is under serious threat due to Distributed Denial of Service (DDoS) attacks. These attacks inflict considerable damage by disrupting network services, resulting in the impairment and complete disablement of system functions. The accurate classification and detection of DDoS attacks is extremely important. We provide a review of different models of Machine Learning (ML)/Deep Learning (DL)-based DDoS attack detection used by researchers that consider different classifiers. Our analysis indicates a heightened emphasis on ML-based classifiers where 22% of studies opted for the widely recognized SVM classifier. For DL-based, 27% of the studies opted for the widely recognized CNN. While the majority of researchers have formulated their datasets, NSL-KDD was employed in 55% of the studies. In addition, we discussed the future directions and challenges of DDoS detection.**

***Keywords*—Classification; DDoS attacks; machine learning; cybersecurity; detection**

I. Introduction

Lately, there has been a noticeable surge in Distributed Denial of Service (DDoS) attacks, as attackers continually devise novel and sophisticated methods to carry out these assaults [1]. This initiates a denial-of-service attack concurrently, affecting a computer network simultaneously [2]. A DDoS attack achieves success by depleting the bandwidth, the processing capacity of routing devices, network or processing resources, memory, and database, as well as the input and output operations bandwidth of server systems [3],[4]. Preventive measures exist to counteract such attacks. Yet, it is crucial to recognize the distinctive traits of the attack to implement the most effective actions and prevent its reoccurrence [5]. Several prevalent forms of DDoS attacks include The Internet of Things (IoT), which refers to the integration of interconnected, internet-enabled objects capable of gathering and exchanging information through wireless networks without manual intervention [6]. Efficient techniques for identifying intrusions, including DoS attacks, SYN floods, and port scans. The exploration of this field has gained significant momentum as a subject of active research. Within the realm of flooding attacks, emphasis is placed on Flags—six distinct bits utilized to convey various conditions. The field of Machine Learning (ML) plays a crucial role in empowering organizations to make diverse decisions. Future classification and prediction can leverage the insights gained from all types of data. ML, an application of artificial intelligence, allows systems to autonomously comprehend and enhance their understanding without explicit programming. It focuses on refining computer programs that can independently absorb and learn from information. Utilizing supervised classification algorithms for categorical datasets is common in tasks involving classification and prediction, drawing upon existing knowledge and experience [7]. There are numerous ML algorithms, including Support Vector Machines (SVM), Artificial Neural Networks (ANN), Decision Trees (DT), Genetic Algorithms (GA), kmeans, Apriori, AdaBoost, Cluster Analysis, Naïve Bayes (NB), PageRank, k-nearest neighbors, and PageRank.

A. DDoS Attacks

Throughout the years, a DDoS attack has posed a continuous security threat to online networks and services. The primary goal of DDoS attacks is to diminish service availability by depleting network or computational resources allocated for traffic and processing. As a result, legitimate users encounter obstacles when attempting to access the intended services [8]. A DDoS attack involves utilizing a vast array of compromised devices strategically dispersed globally within a botnet. This method contrasts with traditional DoS attacks, where a single network connection and one Internet-connected device are employed to inundate the target with malicious traffic [9].

B. How DDoS Attack Works

A DDoS attack can be initiated in various ways [10], with the most prevalent method involving the assailant sending a continuous stream of packets to the targeted server. Utilizing crucial resources in this manner creates challenges for genuine users attempting to access these resources. Another frequently employed strategy involves sending a small number of malformed packets, compelling the targeted servers to freeze or reboot. A different strategy for conducting a denial-of-service involves the deliberate sabotage of devices within the targeted network, depleting crucial resources and rendering the network inaccessible for both internal and external services. Numerous other methods exist for executing such attacks, making them challenging to anticipate and only identifiable after they have been initiated. Fig. 1 shows an example of a DDoS attack.

A DDoS attack unfolds through multiple stages involving three key entities: an assailant, a botnet, and a target. The assailant initiates the attack by dispatching remote instructions to each bot, orchestrating the inundation of connection requests exceeding the server's capacity. This method involves flooding the victim's server or network with copious amounts of random data, depleting the available bandwidth. As the botnet concentrates its efforts on the target's IP address, each bot sends requests, potentially overwhelming the server or network and causing a disruption in regular traffic, resulting in a service denial.

C. Types of DDoS Attacks

There are three types into which DDoS attacks can be classified. Firstly, there are volume-based attacks, where the

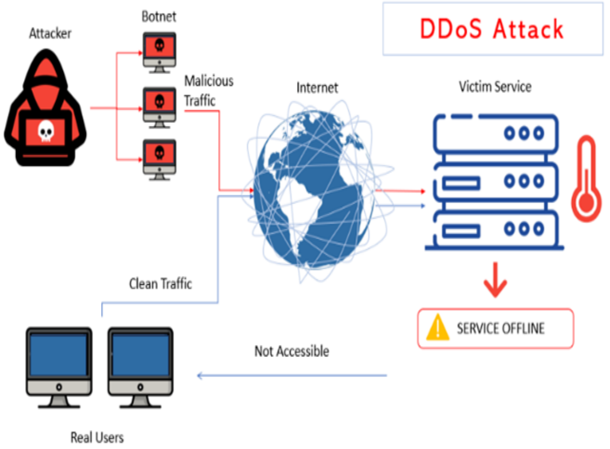

Fig. 1. Example of DDoS attacks.

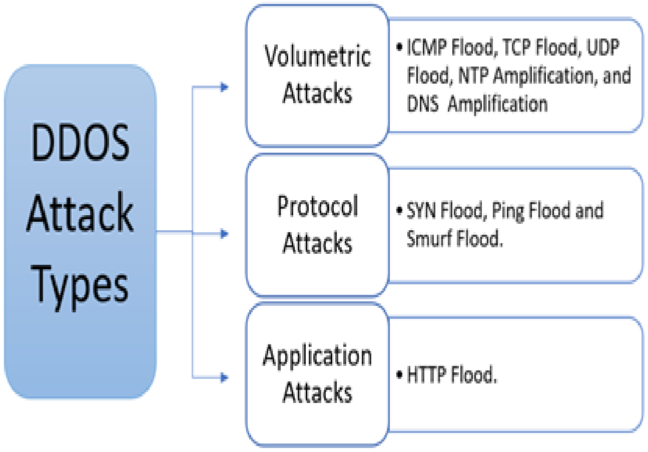
aim is to overwhelm a target with a substantial amount of traffic, exploiting its bandwidth. Secondly, protocol-based attacks focus on exploiting vulnerabilities at layer 3 or layer 4, depleting the processing capabilities of the targeted system or critical resources like firewalls, leading to potential service interruptions. Lastly, application layer attacks involve connecting to a victim in a seemingly legitimate manner to exploit vulnerabilities at layer 7. These attacks utilize transactions and processes to overwhelm the server's resources excessively [11]. Fig. 2 shows the types of DDoS attacks with their examples.



DDOS Attack Types

Volumetric Attacks
- ICMP Flood, TCP Flood, UDP Flood, NTP Amplification, and DNS Amplification

Protocol Attacks
- SYN Flood, Ping Flood and Smurf Flood.

Application Attacks
- HTTP Flood.

Fig. 2. The types of DDoS attacks.

- Attacks involving SYN Flood: In the Transmission Control Protocol (TCP) protocol, the connection is formed through a three-way handshake, during which the server and client exchange synchronization (SYN) and acknowledgment (ACK) messages. SYN Flood attacks occur when a client sends an inaccurate ACK message, containing a forged IP address, in response to the server. Consequently, the server responds to the incorrect IP address with a SYN message and awaits a reply from the client. This waiting period renders the connection idle, preventing the server from catering to legitimate users. This type of attack is particularly susceptible due to its reliance on the vulnerabilities within the three-way handshake protocol [12].
- User Datagram Protocol (UDP) flood attacks: exploiting the characteristics of the UDP, which lacks the handshake process present in the TCP. In this type of attack, packets are directly sent to the target server, allowing the attacker to leverage this property to inundate the server with a significant volume of traffic. Consequently, the network resources of the target server become depleted due to the overwhelming volume of incoming data.
- HTTP flood attack: this is a cyber-attack in which the assailant exploits legitimate HTTP GET or POST requests to target a web application or server. Typically, these attacks leverage a botnet, which is a network of interconnected computers on the Internet.
- Ping of Death: Refers to an obsolete version of an Internet Control Message Protocol (ICMP) ping flood attack. In IPv4, the IP protocol imposes a maximum packet size of 65,535 bytes for communication between two devices. Exploiting this limitation through a basic ping command to transmit malformed or excessively large packets can result in significant harm to an unpatched system.
- SMURF attacks: involve the use of spoofed PING messages, causing a surge in ICMP requests upon pinging the targeted IP address. This influx of requests not only results in the consumption of significant bandwidth but also leads to a slowdown in the computer [13].
- Fraggle attack is a form of DDoS attack wherein a substantial volume of UDP traffic is employed to overwhelm the transmission infrastructure of the switch. It bears similarity to a Smurf attack, but distinguishes itself by utilizing UDP instead of ICMP [14].
- Network Time Protocol (NTP) amplification attack involves exploiting the features of an NTP server to overwhelm a target server or network with an extensive volume of UDP traffic. Consequently, this action renders the destination infrastructure inaccessible to normal, legitimate user traffic [15].

In this paper, Section II discusses the materials and methods through a literature survey and a description of various methods. Section III shows the classification tasks in ML and the ML algorithms performance metrics used to evaluate them. Section IV illustrates the discussion of the results. Open research directions will be presented in Section V. Finally, the last section briefly concludes our paper.

II. Literature Review

In recent times, numerous reports have indicated the occurrence of DDoS attacks targeting both commercial and government websites [16]. As the technique for executing DDoS attacks has advanced, the corresponding research on detection has also progressed. Consequently, numerous approaches have been proposed to mitigate DDoS attacks. In 1990, a proposal was made for a network traffic controller that utilizes ML techniques. The objective of this controller was to optimize call completion within a circuit-switched telecommunications network [17]. This work signified a pivotal moment when ML techniques broadened their scope to encompass the telecommunications networking domain. In 1994, ML was initially employed for classifying internet flow in intrusion detection. This marked the commencement of extensive research utilizing ML techniques in the classification of internet traffic [18]. In this section, we elaborate on recent advancements and developments related to the detection of DDoS attacks. Additionally, we provide insights into the deployments and data utilized to achieve the presented findings.

A. Machine Learning Approaches

Yusof et al. [19] utilized the KDD99 dataset for attack data and employed Information Gain to assess the significance of each feature, leading to the selection of relevant features. The WEKA tool was utilized for the classification of attacks and normal traffic. The proposed ML system by Yusof et al. [19] comprises various methods applied to the dataset. Their hybrid technique, a KNN-SVM method, is proposed for the classification, detection, and prediction of DDoS attacks. The methods employed by Yusof et al. include k-nearest neighbors (KNN), SVM, DT, K-means, NB, and Fuzzy c-means (FCM). Performance metrics such as True Positive (TP), False Positive (FP), True Negative (TN), False Negative (FN), and F-Measure were used by Yusof et al. [19]. Experimental results indicate that Fuzzy c-means clustering outperforms other algorithms in terms of classification accuracy and speed. Sanmorino, A. [20] utilized secondary data collected by other researchers in the development of the ML system. The proposed ML system comprises various methods applied to the acquired information, with a focus on evaluating the accuracy of each ML classification technique in identifying DDoS attacks. Sanmorino, A. applied three methods, namely the DT method, NB, and ANN, and assessed their performance using metrics such as True Positive (TP), False Positive (FP), Precision, Recall, F-Measure, and Receiver Operator Characteristic graphs/ Area Under the Curve (ROC/AUC). The findings indicate that, among the methods employed by Sanmorino, A. [20], the ANN demonstrated the highest accuracy compared to the other two methods for the generated dataset. Radivilova et al. [21] utilized the SNMP-MIB Dataset to investigate various types of attacks, including TCP SYN, UDP flood, ICMPECHO, HTTP flood, Slowpost, Slowloris, and SSH brute force. The study involved analyzing primary approaches for detecting DDoS attacks through the realization of network traffic. The results obtained from employing ML to detect DDoS attacks were presented, with input data comprising simulated realizations of both normal and attacked network traffic exhibiting fractal properties. The classification of traffic realizations took into account various parameters such as the Hurst index, attack type, and intensity. Experimentally, attack levels of 10%, 15%, 20%, and 20% were chosen, and the initiation moment and duration of the attacks were randomly selected. The training process was conducted separately for each attack file, employing the Random Forest (RF) method as applied by Radivilova et al. The results demonstrated that the most effective method employed by Radivilova et al. [21] for detecting attacks in network traffic is RF. Nandi et al. [22] proposed a hybrid approach aimed at identifying top relevant features through the utilization of both established feature selection methods and hybrid techniques on the NSL KDD dataset. The procedure entailed employing five feature selection methods, namely Information Gain, Gain Ratio, Chi-squared, Relief, and Symmetrical Uncertainty, to identify the most pertinent features within the NSL KDD dataset. Subsequently, a hybrid feature selection method was applied to further refine the feature set, selecting the most crucial features. The dataset was then filtered to isolate DDoS packets using the chosen features, as not all anomalous instances in the dataset belonged to the DDoS category. Nandi et al. employed various methods, including NB, Bayes Net, Decision Table, J48, and RF, and their results indicated that the hybrid approach demonstrated superior detection rates compared to existing methods. In their study, Bagyalakshmi et al. [23] introduced two approaches utilizing a dataset sourced from NSL-KDD. The first approach employs Learning Vector Quantization (LVQ) as a filter method, while the second approach utilizes Principal Component Analysis (PCA) as a dimensionality reduction method. Features selected from each approach are employed in the classification process, and the outcomes are compared in relation to their effectiveness in detecting DDoS attacks. Bagyalakshmi et al. applied NB, SVM, and DT as classification methods. The findings presented by Bagyalakshmi et al. [23] indicate that the LVQ-based DT technique outperforms the others in terms of identifying attacks. In their work, Sahoo et al. [24] employed an SVM with kernel principal component analysis (KPCA) for feature selection, while a GA algorithm was utilized to optimize the SVM parameters. To address the issue of noise arising from feature variations, they introduced an enhanced kernel function (N-RBF). Sahoo et al. [24] chose SVM as the primary classifier for predicting malicious traffic, presenting an effective solution for securing Software-Defined Networking (SDN). Their proposed approach integrates SVM with KPCA and GA, using KPCA for feature extraction and SVM for attack classification. To reduce training time, they introduced an improved radial basis kernel function. The optimization of various classifier parameters was achieved through the application of a GA algorithm. The detection module was executed on the controller, and the proposed DDoS detection framework was validated in a simulated environment involving a POX controller, Open vSwitch (OVS), and Mininet emulator. Comparative analysis with other classifiers from [24] revealed that the SVM model they proposed exhibited superior effectiveness and accuracy in classification for attack detection. Chartuni et al. [2] introduced a methodology that centers around the exploration and selection of a dataset representing DDoS attack events. This involves preprocessing the data and creating a sequential neural network model for multi-class classification, utilizing the CIC DDoS2019 dataset. The approach is specifically focused on multi-classification. They highlighted the enhanced value of multi-class classification in comparison to binary classifications, contrasting their models with those presented previously. Their utilized method involves Dense Neural Networks (DNN). The model proposed by Chartuni et al. demonstrated notable performance, achieving approximately 94% in metrics such as $precision$, $accuracy$, $recall$, and $F1-score$. Jaiswar, R. [25] employed the CICIDS 2017 dataset for the attack data in their study. The model was built using correlation analysis to choose relevant features and diminish the dataset's dimensionality. Following that, K-Means Clustering was utilized on a dataset with selected features to produce clusters, subsequently designated as either Benign or Attack. The labeled clustered dataset was fed into an SVM for training and testing the model. Jaiswar, R. utilized an SVM. The findings indicate that Jaiswar, R.'s model successfully categorizes web traffic based on its nature (Benign or Attack traffic). Upon evaluation, the model demonstrated superior performance compared to other classification algorithms tested on the available dataset. Aamir et al. [26] proposed a framework comprising four key stages: dataset acquisition, feature engineering, evaluation of the machine learning (ML) model, and analysis of results. The acquisition of the dataset involves a systematic exploration of published and validated datasets that contain evidence of DDoS attacks. Feature engineering follows dataset selection and entails analyzing the dataset to understand its context, identifying duplication and collinearity among attributes, and making adjustments to render it suitable for training the chosen ML model. The model evaluation process encompasses initial training, fine-tuning hyperparameters based on results, and assessing the modified model. Aamir et al. [26] assessed five ML models—SVM, RF, ANN, NB, and K nearest neighbors (KNN). The classification results indicate that all variants of discriminant analysis and SVM demonstrate good testing accuracy. Ismail et al. [27] employed the UNWS-np-15 dataset, utilizing RF and XGBoost classification algorithms. Following the application of these ML models, a confusion matrix was generated to assess model performance. The findings indicated that XGBoost outperformed other models in terms of precision, making it the preferred choice for the dataset used by Ismail et al. [27].

Kareem et al. [28] conducted an assessment of the efficiency of rapid ML techniques for model testing and generation within communication networks, with a focus on identifying denial-of-service attacks. The CICIDS2017 dataset in the WEKA tool served as the training and testing ground for multiple ML algorithms. The evaluated methods included REP tree (REPT), random tree (RT), RF, decision stump (DS), and J48. Performance metrics such as $accuracy$, $F-score$, $precision$, and $recall$ were employed by Kareem et al. [28]. Their experiments revealed that J48 exhibited superior performance and quicker testing times, especially when utilizing 4-8 features. Alduailij et al. [29] conducted research with the primary objective of enhancing the performance in detecting DDoS attacks. The study involved experiments using the CICIDS 2017 and CICDDoS 2019 datasets. Alduailij et al. [29] employed Mutual Information (MI) and RF Feature Importance (RFFI) methods for their investigation. The methodology utilized by Alduailij et al. [29] encompassed RF, Gradient Boosting (GB), Weighted Voting Ensemble (WVE), K Nearest Neighbor (KNN), and Logistic Regression (LR). The evaluation of their approach was based on performance metrics such as $Precision$, $recall$, $F-score$, and $accuracy$. According to the experimental results, the accuracy achieved by RF, GB, WVE, and KNN with 19 features was 0.99. Table I summarizes previous studies focused on utilizing machine learning methodologies for the identification of DDoS attacks.

Classification algorithms are employed to discern DDoS attacks by classifying traffic packets. Various ML algorithms, including SVMs, ANNs, DT, GA, AdaBoost, k-means, Apriori, k-nearest neighbors, Cluster Analysis, PageRank, and NB, can be utilized for this purpose.

B. Deep Learning Approaches

Numerous DL techniques have been proposed to classify and predict Distributed Denial of Service (DDoS) attacks. Yuan et al. [30] present a DL-based approach for detecting DDoS attacks, wherein high-level features are automatically derived from low-level ones, producing a resilient representation with enhanced inference capabilities. They construct a recurrent deep neural network to identify patterns within sequences of network traffic, enabling the tracking of activities associated with network attacks. Yuan et al. [30] showcased favorable results, demonstrating a significant decrease in the error rate from 7.517

Li et al. [31] underscore the superiority of DL in comparison to traditional DL techniques for detecting DDoS attacks. They introduces a detection model and defense system rooted in DL within a Software-Defined Network framework. The experimental findings highlight the model's significantly improved performance when contrasted with conventional ML approaches. Furthermore, it diminishes reliance on the environment, streamlining real-time updates to the detection system, and easing the challenges associated with upgrading or altering the detection strategy.

In their study, Alguliyev et el. [32] presented an approach for anticipating the onset of DDoS attacks through the identification of pertinent content in social media. They employ a CNN model featuring 13 layers and an enhanced LSTM method to achieve precise classification of texts into positive and negative categories. The prediction of DDoS attacks occurring the following day relies on analyzing the negative and positive sentiments within social media texts. The effectiveness of their proposed method was assessed through experiments conducted on Twitter data.

Shurman et al. [33] introduced two approaches for identifying Distributed Reflection Denial of Service (DDoS) attacks in the context of the IoT. The initial method employs a hybrid Intrusion Detection System (IDS) designed to identify IoT-DoS attacks, while the second method utilizes DL models built on Long Short-Term Memory (LSTM), trained with the most recent dataset specifically tailored for DrDoS incidents. Shurman et al's experimental findings illustrate that implementing these methodologies effectively detects malicious activities, thereby enhancing the security of IoT networks against both Denial of Service (DOS) and DDoS attacks.

Cil et al [34] proposed the utilization of a deep neural network (DNN) as a DL model for detecting DDoS attacks. Employing the CICDDoS2019 dataset in their experiments, they observed a remarkable 99.99% success rate in detecting DDoS attacks on network traffic. Additionally, the classification of attack types achieved an accuracy rate of 94.57% based on the dataset.

In [35], they conducted traffic classification on Software-Defined Network (SDN) traffic provided by Leading India. They employed diverse DL approaches to categorize the traffic into either normal or malicious classes. The findings of Ahuja et al. [36] demonstrated remarkable success, achieving an impressive accuracy rate of 99.75% through the utilization of Stacked Auto-Encoder Multi-layer Perceptron (SAE-MLP).

Agarwal et al. [36] introduced a deep neural network-

based feature selection-whale optimization algorithm (FS-WOA–DNN) for distinguishing between normal and attacked data. The chosen features undergo classification through a deep neural network classifier, utilizing the CICIDS 2017 dataset. The algorithm's performance was evaluated through simulation using the MATLAB tool, demonstrating an experimental accuracy of 95.35% in detecting DDoS attacks.

In their work, Reddy et al. [37] proposed a hybrid neural network structure that integrates a Gradient Boosting DT with a nimble Convolutional Neural Network (CNN). The results from these models are unified through an additive function to merge spatial and temporal characteristics, yielding a hybrid model proficient in differentiating between malicious and benign ultimate traffic flow. The hybrid ensemble learning model, as presented by Reddy et al, showcased enhanced accuracy compared to established detection methods. Boonchai et al. [38] proposed models leveraging deep neural networks designed for efficient multiclass classification of DDoS, utilizing the CICDDoS2019 dataset. They have introduced two models employing a straightforward DNN architecture and a Convolutional Autoencoder. The authors demonstrated enhanced classification accuracy through the application of DL techniques, achieving an accuracy of 91.9

Guo et al. [39] presented GLD-Net, a DL approach that combines topological and traffic features to achieve high accuracy in detecting DDoS attacks. These investigations collectively illustrate the effectiveness of DL in accurately categorizing DDoS attacks. Experiments conducted on the NSL-KDD2009 and CIC-IDS2017 datasets reveal that GLD-Net achieves detection accuracies of 99.3% for two classifications (normal and DDoS flow) and 94.2% for three classifications (normal, fast DDoS flow, and slow DDoS flow). Table II summarizes the papers that use DL approaches to detect DDoS assaults.

III. Classifications, Dataset and Performance metrics

A. Classificaton Methods

In classification tasks, the objective is to anticipate the output variable by analyzing the input features provided. The output varies across different tasks. Several frequently common classification tasks include:

- Binary Classification: involves a target variable with two possible outcomes, usually denoted as 0 or 1. Applications of this classification type include spam detection, fraud detection, and disease diagnosis. A range of studies have successfully applied ML to the binary classification of DDoS attacks. Bakhareva et al. [40] present algorithms designed to identify attacks within enterprise networks by analyzing network traffic. To assess ML methods for binary classification (distinguishing between attack and regular traffic) and multiclass classification (identifying various classes of typical attacks), the researchers utilized the CICIDS2017 dataset. The findings indicated that the CatBoost and LightGBM algorithms demonstrated effective performance in both binary and multiclass classification, successfully categorizing malicious traffic into distinct attack groups.
- Multi-class Classification involves scenarios where the target variable can have more than two potential outcomes, usually denoted as unique labels or classes. Numerous studies have investigated the application of ML in the multi-classification of DDoS attacks. In their work, Sayed et al. [41] introduced a multi-classifier model based on a stacking ensemble deep neural network. This model effectively identifies various types of DDoS attacks, achieving an accuracy rate of 89.4% when evaluated on the CIC-DDoS2019 dataset. Parfenov et al. [42] expanded the feature set for detecting attacks through the application of ML techniques. They explored methods for binary and

multiclass classification of network traffic to identify potential attack patterns. Additionally, a comparative analysis was conducted on ML algorithms including Gradient Boosting, AdaBoost, and CatBoost, utilizing the CICDDoS2019 dataset. The findings revealed that CatBoost demonstrated superior performance in both binary and multiclass classification, achieving accuracies of 99.3% and 97%, respectively. In their study, Mungwarakarama et al. [43] applied an Optimized K-Nearest Neighbor (OKNN) model to a real network dataset. By tuning parameters such as $n_neighbors$, $metrics$, $weights$, and n_jobs, the model demonstrated a notable proficiency in accurately distinguishing between normal traffic flow and DDoS attacks. The experimental outcomes showcased a high level of accuracy in the identification of both normal traffic and DDoS attacks.

- Hierarchical Classification: This classification method involves a target variable with a hierarchical or nested arrangement, where classes are structured in a tree-like form. Instances of hierarchical classification can be observed in species classification and product categorization. Various ML techniques have been suggested for the hierarchical classification of DDoS attacks. In their study, Kang et al. [44] presented a taxonomy that relies on similarity and hierarchical clustering to categorize 12 real DDoS attack tools. The effectiveness of this taxonomy was assessed, revealing its capability to accurately classify complex attack instances. Table III summarizes the papers on classification Tasks in ML approaches.

TABLE III. SUMMARY OF CLASSIFICATION TASKS ML-BASED RESEARCH PAPERS

Ref.	Classification Tasks	Approach	Dataset
[30]	Binary Classification	CatBoost, LightGBM.	CICIDS2017
[31]	Multi-class Classification	Convolution Neural Networks (CNN), Long Short-Term Memory (LSTM), and Gated Recurrent Units (GRU).	CIC-DDoS2019
[32]	Multi-class Classification	Gradient Boosting, AdaBoost, and CatBoost	CICDDoS2019
[33]	Multi-class Classification	Optimized K-Nearest Neighbor (OKNN)	LRN
[34]	Hierarchical Classification	Characteristic tree, and Hierarchical Clustering.	

B. Available Benchmarked DDoS Datasets

The studies analyzed for DDoS attack detection employed datasets listed in Tables I, II, and III, which were commonly utilized across most of the studies. The subsequent section provides descriptions of these datasets: The NSL-KDD dataset: Is an enhanced version of the KDD Cup99 dataset, where several fundamental issues have been addressed and rectified through modifications and removals. Comprising 41 features, this dataset categorizes attacks into four groups [45]. ISCX2012: This dataset, created in 2012 by Ali Shiravi and colleagues, encompasses a comprehensive collection of network data. It spans seven days, specifically from June 11 to June 17, 2010, capturing a spectrum of network activities, ranging from legitimate to malicious traffic. Examples of malicious activities within the dataset include DDoS, HTTP Denial of Service, and Brute Force SSH. Formulated within the framework of a simulated network environment, this dataset comprises both sorted and unbalanced data. It employs two overarching profiles: one delineates attack patterns, while the other characterizes typical user scenarios within the ISCX dataset [46]. UNSW-NB15: This dataset was produced by the Australian Center for Cyber Security. Generated the UNSW-NB15 dataset, employing Bro-IDS and Argus tools alongside several newly developed methods. The dataset comprises around two million records featuring a total of 49 characteristics. It encompasses various attack types [47]. CICIDS 2017: This was generated by the Canadian Institute for Cybersecurity (CIC) in the year 2017. It encompasses a variety of real-time attacks as well as typical network flows. CIC Flow Meter utilizes information derived from logs, source and destination IP addresses, protocols, and identified attacks to assess network traffic [48]. CICIDS 2017 encompasses common attack scenarios, including but not limited to brute force attacks, HeartBleed attacks, botnets, DDoS, DoS, web attacks, and exfiltration attacks [49]. CSE-CIC-IDS2018: In 2018, a collaboration between the Communications Security Foundation (CSE) and CIC resulted in the development of the CSE-CIC-IDS2018 dataset. This dataset was constructed by generating user profiles containing abstract descriptions of various events, which were subsequently amalgamated with a distinctive set of attributes. The dataset encompasses seven different attack scenarios, such as Brute Force, Heartbleed, Botnet, DoS, DDoS, web attacks, and insider network compromise [50]. CICDoS2019: This dataset created by Sharafeldin et al. [51] in 2019, was generated by extracting over 80 traffic features from the original data using the CICFlowMeter-V3 feature extraction software. Table IV summarizes the Datasets and their features.

TABLE IV. SUMMARY OF DATASETS AND FEATURES

Ref.	Dataset	Attacks	Features
[45]	NSL-KDD	4	41
[46]	ISCX2012	6	-
[47]	UNSW-NB15	9	43
[48]	CICIDS 2017	14	77
[50]	CSE-CIC-IDS2018	7	80
[51]	CICDoS2019	13	88

C. Performance Metrics

Performance metrics used in studies to detect DDoS attacks are listed, with a focus on performance indicators as the predominant measures. In binary classification scenarios, common metrics encompass $Precision$, $recall$, $F1_score$, and area under the curve, among others. The confusion matrix serves as a comprehensive summary of the classification model's predictions, incorporating True Positive (TP), True Negative (TN), False Positive (FP), and False Negative (FN) [52]. Eq. (1) defines the true positive rate (TPR), which is alternatively referred to as recall or sensitivity [53]. The TPR should be as high as possible.

$$recall = \frac{TP}{TP + FN} \tag{1}$$

The Precision of the model is determined using Eq. (2), which involves checking the number of correctly predicted positive classes by the model that are truly positive instances.

$$Precision = \frac{TP}{TP + FP} \tag{2}$$

Eq. (3) presents the false positive rate (FPR), which quantifies the proportion of negative occurrences that the model erroneously identifies as positive.

$$FPR = \frac{FP}{TN + FP} \tag{3}$$

The false negative rate (FNR) is the percentage of positive cases wrongly identified as negative. It is calculated using Eq. (4).

$$FNR = \frac{FN}{TP + FN} \tag{4}$$

Eq. (5) illustrates the TNR, also known as Privacy, representing the percentage of accurately predicted negative as negative.

$$TNR = \frac{TN}{TN + FP} \tag{5}$$

In Eq. (6), $accuracy$ is characterized as the proportion of true predictions made by the model across all classes. A preference is given to achieving the highest level.

$$Accuracy = \frac{TP + TN}{Total} \tag{6}$$

Comparing two models becomes challenging when one exhibits high $recall$ and low precision, or vice versa. To address this issue, the $F1 - score$ is employed as a metric for comparison, providing a balanced evaluation of both memory and accuracy. Eq. (7) is utilized for the calculation of the $F1 - score$.

$$F1 - Score = \frac{2 * Recall * Precision}{Recall + Precision} \tag{7}$$

The AUC-ROC curve measures the efficiency of classification problems at various threshold levels. A model is considered to offer more accurate predictions when the area under the curve approaches 1.

IV. DISCUSSION AND ANALYSIS

Detecting DDoS attacks with varying rates and patterns from legitimate traffic poses a significant challenge. Numerous ML/DL techniques have been suggested by researchers to identify DDoS attacks over the years. However, the effectiveness of these methods is constrained due to attackers consistently evolving their strategies and rapidly enhancing their skills, enabling them to execute unknown DDoS or zero-day attacks characterized by distinctive traffic patterns. Our analysis of prevailing classification methods centers on various aspects, such as the commonly employed classifiers and their influence on classification accuracy, as well as the datasets utilized for testing purposes. Researchers employed various ML classifiers in their methodologies, encompassing SVM, KNN, NB, DT, ANN, RF, J48, GA, LR, CatBoost, AdaBoost, and XGBoost. Among these, 22% of studies opted for the widely recognized SVM classifier, 10% employed the KNN classifier, 13% utilized the NB classifier, 9% applied the DT classifier, 6% implemented the ANN classifier, 16% employed the RF dataset, 3% each utilized the J48, GA, LR, CatBoost,

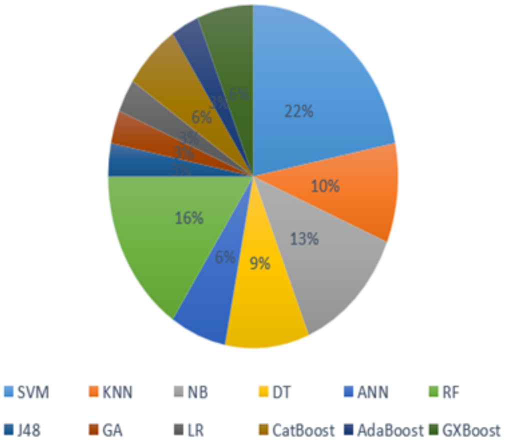

Fig. 3. Classification methods of ML approaches.

AdaBoost, and XGBoost classifiers. Fig. 3 illustrates ML classification methods in the studies.

In recent years, our observations indicate a heightened emphasis on ML-based classifiers. Specifically, in 2021, the SVM classifier took precedence, followed by the RF classifier in 2022, and the NB classifier in 2020, as illustrated in Fig. 4.

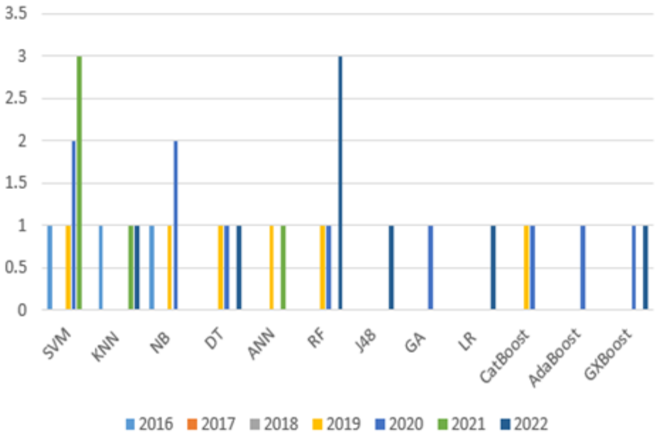

Fig. 4. Classification methods of ML approaches during past years.

The researchers have employed various DL classifiers, such as CNN, RNN, DNN, LSTM, GBDT, and GRU. Notably, 27% of the studies opted for the widely recognized CNN, while 14% utilized RNN, 18% employed DNN, 27% incorporated LSTM, 5% implemented GBDT, and 9% utilized GRU. Fig. 5 visually illustrates the distribution of DL classification methods in the research approaches.

Our analysis indicates that many researchers have formulated their datasets. In various studies conducted over recent years, several researchers employed widely recognized standard datasets, including KDDCUP99, NSL-KDD, UNSW-NB15, CIC-IDS2017, CSE-CIC-IDS2018, ISCX2012, and CICDDoS2019 in most of the studies over the past years, as Fig. 6.

Among the frequently utilized datasets in the literature, NSL-KDD was employed in 55% of the studies, UNSW-NB15 in 28%, KDDCUP99 in 6%, CIC-IDS2017 in 4%, CICDDoS2019 in 5%, CSE-CIC-IDS2018 in 1%, and ISCX2012 in 1%. Fig. 7 presents the distribution of different datasets used for classification.

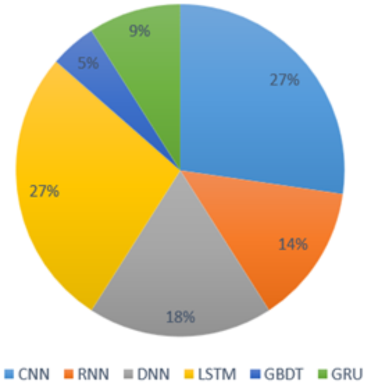

Fig. 5. Classification methods of DL approaches.

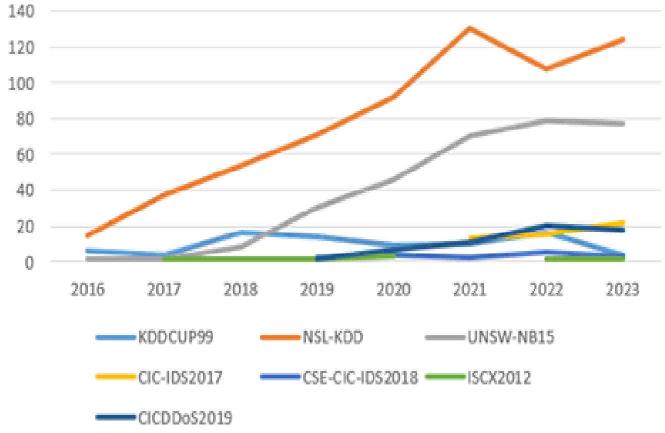

Fig. 6. Dataset that has been used over the past years.

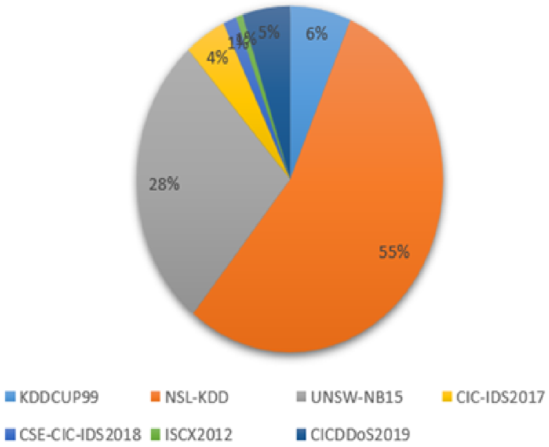

Fig. 7. The different datasets for classification methods.

V. Future Directions

The DDoS detection future research includes using advanced and improved DDoS mitigation techniques as follows:

- ML/DL Models: DL/ML models continue to be used to detect signs of DDoS attacks or analyze behaviors to detect anomalies. In addition to the possibility of mitigating its effects.
- Blockchain Technology: Using blockchain technology to detect DDoS, reducing its effects, and adopting it to raise trust between various entities and facilitate the safe exchange of information.
- Edge and fog computing: Use DDoS detection methods at the network edge to speed up response time. As for fog computing, it will be used to quickly distribute detection tasks and reduce risks.
- Human-centred approach: Develop DDoS detection interfaces based on user experience to increase user effectiveness and integrate experience into decision-making processes, especially when facing DDoS attacks.
- Quantum computing: With the advent of quantum computing, which is thought to break current algorithms, we need to develop DDoS detection techniques, and here quantum-resistant encryption methods must be used.

Continuing research and leveraging AI technologies is crucial to reducing DDoS threats. In addition, the combination of modern technologies and human expertise has a promising future for DDoS detection and reduction.

VI. Conclusion

Differentiating between DDoS attacks exhibiting various rates and patterns and regular traffic poses a considerable challenge. Numerous ML/DL approaches for detecting such attacks have been suggested by various researchers over the years. However, the constant evolution of attackers' tactics significantly restricts the effectiveness of these techniques. This paper provides a summary of the literature, adhering to the recommended taxonomy for DDoS attack detection through ML/DL methods. Our analysis indicates a heightened emphasis on ML-based classifiers where 22% of studies opted for the widely recognized SVM classifier. For DL-based, 27% of the studies opted for the widely recognized CNN. While the majority of researchers have formulated their datasets, NSL-KDD was employed in 55% of the studies. By addressing these future research areas, the field of DDoS detection can evolve to better cope with the increasingly sophisticated nature of cyber threats. Continuous research, and innovation will be key in staying ahead of evolving DDoS attack techniques.

***Abstract*—Surface defect detection is the task of identifying and localizing defects on the surface of an object, which is a widely applied task in various industries. In the logistics industry, logistics companies need to monitor the condition of goods for potential defects throughout the entire logistics process for effective logistics quality control. However, effective defect detection methods are still lacking for courier packages using corrugated cardboard boxes, which rely on judging whether deformation and leakage have occurred by examining areas on their surface with abundant texture. Specifically, the defect rate and supporting structure of the packages are influenced by temperature and humidity, and the openings and bends of defects are inconsistent. This results in defective packages having rich and non-uniform texture features. Moreover, convolutional neural networks struggle to effectively extract low-level semantic texture features of defects and perceive multi-level image features of packages. Considering the above challenges, we propose a novel texture prior-aware multi-level feature fusion network (TPMN). We first introduce prior knowledge and attention mechanisms to enable the neural network to focus on extracting low-level texture features from the image in the early stages. We also design a multi-level feature fusion method to integrate features from different levels, avoiding the gradual loss of low-level semantic information in CNN and enabling comprehensive perception of multi-level image features. To support further research, we contribute the cardboard-boxes-dataset, comprising 1210 images of packages. Experiments on this dataset showcase the superior performance of TPMN, even in few-shot learning scenarios, demonstrating its effectiveness in surface defect detection within the logistics and supply chain domains.**

Keywords—logistics; surface defect detection; multi-level feature fusion; prior attention; corrugated cardboard boxes

I. Introduction

Surface defect detection is a widely applied task in various industries, the goal of which is to identify and locate defects on the surface of objects. Nowadays, an increasing number of surface defect detection methods based on deep learning are being proposed. Lv et al. proposed a single shot multiBox detector-based end-to-end defect detection network for defects on metal surfaces [1]. Huang et al. proposed a method for defect detection in micro-nozzles using canny edge detection and evaluating the texture features of the regions [2]. Many mature methods have also been proposed for applications in other materials, such as steel strips [3], fabric [4], and solar cells [5].

Nevertheless, the logistics industry, which is rapidly developing alongside e-commerce, still lacks reliable methods for surface defect detection. Reliable courier packaging is crucial for logistics quality, especially for fragile items, and tracking courier parcel defect helps logistics companies determine responsibility and improve logistics quality control. However, the corrugated cardboard boxes used for courier packaging differ from other industrial materials as they have limited waterproof properties and compressive strength. It may suffer different degrees of defect in the logistics environment. Corrugated cardboard boxes are highly sensitive to atmospheric conditions, and the defect rate and structural support of the packages can be significantly affected by temperature and humidity [6], [7]. Meanwhile, under the pressure of other goods, corrugated cardboard boxes may also develop inconsistent sizes of openings [8] and bends [9], leading to damage to the cargo. This complex defect scenario renders traditional surface defect detection methods unsuitable for courier parcels. Therefore, logistics companies urgently need a comprehensive and reliable defect detection method to achieve precise detection of

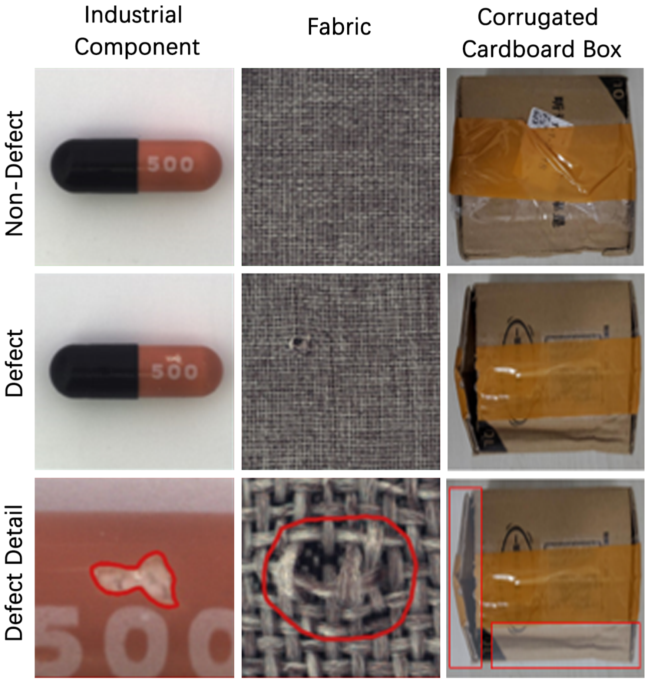

Fig. 1. Surface defects in different materials. In human judgment of whether a corrugated cardboard box has deformed or is leaking, it is typically reliant on image regions rich in textures, such as uneven package edges, folds extending around due to indentation, and edges at defect locations.

courier parcels, especially in cases with significant differences in defect sizes and overall structural. However, we still face the following challenges.

Firstly, the features of datasets for different defect detection tasks vary significantly, and the optimal solutions also differ. For corrugated cardboard boxes, humans judge whether deformation and leakage have occurred by examining areas on the surface with abundant texture (e.g., uneven package edges, depressed folds, defect edges). However, these texture-related low-level semantic features are often overlooked by Convolutional Neural Network (CNN) during the feature extraction process [10]. Additionally, low-level texture features suffer from semantic ambiguity due to their small receptive fields [11], [12]. Therefore, when analyzing the overall image and semantics of corrugated cardboard boxes, it is difficult to extract low-level texture image features.

Secondly, traditional methods often use the last convolutional feature map [13], resulting in insufficient semantic information and the loss of local information in the image. Specifically, courier parcels vary in size, and there is inconsistency in the texture sizes of corrugated cardboard boxes. When employing CNN with multiple convolution layers, local texture information may gradually be lost [14]. Moreover, in large-scale images, CNNs pay more attention to the high-level semantic information of the image [15], such as the overall structure and shape of corrugated cardboard boxes. Therefore, it is difficult to capture multi-level image features, which limits the task of surface defect detection on corrugated cardboard boxes.

In this paper, considering the above challenges, we propose a texture prior-aware multi-level feature fusion network (TPMN). Our method aims to accurately detect defect courier parcels, meeting the logistics company's need to track packaging defect status and providing crucial information for determine responsibility and improving logistics processes. Specifically, we first introduce prior knowledge and attention mechanisms to enable the neural network to focus on extracting low-level texture features from the image in the early stages. Then, we designed a multi-level feature fusion method to integrate features from different levels, avoiding the gradual loss of low-level semantic information in CNN and enabling comprehensive perception of multi-level image features. Additionally, we have contributed a dataset that comprises 1210 images of packages, known as the cardboard-boxes-dataset. On this dataset, we conducted basic experiments, ablation experiments, and few-shot learning experiments, among others. The experimental results demonstrate the superior performance of the TPMN.

To summarize, the primary contributions of this paper are as follows:

- We design the Texture Prior-Aware Multi-Level Feature Fusion Network, which integrates ResNet-18 [16] with multi-scale feature fusion and a prior attention mechanism. This framework enables precise defect classification and localization.
- The proposed TPMN is model-agnostic, allowing for effective extraction and fusion of low-level texture features while comprehensively perceiving multiscale image information.
- We released the Cardboard-Boxes-Dataset, which can be used for the task of detecting express packaging defects and promote further research in this field. The dataset is publicly available at https://github.com/chanllon/corrugated-cardboard-boxes-dataset.

II. Related Work

This section provides an overview of related work in three key fields: surface defect detection, prior attention, and multi-level feature fusion.

A. *Surface Defect Detection*

Surface defect detection is a widely applied task in various industries, with the main goal of identifying and locating defects or flaws on the surface of objects. Before the development of deep learning, surface defect detection primarily utilized traditional image processing techniques to extract features, employing machine learning for classification. Sun et al. utilized learning vector quantization networks and backpropagation networks for classification after segmenting the images [17]. Borwankar et al. introduced an k-nearest neighbors based algorithm for cast iron rocker arm inspection using frequency domain image processing [18]. However, these methods fall short in achieving superior detection accuracy. With the development of deep learning (DL), there are also many DL-based methods utilized for surface defect detection in the industry. Schlüter et al. introduce a simple and intuitive self-supervised method for sub-image anomaly detection and localization [19]. Lv et al. proposed a single shot multiBox detector-based end-to-end defect detection network for defects on the metal surface [1]. Huang et al. proposed a method using canny edge detection and evaluating region texture features for the defect detection of micro-nozzles [2]. Fang et al. designed

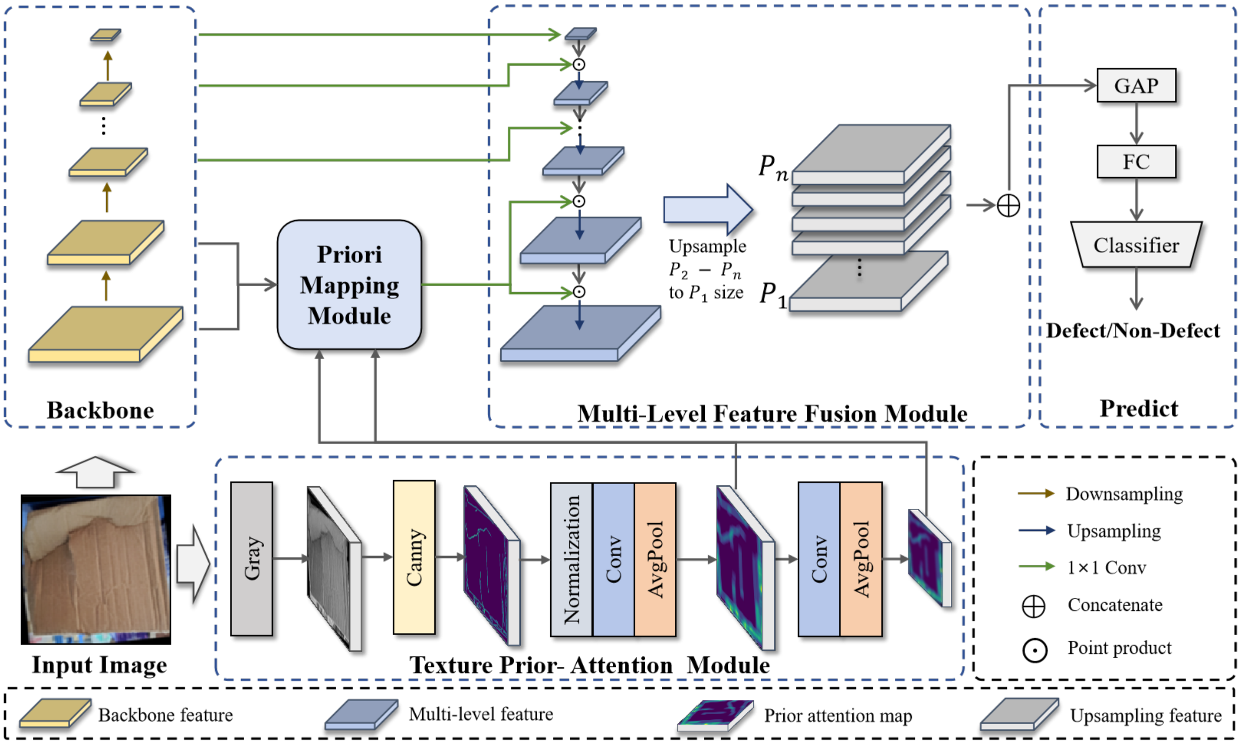

Fig. 2. Texture Prior-Aware Multi-Level feature fusion network.

a convolutional neural network (CNN) integrated with an attention mechanism to enhance training stability and detection accuracy in tactile methods for fabric structural defect detection [20]. However, the methods designed based on the specified material features mentioned above are not applicable to the complex defect scenarios in corrugated cardboard box defect detection [12], [21], [22]. Specifically, as illustrated in Fig. 1, the datasets for various defect detection tasks exhibit significant differences in features. Given the unique features of express packaging materials, we have devised an innovative model for surface defect detection.

B. Prior Attention

Prior attention enables the model to focus on important regions in the image, thereby improving the accuracy of object detection or image classification. Specifically, attention mechanisms allocate different weights to different parts of the input, allowing the neural network to concentrate on specific regions. SENet introduces a structure called the “Squeeze-and-Excitation” block, enabling the model to adaptively learn relationships between input feature channels [23]. DANet incorporates parallel global and local attention modules, focusing on global context and local details, respectively [24]. The role of prior knowledge in attention mechanisms is to introduce previous experience or assumptions to guide the neural network in focusing on specific information during the learning process. Cai et al. introduced image noise and edges as prior knowledge into the neural network, significantly enhancing the detection performance [25]. Wang et al. generate prior attention maps through a binary classifier to enhance lesion detection in COVID-19 CT screenings [26]. Zhang et al. assigns different weights to positions based on the prior that objects are near the image center and perceives object context information through different receptive fields [26]. However, existing prior attention methods are not applicable to the detection of defects in corrugated cardboard boxes, which focus more on regions rich in surface textures.

C. Multi-Level Feature Fusion

The task of multi-level feature fusion aims to effectively integrate feature information from different levels to enhance the performance of deep learning models when handling multi-level input data. HyperNet achieves effective multi-level feature fusion by aggregating hierarchical features and compressing them into a uniform space, enabling superior object detection performance across various levels [13]. Single shot multiBox detector achieves multi-level feature fusion by predicting category scores and box offsets for default bounding boxes using small convolutional filters [27]. Feature pyramid networks utilize a top-down architecture with lateral connections to facilitate effective multi-level object detection by integrating contextual information [28]. This method also finds extensive applications in other fields, such as remote sensing images [29], [30], classification of agricultural pests [31], and medical applications [32], [33], and so on. However, the above methods do not fully consider the texture information of low-level images, making it difficult to effectively integrate texture features on corrugated cardboard boxes at different levels and overall structures.

III. Texture Prior-Aware Multi-Level Feature Fusion Network

The overall architecture of the texture prior-aware multi-level feature fusion network is depicted in Fig. 2. Our network mainly consists of four parts: backbone, texture prior attention module, priori mapping module, and multi-level feature fusion module. We employ data augmentation techniques including mirroring, scaling, rotation, and translation to boost the diversity and complexity of the samples in light of the small number of samples in the dataset. This helps reduce the overfitting problem of the model. Enhanced images are created by randomly augmenting the original images, which are then sent into the backbone and texture prior attention module. Afterwards, we introduce each module of the network separately.

A. Backbone

ResNet-18 [16] provides strong feature learning capabilities for image features at various levels and abstraction levels. It is critical for detecting package defects, which typically manifest as local detail changes in the image, and ResNet-18 is capable of capturing these subtle features. Therefore, we designed the backbone based on ResNet-18. The ResNet-18 was constructed from residual blocks. ResNet-18 has N residual blocks, with each residual block's input set to x_i. The first block's input is an enhanced image, and the inputs of subsequent blocks are drawn from the previous block's output. The calculation for each residual block in ResNet-18 is as follows.

$$F^1_{RB} = ReLU(Conv(BN(Conv(x)))) \tag{1}$$

$$F^i_{RB} = ReLU(Conv(BN(Conv(F^{i-1}_{RB})))), i = \{2, \dots, n\} \tag{2}$$

where F^i_{RB} represents the output of the i-th residual block. $Conv$ stands for convolution, BN for batch normalization, and $ReLU$ for rectified linear unit.

B. Texture Prior Attention Module

Humans frequently rely on "textured" parts, such as zigzag edges and depressed creases, to determine whether corrugated boxes are distorted or leaking. Moreover, the value of each pixel in an RGB image is determined by the richness of the surrounding texture. We propose a canny-based prior attention method for texture recognition that extracts wrapped texture features as priori knowledge, allowing the model to pay more attention to essential texture areas. Experiments have shown that the prior attention map improves model performance significantly.

We first convert the image to grayscale before using the canny algorithm to extract the edges. The texture feature map is then min-max normalized to ensure that the value of each pixel is between 0 and 1, in order to obtain the prior knowledge map. The calculation process is as follows:

$$F_C = Canny(Gray(x), C_{lower}, C_{upper}) \tag{3}$$

$$T = \frac{F_C – min(E_C)}{max(F_C) – min(F_C)} \tag{4}$$

where, $Gray$ represents converting the input image x to a grayscale image, $Canny$ represents the Canny edge detection algorithm, and C_{lower} and C_{upper} indicate the lower and upper thresholds. T denotes the feature map after Max-Min normalization.

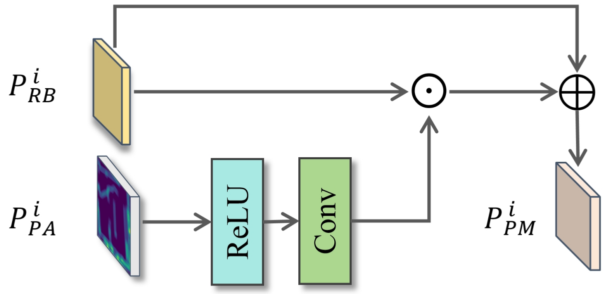

Fig. 3. The priori mapping module.

Included in the texture feature should be the surrounding texture-rich area as well as the texture itself. We extend the attention space even more by using downsampling and average pooling layers. Specifically, through the local perceptiveness of convolution and the information integration of average pooling, the expansion of texture edges can be achieved. This process allows the final Prior Attention Map to cover both the texture edges and the nearby texture information. The size of the output image after average pooling is the same as the size of the RGB branch feature map. Each feature downsampling module includes a 3×3 convolutional layer with 16 channels, followed by a 7×7 average pooling layer. The preceding method is as follows:

$$F^1_{PA} = AvgPool(Conv(T)) \tag{5}$$

$$F^2_{PA} = AvgPool(Conv(F^1_{PA})) \tag{6}$$

where F^i_{PA} represents the prior attention map at the i-th layer. $AvgPool$ is an acronym for average pooling.

C. Priori Mapping Module

The primary function of the Prior Attention Mapping module is to map the prior attention map to the enhanced feature map of the image obtained from the backbone. We consider fusing texture features and image features in the shallow layer of the network since downsampling the prior attention map leads to an erroneous attention range. The overview of this module is illustrated in Fig. 3.

This module gets the backbone feature F_{RB} of size $H \times W \times C$ from the encoder shallow layer and the texture prior attention module's prior attention map F_{PA} of size $H \times W \times 16$ as input and outputs the fusion feature F_{PM}. The process is as follows:

$$K = ReLU(Conv(F^i_{PA})), i = \{1, 2\} \tag{7}$$

$$F^i_{PM} = F^i_{RB} \odot K + F^i_{RB} \tag{8}$$

where, $\odot$ stands for dot-product. To prevent the above procedure from producing too small values and causing the gradient to vanish, we use the residual technique to let another F^i_{RB} skip the priori mapping module and add it to $F^i_{RB} \odot K$. This ensures that the performance of the network with the attention map will not be poorer than the original performance. Specifically, this module is applied to the output of block1 and block2 of the encoder.

D. Multi-Level Feature Fusion Module

In order to better incorporate high-level semantic information from images and prevent low-level semantic information, including texture features, from vanishing during the training process. We design the multi-level feature fusion module based on the feature pyramid network mechanism. Consider that there are n blocks in the multi-level feature fusion module. Defined the input consists of the priori mapping map F^1_{PM}, F^2_{PM} obtained in the priori mapping module and the backbone feature F^i_{RB} of various sizes obtained in the backbone. The output of each block as F^i_{MF}, where, $i \in \{1,..,n\}$. The module's ultimate output is the final fusion map P, which integrates feature maps from all levels. The final output of this module is the fusion of feature maps from all levels, denoted as P. Later, we will explain the specific details.

In order to preserve the rich texture information contained in low-level semantics, the lowest-level multi-level features need to be fused with the priori mapping map F^i_{PM} and the upper-level multi-level features F^{i+1}_{MF}. The process is as follows:

$$F^1_{MF} = Conv(F^1_{PM}) \odot F^2_{MF} \tag{9}$$

$$F^2_{MF} = Conv(F^2_{PM}) \odot F^3_{MF} \tag{10}$$

where $Conv$ stands for the convolution. $\odot$ stands for dot-product. F^1_{MF} and F^2_{MF} represent the priori mapping maps for the first and second layers, respectively. F^i_{MF} denotes the multi-level features for the i-th layer.

In multi-level features from the third layer and above, the model focuses more on the high-level semantic information of corrugated cardboard boxes. Therefore, the fusion of multi-level features from the third layer and above involves the backbone feature F^i_{RB} from the backbone and the upper-level multi-level features F^{i+1}_{MF}. The computation is as follows:

$$F^i_{MF} = Conv(F^i_{RB}) \odot F^{i+1}_{MF}, i = \{3, ..., n-1\} \tag{11}$$

$$F^n_{MF} = Conv(F^n_{RB}) \tag{12}$$

where F^i_{RB} represents the backbone feature for the i-th layer. For the multi-level feature F^n_{MF} in the nth layer, which doesn't have upper-level features, we only need to consider the nth layer's backbone feature F^n_{RB}.

In order to further fuse maps of different levels, we upsample each F^i_{MF} to the same size as F^1_{MF} using different factors, denoted as p_i. After that, we process the features with the following:

$$P = Concate\{F^1_{MF}, p^2, \ldots, P^n\} \tag{13}$$

where $Concate$ represents connecting features by channel dimension.

E. Predict and Loss Function

In addition to the aforementioned modules, it is essential to incorporate an additional classifier that takes the final fusion map as input to detect whether the corrugated cardboard box has defects. Specifically, the features that the multi-level feature fusion module outputs are average pooled and input to a fully connected network classifier for classification. The training goal is to minimize the cross-entropy loss function, aiming to make the predicted probability $\hat{y}$ closely match the true label y:

$$L = -\frac{1}{N}\sum_{i=1}^{N}(y_i \log(\hat{y}_i) + (1-y_i)\log(1-\hat{y}_i)) \tag{14}$$

where N denotes the total number of samples in the test set. y_i represents the ground truth label of the i-th sample, taking binary values (0 or 1). $\hat{y}_i$ represents the predicted probability of the i-th sample.

IV. Experiment

In this section, we first introduce the data we collected, known as the cardboard-boxes-dataset. Then, we detail a series of experiments we conducted to test on cardboard-boxes-dataset. Additionally, we analyze the critical roles of several key modules designed by us in neural network learning through visualization.

A. Dataset

We provide a detailed overview of the data collection and feature labeling processes, as well as the specific details of dataset split.

1) Data Collection and Feature Labeling: In cardboard-boxes-dataset, we collected a total of 1210 images of packages. Among them, 761 images are from packages that have undergone express delivery and were actually delivered. The remaining images were obtained by purchasing new corrugated cardboard boxes of different sizes and manually simulating various types of defects that might occur to packages before capturing images.

We used LabelMe* to annotate detailed auxiliary information for 990 images, which can be used for tasks such as package localization and defect detection.

The annotation process involved two experts and was conducted in two rounds due to slight differences in their psychological expectations regarding whether the packages were defective. In the first round, each expert independently labeled each package image without any communication. Images that both experts found ambiguous or impossible to categorize were eliminated (225 images). In the second round, the experts continued to label the images without communication. The consistency of the labeling results was assessed using Cohen's Kappa:

$$k = \frac{p_0 - p_e}{1 - p_e} \tag{15}$$

where p_0 is the actual probability of agreement between the two experts, and p_e is the probability of agreement due to chance.

variance	**0.0215**	0.0288	**0.0199**	0.0339

The final result is 0.6179, indicating a high level of consistency ($\geq$ 0.61 and $<$ 0.8) in the labeling results between the two experts. This implies a highly unified standard regarding whether the packages are defective. After removing inconsistent images labeled by both experts, there are a total of 350 images of non-defective packages and 447 images of defective packages.

2) Dataset Split: The dataset is randomly split into training, validation, and test sets with a ratio of 6:2:2, ensuring a balanced distribution of positive and negative samples in the validation and test sets to avoid data imbalance during validation and testing. Details are shown in Table II.

B. Hyperparameter Setting

TPMN is implemented by TensorFlow 2.8.The GPU used for training is the NVIDIA GeForce RTX 3090 24G. The input size of the backbone is 224×224×3, and the input size of the texture prior attention module is 224×224×1. The canny's upper threshold is 140 and its lower threshold is 80.

The chosen optimizer is Adam, with a learning rate of 0.001 and a decay of 0.002. The batch size is set to 128. Early stopping is implemented with a patience of 10, monitored by the cross entropy. The fully connected layers have 32 and 64 units, and the channels of multi-level feature fusion module are set to 32. Label smoothing is applied with a coefficient of 0.2.

C. Experimental Results

The model evaluation metrics include cross entropy (CE) and accuracy (Acc). Additionally, to better assess the model's performance, we will also separately consider metrics such as average cross entropy, average accuracy, minimum cross entropy, maximum accuracy, as well as the variance of cross entropy and accuracy. We additionally designed the Backbone of the TPMN based on MobileNet, known as MN-TPMN. The model was trained and tested a total of 10 times. All models were trained and tested in the cardboard-boxes dataset for a total of 10 times, and predicted whether the package was defective in the validation set.

The basic experimental prediction results, as shown in Table.III, demonstrate that the TPMN performs exceptionally well, exhibiting lower CE values and a higher average Acc. Compared to MN-TPMN, TPMN has a 1.5% lower average CE and a 1.2% higher average Acc. Each variance indicates that TPMN shows better stability.

We also compared our method with other attention mechanism networks: AttNet, SENet [16], and DANet [24]. The backbone network for these three models is ResNet-18, and the other training parameters are kept consistent with our training approach. AttNet is a spatial attention network that we re-implemented based on ResNet-18 [16]. The results, as shown in Table I, demonstrate that TPMN achieves optimal performance in terms of both CE and Acc compared to other

attention mechanism networks. The higher variance of 1.2% is attributed to the complexity of texture patterns, leading to frequent changes in attention weights. In summary, TPMN exhibits substantial advantages in the logistics package defect detection task, proving the efficacy of our designed Texture Prior Attention Module.

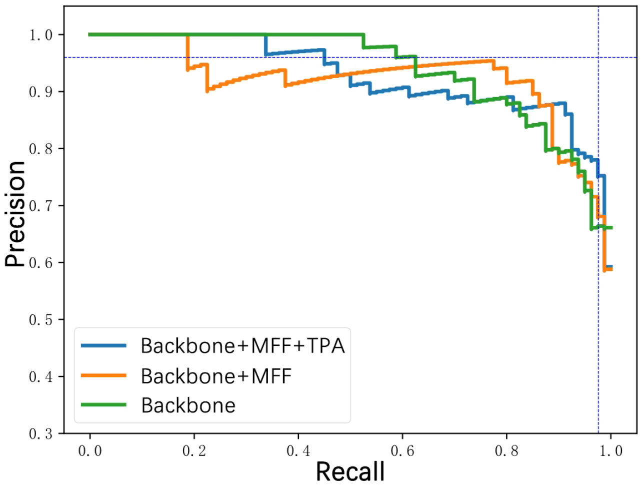

Fig. 5. PR curves from ablation experiments.

D. Ablation Study

To demonstrate the effectiveness of each module of TPMN, we conducted the following ablation studies: 1) The complete network, TPMN; 1) backbone whitout the texture prior attention module (TPA) from our proposed model; 2) backbone whitout the texture prior attention module(TPA) and the multi-level feature fusion module (MFF). As shown in Table.IV , compared to the backbone, we can observe that the utilization of MFF leds to an decrease in the average CE from 0.522 to 0.489, and a increase in the average ACC from 0.832 to 0.852. Considering the optimal values the model can achieve, the maximum accuracy increase by 1.26%. Furthermore, compared to the backbone, the combined use of TPA and MFF shows a significant decrease of 5% in the average CE, and decrease of 2.3% int the minimum CE. Meanwhile, Backbone-only model exhibits a pattern where its average ACC is 2.01% lower than backbone without TPA and 3.2% lower than the complete network. This indicates that, with the TPA and MFF, the model's average performance is much better than both backbone and backbone without TPA. Experiments prove the effectiveness of the two modules we designed.

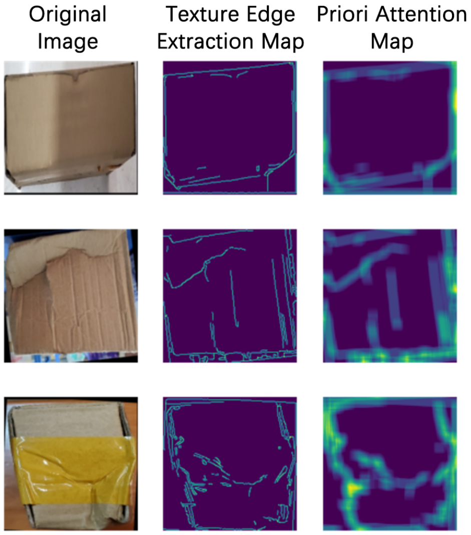

Fig. 6. Visualization of texture feature extraction.

are shown in Fig. 5, providing a preliminary insight into the workings of the two main modules. In situations where high precision is emphasized, the TPMN performs relatively worse compared to backbone with MFF, potentially misclassifying more intact packages as defective. Nevertheless, when Recall is greater than 0.85, TPMN outperforms the other control group, and backbone with MFF performs better than backbone-only model when Recall is greater than 0.7. This indicates that the TPMN is highly sensitive to defective packages. The texture prior attention module highlights the importance of texture, yielding better results for packages with rich textures. However, when the packages are non-defect, the model is less affected by effective textures, leading the attention towards patterns and text on the packages, which interferes with model training.

E. Visual Analysis

We first visualized the extraction of prior information from texture features. Then, we conducted a visual analysis of the impact of the prior attention map on the model training.

1) Visualization of Texture Extraction: We conducted an analysis of the effectiveness of the Texture Prior-Attention Module in extracting texture features. In Fig. 6, after Canny edge detection, the texture edges of the corrugated cardboard were successfully extracted, but the nearby texture information was not included. The final Prior Attention Map, obtained through convolution and average pooling, expands the attention range along the texture edges, thereby accommodating richer texture information. Through the local perceptiveness of convolution and the information integration of average pooling, the expansion of the attention range on the texture can be achieved.

2) Visual Analysis of Model Effectiveness: To provide additional evidence of the effectiveness of our approach, we conduct visual analysis on both the backbone-only model and the complete TPMN model. We analyze the model and classification results from the perspective of original images and convolutional layer attention. The attention map of the convolutional layer is obtained using the GradCAM [34] applied to the model's output and its last convolutional layer. Fig. 4a Fig. 4b and Fig. 4c demonstrate the advantages of the two main modules. TPMN can more accurately locate and focus on edge features, leading to accurate predictions. Without the two modules, backbone can only make predictions by broadly attending to various regions of the image, making it difficult to achieve the same performance. Fig. 4d, illustrates another extreme. When there are clear patterns or text on non-defect packages, the performance of the TPMN tends to decline. Due to the attention mechanism, the model's attention is forced to concentrate on information unrelated to the defect of package, resulting in prediction errors.

F. Few-Shot Learning Experiment

This section aims to investigate whether the model can maintain excellent performance with a reduced amount of data. Five sets of experiments were designed, each trained on different-sized training sets, and their final performance was measured. Despite variations in training set sizes, all datasets were processed using the data augmentation methods mentioned earlier.

The experimental results are shown in Table V. Regardless of the dataset size, TPMN has the highest Acc among all models, and CE also reaches the lowest in all five experiments. This indicates that the TPMN is able to maintain great performance even under conditions of limited data.

Attention mechanisms based models on often require larger datasets for training [35]. However, the TPMN excels on smaller datasets, because our designed prior attention and multi-level feature fusion methods effectively extract low-level texture features and Fusion multi-level features.

V. Conclusions and Future Work

In this study, we proposed a novel approach named the Texture Prior-Aware Multi-Level Feature Fusion Network to address the challenges in surface defect detection for corrugated cardboard boxes used in the logistics industry. Our method integrates a multi-level feature fusion technique that preserves and utilizes information from different semantic levels, overcoming the limitations of traditional Convolutional Neural Network (CNN)-based methods, which often suffer from the loss of local information and insufficient semantic details. The introduction of a prior attention mechanism enables the neural network to focus on extracting low-level texture features from the images in the early stages. The TPMN model, being model-agnostic, effectively extracts and fuses low-level texture features while comprehensively perceiving multiscale image information.

We conducted extensive experiments on our newly contributed Cardboard-Boxes-Dataset, which comprises 1210 images of packages. The results consistently demonstrated the superior performance of the TPMN model in precise defect classification and localization compared to traditional methods. The integration of ResNet-18, multi-scale feature fusion, and a prior attention mechanism proved effective in addressing the challenges unique to the logistics industry, where courier parcels, especially those made of corrugated cardboard, can exhibit varying defect sizes and structural complexities.

In the Future, there are several promising directions for further research and enhancement of TPMN. Firstly, expanding the dataset by incorporating diverse samples under varying environmental conditions would strengthen the model's robustness and generalization capabilities. Additionally, extending the application of the TPMN model to detect defects in different packaging materials commonly encountered in logistics, such as plastic or composite materials, could enhance its versatility. Exploring optimization strategies for real-time deployment, considering computational efficiency and resource constraints, is crucial for practical implementation in logistics settings. Integration with robotic systems for automated surface defect detection in logistics warehouses represents a potential avenue to improve efficiency and reduce manual intervention. In summary, the TPMN model lays a foundation for effective surface defect detection, and future research endeavors can capitalize on these insights to address evolving challenges in the dynamic logistics industry.

Abstract—**Multiple Organ Dysfunction Syndrome (MODS) is one of the most common and severe conditions affecting patients admitted to intensive care units (ICUs). It is characterized by the simultaneous failure or dysfunction of at least two organ systems. Although no specific remedy for MODS has been identified to date, early diagnosis and adequate organ support can significantly improve patient outcomes. Identifying patients at risk of developing MODS in the ICU is challenging. Currently, several methods are used for this purpose, including scoring systems like SOFA and MOD Score, as well as machine learning-based approaches. However, these methods often have limitations. Some require invasive features, making them complex to use in a smart healthcare system. Others suffer from a lack of performance due to various problems, which can potentially lead to unreliable predictions. Feature selection can improve ML models' performance. Recently, bio-inspired feature selection techniques have shown promise in improving the performance of machine learning methods in many domains, but their effectiveness in MODS prediction has not yet been evaluated. Additionally, research on early MODS prediction, particularly utilizing time-series data and dynamic ensemble methods, remains limited. To fill this gap, the present research used state-of-the-art machine learning algorithms, namely dynamic ensemble techniques, to predict patients at risk of developing MODS in the ICU. Dynamic ensembles are new methods that select an ensemble of the best-performing models for every new test case. We compared the performance of these models with full features and with feature selection. Three nature-inspired meta-heuristic optimization models, namely the binary bat algorithm (BBA), grey wolf optimization (GWO), and genetic algorithm (GA), were evaluated to select the optimal feature subset. The models were built using non-invasive patient features and time-series data from the first 12 hours of ICU admission. The results showed that feature selection significantly improved the performance of dynamic ensemble models. Notably, the METADES model, employing grey wolf optimization for feature selection, demonstrated the best performance in terms of accuracy(96.5%), F1 score (96.4%), precision (97.2%), recall (95.7%), and area under the ROC curve (AUC) (98.4%). These findings highlight the potential and effectiveness of our approach for early MODS prediction in ICUs.**

Keywords*—*Ensemble dynamic model; MODS prediction; decision support system; Bio-Inspired feature selection

I. Introduction

Multiple Organ Dysfunction Syndrome (MODS) is widely recognized as a primary cause of death in critically ill patients, affecting 11% to 40% of adults admitted to intensive care units (ICUs) [1]. Accordingly, the high mortality rate of this syndrome, ranging from 44% to 76%, underlines its seriousness. MODS typically arises in response to severe illness or injury, often as a result of conditions like sepsis, severe trauma, major surgery, or prolonged shock. It involves the simultaneous dysfunction or failure of at least two organ systems, such as the heart, lungs, liver, and kidneys, etc. While the dysfunction is typically acute and severe, there is potential for reversibility, especially with prompt identification and treatment of underlying causes or triggers [2].

Despite extensive research, effective treatments for MODS remain elusive. Current interventions have not adequately controlled the excessive immune response or facilitated organ recovery. This has led to invasive organ support as the primary treatment approach in ICUs [1]. Additionally, a survey by the American Hospital Association (AHA) revealed that there are over 6,300 intensive care units in 3,200 acute care hospitals in the United States, providing a total of 94,000 ICU beds [3]. Consequently, the shortage of medical staff in ICUs exacerbates work pressures, affecting patient care quality and potentially leading to oversight of crucial changes in patient conditions [4]. Therefore, rapid diagnosis becomes essential for optimal resource allocation to the neediest patients. It's important to note that the implementation of early-phase management strategies, including a resuscitation approach focused on damage control and scoring systems, has contributed to an increased survival rate among injured patients upon admission to intensive care. Hence, fundamental aspects of MODS treatment involve early identification and support of organ functions. Several scoring systems have been developed to assess the severity of Multiple Organ Dysfunction Syndrome (MODS) and predict outcomes using clinical parameters. Among these, the SOFA score (Sequential Organ Failure Assessment) [5] is commonly utilized. The SOFA score is designed to monitor and predict the progression of organ failure by assessing the function of six organ systems: cardiovascular, liver, respiratory, coagulation, renal, and neurological [6]. Furthermore, each organ system is assigned a score ranging from 0 to 4, as shown in the Table I. A higher score reflects more severe failure. Organ failure is typically identified by a SOFA score exceeding 2 in one of the six assessed organ systems [7]. The total SOFA score is the sum of these individual scores, ranging from 0 to 24. However, the SOFA score is a complex tool that necessitates meticulous patient evaluation and the continuous collection of numerous parameters. Consequently, it may exhibit variability in predicting the outcome of MODS.

TABLE I. SOFA Score Parameters

Organ Systems	SOFA	Score
Respiratory	PaO2/FiO2 and ventilation	0 to 4
Coagulation	Platelet number	0 to 4
Hepatic	Bilirubin	0 to 4
Cardiovascular	Blood pressure and vasopressor use	0 to 4
Central nervous system	Glasgow Coma Scale	0 to 4
Renal	Creatinine urine output	0 to 4
Aggregate	Calculated daily	0 to 24

In recent years, there has been a gradual increase in research on intelligent intensive care units, with a focus on monitoring and risk prediction. By leveraging modern scientific and technological advancements such as 5G communication technologies, the Internet of Things, and big data analysis, coupled with machine learning techniques[4], these innovations hold promise in predicting the likelihood of an individual developing MODS in the ICU.

Many researchers have employed ensemble classifiers for clinical classification problems, with promising results [8] [9] [10][11]. Additionally, they have also explored Dynamic Ensemble Selection (DES) models [12][13] [14] that select an ensemble of classifiers dynamically for each test data item. This allows DES to identify patterns in complex domains like biomedicine, credit scoring, and handwriting recognition instead of relying on a single classifier for the entire dataset. While existing research on predicting Multi-Organ Dysfunction Syndrome (MODS) in ICU patients suggests room for improvement, we investigated DES techniques for this purpose. Our study compares them with diverse feature selection methods utilizing nature-based algorithms. Feature selection helps alleviate the “curse of dimensionality,” facilitating faster, simpler, and potentially more performant machine learning models. Analyzing relevant studies [15], [16], [17], [18], [19], we identified the Binary Bat Algorithm (BBA), Genetic Algorithm (GA), and Grey Wolf Optimization (GWO) as effective and prevalent feature selection algorithms. Our study employed these bio-inspired feature selection methods.

Following feature selection, we employed seven state-of-the-art DES models (META-DES, DESP, KNORA-U, DESKNN, KNORA-E, MCB, and KNOP) for classification. We comprehensively evaluated their performance using metrics like F1-measure, recall, sensitivity, precision, accuracy, and ROC curve analysis to select the optimal classifier. Additionally, Area Under the Receiver Operating Characteristic (AUROC) curve analysis assessed the impact of feature selection.

Our main objective is to develop a decision support system capable of accurately classifying and predicting patients at risk of having MODS in the ICU using only non-invasive features and time-series data from the first 12 hours after ICU admission. This system has the potential for integration into a smart healthcare monitoring system for intensive care units[8], as illustrated in Fig. 1.

The remainder of the document is structured as follows: Section II provides an overview of the current state of research in MODS, followed by Section III, which outlines the proposed methodology. Section IV presents the experimental results and subsequent discussion. Section V addresses the limitations of this study and suggests avenues for future research, while Section VI serves as the conclusion.

II. Related Works

To date, extensive research efforts have been dedicated to investigating the diagnosis of Multiple Organ Dysfunction Syndrome (MODS).Various medical and artificial intelligence-based methods have been employed, yielding significant results. This section undertakes a thorough examination of the literature concerning MODS diagnosis and related triggers, such as sepsis:

Bowen et al. [20] proposed an approach based on machine learning for predicting multi organ dysfunction syndrome (MODS) recovery in pediatric patients with sepsis. The authors highlight the lack of effective predictive models for early recovery from MODS in this patient group. The study introduces a novel methodology that anticipates the transition from MODS to milder states, utilizing datasets from Swiss and U.S. pediatric sepsis cohorts. The model demonstrated promising performance, achieving approximately 79.1% AUROC and 73.6% AUPRC during internal validation and 76.4% AUROC and 72.4% AUPRC during external validation. The suggested approach exhibits the potential for integration into electronic health record systems, thereby aiding in patient evaluation and prioritization within pediatric sepsis care. Furthermore, the researchers employ SHAP values to elucidate pivotal recovery factors as identified by the model. The study also explores associations between predicted outcomes and factors such as pathogens, infection sites, and age groups, contributing to an enhanced interpretation of the model’s predictions.

Guanjun et al. [21] proposed a study to develop models to predict multiple organ dysfunction syndrome (MODS) among trauma patients utilizing noninvasive predictors alone. Traditional methods of predicting MODS are invasive and difficult to implement in a pre-hospital environment. The study uses records from 2319 patients and employs seven machine learning methods to create real-time MODS prediction models. A comparison was made between the models and the four conventional scoring systems. The best-performing model is based on LightGBM (LGBM) and Adaboost, achieving a high AUC of 0.959 when using all parameters. Even when reducing the parameters to non-invasive ones only, the LGBM model still outperformed traditional scoring systems, with an AUC of 0.940. The study concludes that the accurate, real-time prediction approach using non-invasive features is superior to conventional scoring systems, which could facilitate early diagnosis and improve patient survival rates in the pre-hospital setting.

Chang et al. [22] proposed an advanced approach to the challenge of predicting and preventing multiple organ dysfunction syndrome (MODS), The study used machine learning

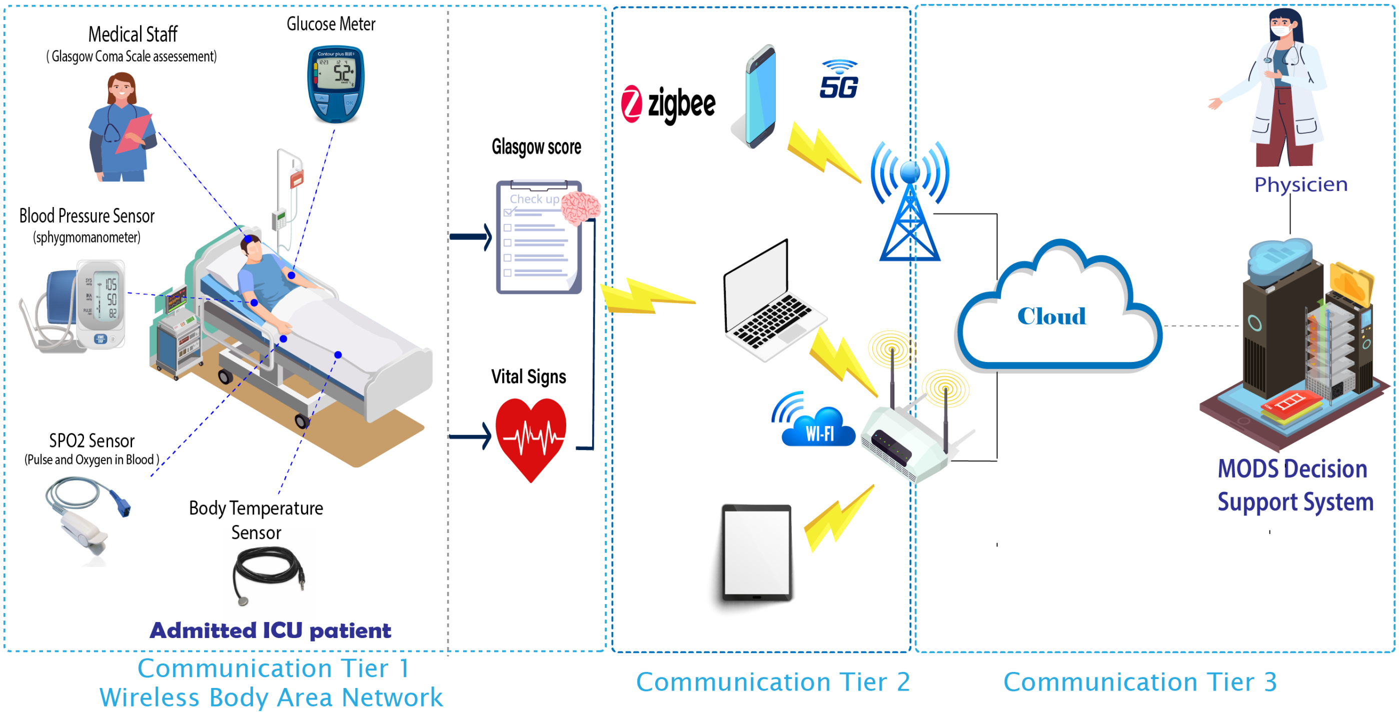

Fig. 1. General architecture of the predictive system for MODS in ICU.

algorithms to create early warning models for MODS risk assessment. The researchers developed a customizable model called SuperLearner by integrating several machine learning approaches, which resulted in high robustness in detection and favorable assessment measures such as sensitivity and accuracy. In addition, the deep neural network (DWNN) model showed excellent performance, with a notable AUC of 0.960 on the MIMIC-IV test set. This result highlighted the exceptional predictive power of the DWNN model in the context of MODS prediction. The research introduced additive Kernel-SHAP and various DiCE (counterfactual explanations) to interpret the results of the predictions and recommend interventions, enabling the prediction of MODS risk 12 hours in advance. The study utilized clinical features, scoring characteristics, and database data for model training, showcasing the potential application value of their approach for early MODS prediction and intervention. The integration of Q-learning for model selection and the combination of SuperLearner and SubSuperLearner structures were innovative contributions. The researchers also introduced a utility score for comprehensive performance assessment and incorporated DiCE to facilitate automatic intervention recommendations for improved practicality.

Tunc et al. [23] introduced a solution for monitoring sepsis-related symptoms and the condition of organ systems without the need for lab tests. Their work proposed the Deep SOFA-Sepsis Prediction Algorithm (DSPA), which combines features from Convolutional Neural Networks (CNNs) with the Random Forest (RF) algorithm to predict Sequential Organ Failure Assessment (SOFA) scores of patients diagnosed with sepsis using only seven vital signs collected in the Intensive Care Unit (ICU). They evaluated their model using the MIMIC III dataset and achieved a mean absolute error (MAE) of 0.65, a correlation coefficient (CC) of 0.86, and a root-mean-square error (RMSE) of 1.23 in predicting SOFA scores at the onset of sepsis. Their model demonstrated superior performance compared to traditional machine learning and deep learning models in regression analysis. Furthermore, they showcased strong classification performance, achieving an area under the curve (AUC) of 0.982 for predicting early sepsis, surpassing previous studies. The proposed framework offers a non-invasive and timely approach for predicting sepsis and monitoring organ states.

Alexis et al. [24] conducted a study on multiple dysfunction syndrome in children after congenital heart surgery involving cardiopulmonary bypass (CPB). The study involved 306 surgical patients under the age of 18 and collected biomarkers and clinical information. The model, called PERSEVERE-CPB, incorporated the level of interleukin 8 (IL-8) 12 hours after bypass surgery, the change in serum chemokine ligand 3 (CCL3) between 4 and 12 hours, and the infant's age category. PERSEVERE-CPB was able to efficiently stratify patients into categories of low, intermediate, and high risk for the development of persistent MODS, demonstrating the potential for targeted interventions and improved outcomes through the identification of high-risk patients. The discriminative performance of the model was comparable to reference tools such as the STAT model and the PRISM III score, with an AUROC of 0.86 (95% CI 0.81; 0.91) for discrimination between patients with and without persistent MODS. After 10-fold cross-validation, the PERSEVERE-CPB model maintained good performance, with a corrected AUROC of 0.75 (95% CI 0.68-0.84).

This concise overview underscores the significant interest within the scientific community regarding the diagnosis and prediction of Multiple Organ Dysfunction Syndromes (MODS). Despite the limited number of studies utilizing machine learning models for MODS prediction and the scarcity of research involving non-invasive features, resulting in the complexity of implementing these models into an intelligent decision support system for early MODS prediction, it is clear that machine learning tools have yet to achieve widespread application in MODS diagnostic systems. This holds especially true in developing countries, where the mortality rate due to MODS remains alarmingly high, leaving considerable room for improvement. In this study, we introduce a novel approach based on a dynamic ensemble model and an advanced feature selection method for selecting the optimal feature set. Setting it apart from other methods, this approach is straightforward to implement, utilizes non-invasive features to forecast the risk of MODS occurrence in the ICU, and has exhibited outstanding performance in the detection and prediction of Multiple Organ Dysfunction Syndrome (MODS).

III. Proposed Methodology

In this study, our goal is to develop a Decision Support System based on a predictive model for predicting which patients are at risk of developing MODS in the ICU. To achieve this, we compared seven state-of-the-art Dynamic Ensemble Selection models (DES) that assess the skill of individual classifiers from a classifier pool. The most skilled classifier, or a set containing the most skilled classifiers, is then used to predict the correct label for a given test sample. We formulated a classification problem aimed at predicting the risk of a patient developing MODS based on extracted data gathered in the initial 12 hours following their admission to the intensive care unit.

The evaluation of the base classifiers was carried out through the cross-validation technique, and the DES models were assessed using a validation test set to estimate the ability of our model to generalize outside its trained dataset. Throughout our research, we explored various models and architectures, testing different feature sets by applying three nature-based optimization techniques.

The proposed methodology is outlined and visually represented in Fig. 2.

A. Study Design and Datasource

In this study, we employed MIMIC-III, a medical database containing anonymized records from more than 46,520 patients admitted to the intensive care units at Beth Israel Deaconess Medical Center in Boston, Massachusetts. The data spans from 2001 to 2012. The database has received ethical approval for use and is managed by the Massachusetts Institute of Technology's Computational Physiology Laboratory (MIT) under the PhysioNet-accredited Health Data 1.5.0 license. This extensive database comprises 26 tables containing a diverse range of data, such as demographic information, vital sign measurements, laboratory test results, medical procedures, medication records, caregiver notes, imaging reports, and mortality data upon discharge. These data are interconnected using key identifiers such as subject-ID, hadm-ID, and ICUSTAY-ID. In order to ensure patient confidentiality, a rigorous de-identification process was applied, aligning with the Health Insurance Portability and Accountability Act (HIPAA) standards in the United States. This process involved the removal of personally identifiable information, such as patient names, phone numbers, and specific dates. Additionally, a date-shifting method was employed to preserve temporal intervals in the data. We obtained approval to extract data from this database under (Record ID: 53063368).

B. Data Pre-Processing

These steps are designed to improve the overall quality of the selected dataset. The MIMIC III dataset contains a number of issues, such as outliers, missing values, etc. This can be the consequence of a sensor or data transfer failure, an error in data storage, etc. Building a model with such poor, incomplete data is regarded as the major factor behind underperforming models. The initial process of data preprocessing involves converting raw data to a convenient and useful format. This stage involves three distinct steps: cleaning the data, data transformation, and data reduction. Data cleaning focuses on resolving problems associated with missing data and anomalies. The data transformation phase aims to reshape the data so that it is more adaptable for data mining. Commonly used transformation techniques include attribute selection, normalization, etc. Finally, data reduction avoids the complications associated with processing large datasets. The next subsections deal with the measures taken to deal with these data problems.

1) Data extraction: Data were extracted from the MIMIC-III dataset (v1.4). Apache Spark software was used to extract baseline features (subject ID, ID of ICU stay, age, gender), vital signs, and non-invasive features as shown in Table II from patients meeting the criteria using SQL (Structured Query Language) as shown in the cohort selection Fig. 3, and to extract pertinent features to compute the SOFA scoring system.

Our decision to employ Apache Spark for data extraction from MIMIC-III was driven by its remarkable capability to efficiently handle large volumes of distributed healthcare data. Spark excels in distributed processing and provides a unified suite of tools, rendering it highly suitable for extracting and processing complex medical data at scale. Its fault tolerance and capacity to distribute workloads across a cluster of machines ensure the reliability and performance necessary for analyzing clinical data from MIMIC-III.

In addition to its data extraction capabilities, Apache Spark also offers a versatile environment for further data analysis, enabling researchers and healthcare professionals to gain valuable insights from this extensive medical dataset. The combination of MIMIC-III and Apache Spark has proven to be a powerful solution for in-depth healthcare analytics and research.

2) Missing data handling: A thorough understanding of data is of crucial importance when analyzing data in the healthcare context. The challenges inherent in this field call for proper management of missing data. Although the simplistic method of removing missing values is commonly used, it has the notable disadvantage of leading to a loss of significant information, thus reducing the number of data instances available for model training. In response to this problem, various strategies have been proposed for filling in missing values using alternative records, such as forward filling and

the use of K-Nearest Neighbors. During the MIMIC III data pre-processing phase, a substantial proportion of crucial data (between 40 and 55%) is unfortunately lost. However, given its importance to the forecasting process, deleting this data was not an option. Faced with this challenge, we decided to select cases with two or more values in each measure, and then apply the forward filling method to impute the remaining missing values.

3) Outliers detection: In our study, special emphasis was placed on handling outliers within the medical dataset. The detection of outliers was performed using the interquartile range method to avoid the indiscriminate removal of records. Outliers were addressed in two steps: first, they were replaced with null values, considered missing, and then imputed using the forward-filling method.

4) Irregular time interval: In the MIMIC III dataset, the recording of vital signs occurred at irregular intervals, varying from measurements taken every few minutes to every few seconds. This irregularity in time intervals presented a challenge for machine learning techniques that typically operate with uniformly sampled data. To overcome this challenge, we aggregated patient vital sign observations, consolidating them into a single record every hour. This aggregation involved incorporating key statistical measures, including the standard deviation, mean, minimum value, maximum value, and count of all measurements within each hourly interval. As a result, each record now contains consistent values. In addressing further irregularities within the temporal intervals of time-series data, particularly with regard to balancing measurements for patients diagnosed with MODS in the dataset, we implemented a targeted approach. The initial step involved organizing the data by MODS patient ID and timestamp. Subsequently, each patient underwent individual processing to tackle irregular measurements by either eliminating excess or filling gaps with randomly generated dates. The handling of null values was achieved through the forward and backward filling methods, strategically replacing missing values based on predefined criteria. These meticulous steps ensure the consistency of measurements across temporal datasets, ultimately enhancing the quality and reliability of future analyses.

C. Data Preparation

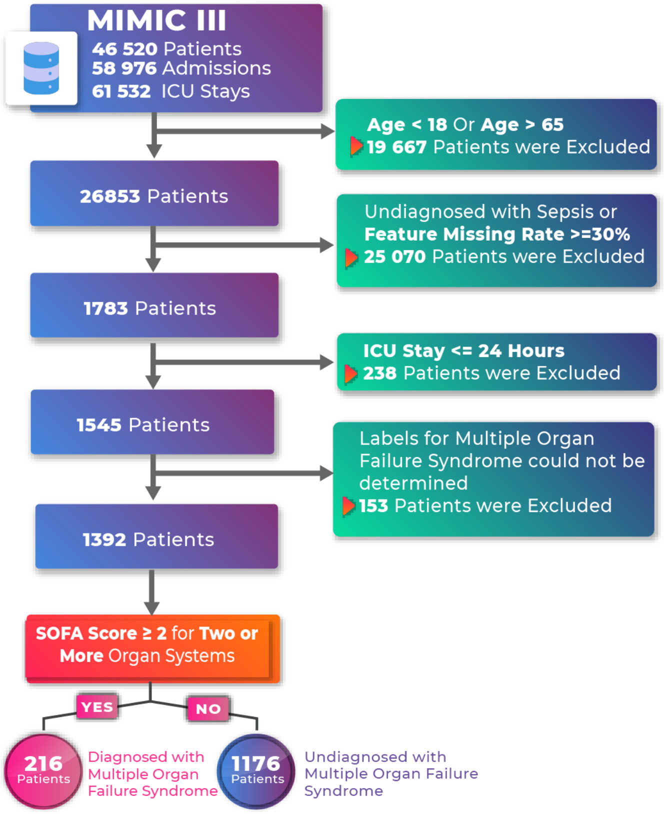
1) Data balancing: The imbalance of classes is one of the most well-known and crucial issues that can influence the performance of machine learning algorithms. This issue occurs when classes are unequally represented. In unbalanced data, majority classes dominate minority classes. Consequently,

TABLE II. FEATURES USED IN THIS STUDY

Feature	Definition
Age	Admission age of the patient
Gender	Gender of the patient
Height	The measurement of a patient's vertical size. Used for assessing body proportions.
Weight	The measurement of a patient's mass. Used for various health assessments, including medication dosages.
Diastolic blood pressure	The pressure in the arteries when the heart is at rest. It is an essential indicator of cardiovascular health.
Systolic blood pressure	The pressure in the arteries when the heart contracts. Important for assessing cardiovascular health and blood flow.
Fraction inspired oxygen	The proportion of oxygen in the air or a gas mixture that is being inhaled. Important for assessing respiratory function and oxygen delivery.
Glucose	The level of glucose in the blood. A critical indicator of glycemic control and metabolic health.
Heart Rate	The number of heartbeats per minute. Crucial for assessing cardiac function and rhythm.
Oxygen saturation	The percentage of hemoglobin in the blood that is saturated with oxygen. It is important for evaluating respiratory function and oxygenation.
Respiratory rate	The number of breaths taken per minute. Essential for monitoring respiratory health and efficiency.
Temperature	The measurement of a patient's body heat. Crucial for monitoring body temperature and detecting fever or hypothermia.
pH	The measure of the acidity or alkalinity of the blood. Essential for evaluating acid-base balance and overall metabolic health.
Mean blood pressure	The average pressure refers to the average pressure in the arteries throughout one cardiac cycle. It serves as a crucial indicator of overall blood pressure.
Glasgow Coma Scale Eye Opening	used to evaluate a patient's level of consciousness by assessing their eye response.
Glasgow Coma Scale Motor Response	used to evaluate a patient's level of consciousness based on their motor response.
Glasgow Coma Scale Verbal Response	used to evaluate a patient's level of consciousness by assessing their verbal response.

since there are not enough instances of the minority class, an imbalanced classification has the disadvantage that a model cannot effectively learn the decision boundary, and machine learning approaches have a higher probability of classifying each new observation in the majority class. Consequently, the issue of unbalanced data can lead to the misclassification of minority classes. However, there is a significant need for an effective method that could address the class imbalance problem. In this study, the minority class has 172 samples, while the majority class has 940 samples, resulting in a ratio of 5.4:1, as depicted in Fig. 4. Thus, we employed an unsupervised technique, namely the Synthetic Minority Oversampling Technique (SMOTE)[25], to address the class imbalance issue in the datasets as depicted in Fig. 5.

2) *Feature scaling:* Feature scaling is a preprocessing technique used in statistics and machine learning to normalize the values of different features in a dataset. Often, datasets contain features that vary widely in terms of size, units, and range. The goal is to adjust the scales of features so that they are comparable, and no single feature dominates others due to its units or magnitude. The range of intensive care unit data points considered in this study is very diverse, and therefore it is necessary to perform feature scaling to minimize any effects on model performance. In our study, we have chosen Z-score scaling as our standardization method. This decision stems from the need to make our features robust to outliers, a crucial aspect in the context of our data. Unlike other methods, such as normalization, Z-score scaling minimizes the impact of extreme observations, ensuring a more balanced scaling of features. Moreover, this approach facilitates the interpretation of results, especially in the context of linear models, by providing directly comparable coefficients. By prioritizing standardization, our goal is to optimize the stability and convergence of machine learning models, thereby contributing to more reliable analyses and robust results within our study.



MIMIC III
46 520 Patients
58 976 Admissions
61 532 ICU Stays
Age < 18 Or Age > 65
19 667 Patients were Excluded
26853 Patients
Undiagnosed with Sepsis or

3) Feature selection: Feature selection is an important component of feature engineering and plays a key role in improving the capability of machine learning algorithms [26]. The primary contribution of the proposed approach lies in its capability to carefully select a subset of features of interest from the set of extracted features, resulting in significantly improved prediction results. This diagnostic model employs an optimal feature selection approach. The primary objective is to emphasize relevant features while reducing the number of features to address redundancy issues. Overall, this methodology aims to minimize the feature set during the construction of the predictive model, leading to a reduction in computational costs and an enhancement in overall model performance. Recent studies highlight the effectiveness of Nature-Inspired optimization feature selection approaches, contributing to a notable increase in model performance and efficiency. The feature selection algorithms employed in this study involve:

a) Grey Wolf Optimization (GWO): The Grey Wolf Optimizer (GWO) [27] is a nature-inspired optimization algorithm. This algorithm simulates the cooperative and hierarchical hunting strategy of wolves, and its key steps are as follows:

Surround the Prey (Initialization): The algorithm begins by randomly placing a population of wolves in the search space, each representing a potential solution.

Hunting Behavior (Fitness Evaluation): Each wolf's fitness is evaluated using a fitness function, measuring its alignment with optimization goals and reflecting its hunting success in finding the optimal solution.

Hierarchy: Alpha, Beta, and Delta (Leadership Selection): Wolves are sorted based on their fitness levels. The top three wolves are identified as alpha, beta, and delta, establishing a leadership hierarchy within the pack.

Update Positions (Pack Movement): The positions of wolves are adjusted using a formula inspired by the social behavior observed in wolf packs. Alpha, beta, and delta play pivotal roles in directing the movement of other wolves toward potentially optimal solutions.

Exploration and Exploitation (Hunting Strategy): The hierarchy ensures a balance between exploration and exploitation. Alpha, beta, and delta lead the exploration, while other wolves follow, exploring around their positions to discover potential solutions.

Surrounding the Prey (Optimization): The algorithm iterates through these stages, progressively refining the positions of wolves. This mimics the way a wolf pack surrounds prey during a hunt, improving the chances of finding the optimal solution.

Criteria for Completion (End of Hunt): The algorithm continues these stages for a defined number of iterations or until a predefined termination criterion is met. The final positions of the wolves represent the optimized solutions.

b) Binary Bat Algorithm (BBA): The Binary Bat Algorithm (BBA), detailed in [28], is an optimization algorithm inspired by the echolocation behavior of bats. It is specifically engineered for tackling binary or combinatorial optimization problems. It simulates bats' use of ultrasonic pulses for navigation and prey location, incorporating features like frequency and intensity modulation, as well as global and local search mechanisms. BBA has demonstrated versatility and effectiveness in addressing various optimization problems since its inception.

The Binary Bat Algorithm (BBA) comprises the following key steps:

Sonar Scanning (Initialization): Initialize a population of binary bats randomly within the search space, representing potential feature subsets.

Fitness Echo (Objective Function Evaluation): Evaluate the fitness of each bat solution using a task-specific objective function for feature selection.

Leadership Hierarchy (Alpha, Beta, and Delta Bats): Establish a leadership hierarchy by designating the top-performing bats as alpha, beta, and delta.

Echo-Driven Movement (Flight Adjustment): Adjust the positions of bats, guided by alpha, beta, and delta, influencing the exploration of potential optimal feature subsets.

Adaptive Echolocation (Exploration and Exploitation): Maintain a balanced exploration and exploitation strategy, with alpha, beta, and delta leading exploration and other bats following suit.

Echo-locative Refinement (Optimization Iterations): Iteratively refine bat positions, mimicking the echolocation process and progressively enhancing the chances of identifying an optimal feature subset.

Termination by Convergence (End of Echolocation): Continue iterations until a predefined convergence criterion is met or a specified number of iterations is completed. The final bat positions represent the optimized feature subsets.

c) Genetic Algorithm (GA): The Genetic Algorithm (GA) [29] introduced the idea of using a population-based search inspired by biological evolution to solve optimization problems. The concept has since evolved, and various adaptations of genetic algorithms have been proposed and applied to different domains, including feature selection in machine learning.

The Genetic Algorithm (GA) comprises the following key steps:

Initialization: Generate an initial population of potential solutions, each representing a binary feature subset.

Evaluation: Assess the fitness of each solution based on a fitness function, evaluating its performance with the selected features.

Selection: Choose individuals from the population to act as parents for the next generation, favoring those with higher fitness.

Crossover (Recombination): Combine genetic material from selected parents to create new offspring.

Mutation: Incorporate minor random alterations to select individuals to uphold genetic diversity.

Replacement: Substitute a portion of the current population with the newly generated offspring.

Termination Criteria: Verify if a termination criterion has been satisfied, which could entail reaching a maximum number of generations or attaining a designated fitness threshold.

Result Extraction: Extract the final chromosome or feature subset from the population as the optimized set of features.

D. Machine Learning Algorithms

1) Dynamic Ensemble Selection Models (DES): are a promising and relevant technique belonging to the category of MCS approaches. Using base classifiers, they dynamically choose the most skilled classifiers for every new test item being classified, with each classifier being competent in a local 'feature space' region. These approaches have shown superior results compared to traditional ensemble methods that combine the results of base classifiers.

a) META-DES (Dynamic Ensemble Selection using Meta-Learning): [30] is a machine learning algorithm designed for dynamic ensemble selection in the field of classification. Its main objective is to approach classification dynamically by treating it as a meta-problem involving determining whether a particular classifier, chosen from a set of classifiers, is competent enough to accurately classify specified test data. This process involves two main steps. First, meta-features such as a posteriori probability for every label, the classifier's overall local accuracy, a vector indicating the difficulty of classifying neighboring instances, and the classifier's confidence based on the perpendicular distance separating the input sample from its decision boundary are derived. Subsequently, meta-classifiers exploit these meta-features to predict the ability of the selected classifier to provide accurate predictions for the designated test data. The classifiers identified by the meta-classifiers are then merged to construct a set of classifiers for the specified test data. META-DES essentially adopts a meta-perspective on classification, striving to dynamically choose the best-performing classifiers for a particular task, based on extracted meta-features.

b) DESP (Dynamic Ensemble Selection with Probability): [31] is an algorithm designed for dynamically selecting the best classifiers from an ensemble by eliminating those deemed incompetent. This is done by evaluating the performance of a single classifier against a random one. The performance given by the random classifier is determined by taking 1/M, with M being defined as the total number of classes that exist in the dataset. Classifiers are dynamically selected for each test data set on the basis of their performance relative to the performance achieved by the random neighborhood classifier selected for the test data set. If the performance of a classifier outperforms the random one, it is deemed suitable for selection into the ensemble for this particular test data set. If no classifier is selected, all classifiers in the ensemble are chosen for the given test dataset. In summary, the algorithm aims to create a dynamic ensemble of classifiers by eliminating incompetent ones and favoring those with better performance than a random classifier in a specified neighborhood.

c) KNORA-U (K-Nearest-Neighbor Algorithm for Dynamic Classifier Selection): The KNORAU algorithm, as outlined in [32], is designed to enhance the accuracy of classifying test samples. It utilizes the concept of k-nearest neighbors (KNN) by identifying the K closest neighbors for each test sample based on distances in feature space. KNORAU then selects classifiers from the initial pool that have accurately classified at least one neighbor among the K nearest, thereby forming a sample-specific ensemble. The prediction of the test sample's label employs the majority vote rule within this ensemble, with vote weights determined by each classifier's past performance in the K-nearest neighborhood. In essence, KNORAU strategically leverages classifier performance within the vicinity of the K-nearest neighbors to improve classification accuracy.

d) Dynamic Ensemble Selection KNN (DESKNN): The DES-KNN method, as introduced in [33], is an ensemble classifier selection algorithm aimed at identifying an optimal set from an initial group of classifiers. It employs diversity and accuracy as selection criteria. Initially, the algorithm identifies the most accurate classifiers within the competence region of a given test dataset. It then proceeds to select the most diverse classifiers among the most accurate ones using a measure known as the double-fault measure. Percentage-based selection, informed by prior research, dictates the proportion of classifiers chosen based on their accuracy and diversity. These percentages have been determined based on the superior performance observed in previous studies.

e) KNORA-E (K-Nearest-Neighbor Algorithm for Ensemble): [32] is a dynamic ensemble selection approach. It aims to choose a set of classifiers from a pool that can accurately classify all K nearest neighbors in a test dataset within a specific training set. The selection process is dynamic, eliminating classifiers that fail to classify at least one nearest neighbor correctly. Once the classifier set is identified, it is used for majority voting in subsequent classifications, following the majority voting rule. If an ensemble isn't found with the initial K value, KNORAE progressively adjusts the K value downward until at least one classifier set is identified. In summary, KNORAE, based on DES, seeks to select a robust set of classifiers capable of correctly classifying the nearest neighbors of a test point within a specific training set.

f) Multiple-Classifier Behavior (MCB): The MCB method[34] involves determining the competence region of a new test sample using the behavioral knowledge space (BKS) and the accuracy of the local classifier. Output profiles are generated for the test sample and its competence region. The similarity between the output profiles of the test sample and those of its skill region is measured. Samples with similarities below a specified threshold are ignored, allowing the size of the proficiency region to be adjusted. The skill of the base classifier is assessed on the basis of its classification accuracy in this adjusted skill region. If a selected classifier has a significant performance advantage over the others (with a difference in skill exceeding a predetermined threshold), it is used for classification. Alternatively, all classifiers are then combined using the majority vote rule.

g) k-Nearest Output Profiles (KNOP): The KNOP method[35] consists of the selection of classifiers that have classified one or more samples within the expertise area of the sample being queried. The region of competence is determined by analyzing the decisions made by the base classifier, known as output profiles. Rather than considering the feature space, the degree of similarity that exists between the queried sample and the validation sample is evaluated through the decision space. Every classifier chosen is allocated a number of votes equivalent to the actual number of samples in the skill region where it accurately predicts the label. The cumulative votes of all core classifiers are then combined to produce the final ensemble decision.

IV. Results

A. Performance Evaluation Metrics

In our evaluation of the proposed approach, we gauge its performance using essential performance metrics. Accuracy assesses the overall correctness of a classification model by comparing correctly predicted instances to the total. Precision quantifies the relevance of positive predictions, while recall evaluates the model's capability to identify actual positives. AUC (Area Under the ROC Curve) serves as a binary classification metric, representing the area under the curve that plots the true positive rate against the false positive rate at various thresholds.

a) Accuracy: Accuracy stands as a prevalent evaluation metric utilized to assess the overall performance of a classification model. It denotes the ratio of correctly predicted instances to the total number of instances within the dataset.

$$\text{Accuracy} = \frac{\text{Number of Correct Predictions}}{\text{Total Number of Instances}}$$

b) Precision: Precision serves as a metric that quantifies the proportion of true positive predictions out of all positive predictions made by the model. It offers a measure of how many of the predicted positive instances are indeed relevant.

$$\text{Precision} = \frac{\text{True Positives}}{\text{True Positives + False Positives}}$$

c) Recall (Sensitivity or True Positive Rate): The recall, also referred to as sensitivity or true-positive metric, evaluates the ratio of true-positive instances that are correctly classified by the model.

$$\text{Recall} = \frac{\text{True Positives}}{\text{True Positives + False Negatives}}$$

d) AUC (Area Under the Receiver Operating Characteristic Curve): AUC, commonly used for binary classification problems, is a performance metric that represents the area under the receiver operating characteristic (ROC) curve. The ROC curve plots the true positive rate against the false positive rate at various threshold levels.

The AUC is calculated by integrating the ROC curve:

$$\text{AUC} = \int \text{TPR}(\text{FPR})\, d\text{FPR}$$

e) F1-score (F1-measure): The F1-score is a measure of a model's accuracy, balancing both precision and recall.

$$\text{F1-score} = 2 \times \frac{\text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}}$$

B. Machine Learning Models Analysis

In this section, we delve into the analysis of the performance of various dynamic ensemble selection methods for the classification and prediction of Multiple Organ System Dysfunction (MODS) using vital signs from the initial 12 hours in the Intensive Care Unit (ICU). Experiments were conducted on a computer with an Nvidia GeForce MX 350 graphics card, an Intel Core i7-10700T processor, and 16 GB of RAM based on scikit-learn 1.1.2 in Python 3.10.8.

We conducted four experiments, each in search of the combination of the best classifier and the most efficient feature selection method for MODS prediction, respectively. Our approach involved testing various state-of-the-art dynamic ensemble models with and without bio-inspired feature selection methods. Model selection was based mainly on comparing their performance statistically. As shown in Fig. 7, four distinct results were reported for the tested models: without feature selection as shown in Fig. 7d, with the genetic algorithm as shown in Fig. 7a, with the binary bat algorithm as shown in Fig. 6b, and with the grey wolf optimization as shown in Fig. 7c.

The dataset was split into two subsets: 70% for training and 30% for testing. The training set was utilized to perform optimization and training of baseline classifiers using cross-validation, while the test set was used to evaluate the performance of dynamic ensemble selection (DES) models based on various metrics.Seven state-of-the-art DES models were applied: META-DES, DESP, KNORA-U, DESKNN, KNORA-E, MCB and KNOP. In addition, three bio-inspired feature selection algorithms were used to identify the most appropriate feature subset: GWO, BBA and GA. The models were applied to both the entire feature set and the selected features.

a) Analysis of Results using All Features: In this section, we investigate the performance of dynamic ensemble models with full features. Table III provides details of the results achieved by the ML models on several evaluation measures. We summarise the results as follows: Using DESKNN and KNOP with full feature sets produced minor

TABLE III. Performance Metrics for Ensemble Models with Different Feature Selection Techniques

Ensemble Models	Feature Selection	Accuracy	Precision	Recall	F1	AUC
KNORA-E	GWO	**0.945**	**0.933**	**0.957**	**0.945**	**0.973**
	BBA	0.853	0.951	0.741	0.833	0.864
	GA	0.906	0.942	0.863	0.901	0.915
	Without FS	0.926	0.943	0.905	0.924	0.965
METADES	GWO	**0.965**	**0.972**	**0.957**	**0.964**	**0.984**
	BBA	0.915	0.934	0.891	0.912	0.959
	GA	0.89	0.927	0.843	0.883	0.935
	Without FS	0.936	0.944	0.927	0.936	0.973
KNORA-U	GWO	**0.942**	**0.929**	**0.957**	**0.943**	**0.971**
	BBA	0.84	0.916	0.744	0.821	0.867
	GA	0.902	0.929	0.868	0.898	0.917
	Without FS	0.915	0.922	0.905	0.913	0.964
DESKNN	GWO	**0.94**	**0.924**	**0.957**	**0.94**	**0.968**
	BBA	0.836	0.907	0.744	0.817	0.871
	GA	0.898	0.922	0.868	0.894	0.909
	Without FS	0.891	0.869	0.92	0.894	0.951
MCB	GWO	**0.94**	**0.93**	**0.949**	**0.94**	**0.967**
	BBA	0.837	0.91	0.744	0.818	0.863
	GA	0.898	0.922	0.868	0.894	0.896
	Without FS	0.909	0.906	0.912	0.909	0.955
DESP	GWO	**0.934**	**0.927**	**0.939**	**0.933**	**0.978**
	BBA	0.838	0.913	0.744	0.82	0.852
	GA	0.898	0.922	0.868	0.894	0.909
	Without FS	0.915	0.932	0.894	0.912	0.962
KNOP	GWO	**0.941**	**0.928**	**0.954**	**0.941**	**0.974**
	BBA	0.835	0.897	0.751	0.818	0.869
	GA	0.873	0.875	0.868	0.871	0.917
	Without FS	0.886	0.86	0.92	0.889	0.951

performance (accuracy=0.891, precision=0.869, recall=0.92, F1-score=0.894, and AUC=0.951) and (accuracy=0.886, precision=0.86, recall=0.92, F1-score=0.889, and AUC=0.951), respectively.MCB , DESP and KNORA-U improved their performance by approximately 3% compared with KNOP. KNORA-E improved its performance by approximately 1.1% compared with KNORA-U. The highest performance was achieved with METADES (accuracy = 0.936, precision = 0.944, recall = 0.927, F1 score = 0.936 and AUC = 0.973). Fig. 6d depicts the AUC and ROC curves of the models with full features. The METADES model achieves the highest AUC (0.973), while the KNOP model achieves the lowest AUC (0.951). Fig. 7d shows the radar plot for models with full features, and places the METADES model in the outperforming category.

b) Results Analysis using the Grey Wolf Optimization (GWO) for Feature Selection: In this section, we investigate the performance of the Ensemble Dynamic Models with selected features by the GWO. Table III provides details of the results achieved by the ML models on several evaluation measures. We summarise the results as follows: Using DESP with selected feature sets produced minor performance (accuracy = 0.934, precision = 0.927, recall = 0.939, F1-score = 0.933 and AUC = 0.978) . MCB and DESKNN improved performance with about 0.6% above DESP. KNORA-U and KNORA-E improved their performance by approximately 0.2-0.3% above MCB and DESKNN. The highest performance was achieved with METADES (accuracy=0.965, precision=0.972, recall=0.957, F1-score=0.964, and AUC=0.984). Fig. 6c depicts the AUC and ROC curves of the models with selected features by GWO. The METADES model achieves the highest AUC =0.984, while the MCB model achieves the lowest AUC (0.967). Fig. 7c shows the Radar Plot of the models with selected features by GWO and places the METADES Model in the outperforming category.

c) Results Analysis using the Binary Bat Algorithm (BBA) for Feature Selection: In this section, we investigate the performance of the Ensemble Dynamic Models with selected features by the BBA. Table III provides details of the results achieved by the ML models on several evaluation measures. We summarise the results as follows: Using KNOP and DESKNN with selected feature sets produced minor performance (accuracy=0.835, precision=0.897, recall=0.751, F1-score=0.818, and AUC=0.869) and (accuracy=0.836, precision=0.907, recall=0.744, F1-score=0.817, and AUC=0.871), respectively. MCB and DESP improved performance by about 0.1–0.2% above KNOP and DESKNN. KNORA-U and KNORA-E improved their performance by approximately 1.6% above KNOP and DESKNN. The highest performance was achieved with METADES (accuracy=0.915, precision=0.934, recall=0.891, F1-score=0.912, and AUC=0.959). Fig. 6b depicts the AUC and ROC curves of the models with selected features by BBA. The METADES model achieves the highest AUC of 0.959, while the DESP model achieves the lowest AUC of 0.852. Fig. 7b shows the Radar Plot of the models with selected features by BBA and places the METADES Model in the outperforming category.

d) Results Analysis using the Genetic Algorithm (GA) for Feature Selection: In this section, we investigate the performance of the Ensemble Dynamic Models with selected features by the GA. Table III provides details of the results achieved by the ML models on several evaluation measures. We summarise the results as follows: Using KNOP with selected feature sets produced minor performance (accuracy = 0.873, precision = 0.875, recall = 0.868, F1-score = 0.871, and AUC = 0.917). METADES improved their performance by approximately (1.7)% above KNOP and DESKNN, MCB and DESP improved performance by about 0.8% above METADES, and KNORA-U improved performance by about 0.22% above DESKNN, MCB, and DESP. The highest performance was achieved with KNORA-E (accuracy=0.902, precision=0.929, recall=0.868, F1-score=0.898, and AUC=0.917). Fig. 6a depicts the AUC and ROC curves of the models with selected features by GA. The METADES model achieves the highest AUC (0.935), while the MCB model achieves the lowest AUC (0.896). Fig. 7a shows the Radar Plot of the models with selected features by GA and places the KNORA-E Model in the outperforming category.

e) Comparison Between All Models: In this paper, we investigate the performance of dynamic ensemble models utilizing all features as well as features selected using bio-inspired feature selection algorithms. As shown in Table III, a confusion matrix in Fig. 8 is used to depict and display the performance of dynamic ensemble models using GWO as a feature selection technique and to give an overview of the model's classification errors. The METADES model with GWO as feature selection technique achieved the highest performance compared to both complete features and features selected by GA and BBA, with an accuracy of 96.5%,a precision of 97.2%, a recall of 95.7%, an F1-score of 96.4%, and an AUC of 98.4%. Conversely, the METADES model with GA-selected features demonstrated the lowest performance.

These findings emphasize the effectiveness of the approach using the METADES model and the GWO feature selection method in predicting patients at risk of developing MODS, suggesting its potential for clinical application.

V. Limitations and Future Directions

Although our proposed approach is promising for the early prediction of MODS in the ICU, it has certain limitations: Firstly, the dataset used in this study includes only MIMIC III patients, specifically those admitted to the intensive care units (ICUs) of Beth Israel Deaconess Medical Center in Boston, Massachusetts, USA. To ensure the generalizability of the model, we are planning to test it with other real-world datasets. Secondly, although dynamic ensemble models outperform deep learning models in terms of speed, the use of time-series datasets using deep learning methods such as LSTM and CNN may enhance performance. Thirdly, to be clinically accepted as a decision-support system, the approach must be interpretable. For this reason, we plan to study various methods of explainability, such as eXplainable Artificial Intelligence (XAI). Future studies will address all these limitations.

VI. Conclusion

In this work, we proposed a decision support system for the early prediction of Multi-Organ Dysfunction Syndrome (MODS) in the intensive care unit (ICU). Utilizing only non-invasive features and time-series records gathered from the initial 12 hours of admission in the ICU, the system aimed to support doctors by accelerating their decision-making process. We explored the effectiveness of dynamic ensemble selection models in predicting the risk of developing MODS within the ICU. We compared the performance of models with full features and with feature selection methods, evaluating three nature-inspired metaheuristic optimization feature selection techniques: the binary bat algorithm (BBA), grey wolf optimization (GWO), and genetic algorithm (GA) in order to select the optimal feature subset.

The proposed system was trained and evaluated on a cohort of 1,392 patients extracted from the MIMIC III dataset. The METADES model with GWO as the feature selection technique achieved the highest performance compared to models using all features or features selected by other methods. It demonstrated an accuracy of 96.5%, a precision of 97.2%, a recall of 95.7%, an F1-score of 96.4%, and an AUC of 98.4%. Conversely, the METADES model with GA-selected features exhibited the lowest performance.

These findings highlighted the effectiveness of our approach using the METADES model and the GWO feature selection method in predicting patients at risk of developing MODS, suggesting its promising potential for clinical application.

Abstract—**In the field of orthodontics, the accurate identification of cephalometric landmarks in dental radiography plays a crucial role in ensuring precise diagnoses and efficient treatment planning. Previous studies have demonstrated the impressive capabilities of advanced deep learning models in this particular domain. However, due to the ever-changing technological landscape, it is imperative to consistently investigate and explore emerging algorithms to further improve efficiency in this field. The present study centers around the assessment of the effectiveness of YOLOv8, the most recent version of the 'You Only Look Once (YOLO)' algorithm series, with a particular emphasis on its autonomous capability to accurately identify cephalometric landmarks. In this study, a thorough examination was conducted to evaluate the YOLOv8 algorithm efficiency in detecting cephalometric landmarks. The assessments encompassed various aspects such as precision, adaptability in challenging conditions, and a comparative analysis with alternative algorithms. The predefined proximities of 2mm, 2.5mm, and 3mm were utilized for the comparisons. By focusing on its potential as a noteworthy breakthrough, the investigation seeks to ascertain whether the recent enhancements indeed bring about a significant stride in the precise identification of cephalometric landmarks.**

Keywords*—*Cephalometry; YOLOv8; landmark detection; orthodontics

I. Introduction

Since its introduction by Broadbent in 1931, the cephalometer has garnered extensive recognition as a universally adopted diagnostic instrument within the realms of orthodontic practice and research [1]. Cephalometry, a field of study focused on the measurement of cranial dimensions, involves the meticulous quantification of these dimensions using either direct measurements or radiographic techniques. This process involves identifying specific anatomical landmarks as reference points for accurate and standardized measurements. The incorporation of suitable standards plays a pivotal role in the assessment of facial growth and development, rendering them an indispensable component in the diagnostic and treatment planning stages of orthodontics. In the realm of cephalometrics, the arduous task of manually identifying and annotating cephalometric landmarks on radiographic images has long been entrusted to proficient experts in the field. Hand annotation, while a valuable technique, is known for its labor-intensive nature and vulnerability to human error-induced discrepancies [2] [3].

The advent of deep learning in the field of medical imaging has brought about a profound transformation in various diagnostic techniques, such as cephalometric analysis. In this emerging era of digital diagnostics, machine learning algorithms have taken the lead, paving the way for significant advancements in orthodontic diagnostic practices and treatment strategies. Prior research has clarified the impressive potential of deep learning models in automating this critical procedure, resulting in significant improvements in both precision and speed.

In the domain of diagnostic automation, deep learning has witnessed remarkable progress. However, the quest for enhanced speed, better precision, and unwavering reliability remains unyielding. Our research is conducted within the context of an ongoing pursuit of continuous improvement.

In this study, we aim to evaluate the capabilities of YOLOv8, the most recent version of the renowned "You Only Look Once (YOLO)" models, in the realm of automated cephalometric landmark detection. This inquiry transcends pure theory and holds significant practical implications for the field of orthodontics. Previous studies have highlighted its potential, but a comprehensive exploration of its performance, especially in diverse clinical scenarios, remains lacking [4].

In our investigation, we delve into the intricate details of YOLOv8, meticulously examining its precision, speed, and robustness metrics. Simultaneously, we remain vigilant in assessing its practicality and suitability for real-world orthodontic clinical scenarios. Our main goal in this study is to find out how well YOLOv8 can bridge the gap between extremely advanced technology and the practical needs of orthodontic practice, setting new standards in the field that have never been seen before.

In this article, we will start by elucidating the underlying impetus behind our research, thereby furnishing a lucid comprehension of the motivation that propelled this work forward. In the subsequent sections, we shall embark on an in-depth examination of pertinent literature, thereby furnishing crucial background information for our research endeavor.

In the sections that follow, we will talk about all of our materials and methods in detail, including the organized way we gathered data, how carefully we prepared it, and how strictly we followed our training procedures. In this section, we will delve into the intricate methods utilized, providing a thorough understanding of the meticulous approach undertaken during the research endeavor.

In the upcoming parts, we will give the results obtained from our thorough inquiry, offering a concise summary of the findings acquired from our analysis of data and experimentation. In the last part of this essay, we will conduct a thorough examination, combining the results, extracting meaningful observations, and possibly suggesting avenues for further research.

II. Motivation

In the field of medical diagnostics, the importance of cephalometry cannot be emphasized enough. The field of craniofacial imaging has played a vital role in the medical industry for many years. Its significance lies in its ability to diagnose craniofacial malformations, facilitate detailed surgical planning and evaluation, and contribute to essential growth studies. Cephalometry, a field of study focused on craniofacial analysis, centers around the meticulous identification of craniofacial landmarks. This crucial process involves the precise detection of cephalometric landmarks on the cephalogram, serving as the fundamental initial stage in conducting any cephalometric analysis [5] [6] [7]

In the past few years, the field of deep learning has witnessed the emergence of highly sophisticated models that have demonstrated exceptional capabilities in this particular domain [8] [9] [10]. The advent of these models has brought about a paradigm shift in the field, presenting ingenious approaches to tackle the complex challenge of landmark identification. In light of the ever-changing technological terrain, it is crucial to consistently delve into and scrutinize nascent algorithms. The need to maximize efficiency and precision fuels the relentless pursuit of advancement in cephalometric analyses.

In our relentless quest for perfection, we embarked on a comprehensive exploration of the most recent breakthroughs in the realm of object detection. In our study, we sought to enhance the accuracy and efficiency of cephalometric landmark identification by harnessing the advanced capabilities of the YOLOv8 algorithm. This algorithm has gained widespread recognition for its exceptional performance in detecting objects. The YOLOv8 model distinguishes itself in the field of computer vision with its remarkable precision and efficiency. The model's exceptional performance is a result of meticulous training on an extensive and varied dataset, ensuring its ability to handle diverse visual scenarios.

The utilization of cephalometry in the medical field is of utmost importance, and with the constant advancements in technology, our investigation of YOLOv8 marks a significant leap forward. Through the utilization of this cutting-edge algorithm, our objective is to not only augment the accuracy of cephalometric landmark detection but also make substantial contributions to the continuous progress in medical diagnostics.

The motivation behind this research was clearly defined in this part. In the following section, we will conduct a thorough examination of the pertinent literature in the topic, providing useful insights into the existing body of knowledge.

III. Related Works

In the field of orthodontics, the convergence of cutting-edge machine learning and computer vision, specifically through the utilization of deep learning techniques, presents a remarkable opportunity for an upheaval. The precise diagnosis of cephalometric landmarks can be significantly improved through the implementation of automated detection techniques [11].

In the realm of orthodontics, the lack of medical imaging data presents an immense barrier. However, the imperative for collaboration between orthodontic professionals and skilled data scientists remains essential. The integration of specialized datasets and advanced techniques holds great potential in bridging the gap between deep learning algorithms and the intricacies of orthodontic imaging. The integration of advanced technologies in dental healthcare not only enhances the efficiency of diagnosis and treatment planning but also serves as a catalyst for innovation in the field [12].

Acknowledging the importance of automatic landmark detection, The ISBI, which stands for the International Symposium on Biomedical Imaging, has led the organization of a number of challenges related to the matter, namely in 2014 [13], in 2015 [14], and is set to continue its impact in the year of 2023 [15].

Over the past few decades, extensive research has been conducted on a multitude of automated techniques aimed at detecting landmarks. In first studies, Wang et al. [13] [14] spearheaded pioneering initiatives that involved the organization of public challenges. These challenges served as platforms to exhibit innovative algorithms that are at the forefront of scientific advancement. Researchers have successfully utilized random forests, a machine learning technique, to classify intensity appearance patterns with remarkable accuracy. Moreover, they have employed statistical shape analysis to gain insights into the complex spatial relationships among landmarks. This innovative approach has yielded impressive results, showcasing the potential of these cutting-edge techniques in various scientific domains.

In another study, Ibragimov and colleagues [16] have presented impressive findings by harnessing the power of Random Forest and Game Theoretic techniques. Researchers such as Chu et al. have successfully utilized tree-based methods in their studies. These methods include hierarchical random forest regression and binary pixel classification with randomized trees [17].

In same vein, Lee et al. and Arik et al. have made significant strides in the field of pixel classification by leveraging convolutional neural network (CNN) concepts. Their work has paved the way for the development of cutting-edge algorithms in this domain [18], [19]. Subsequent studies delved into the realm of deep learning, utilizing U-shaped deep convolutional neural network (CNN) structures to achieve accurate landmark estimation [20] [21].

Mehmet Ugurlu and Alshamrani Khalaf, two researchers, have achieved significant progress in the field of automated cephalometric landmark detection implementing an altered architecture known as the Feature Aggregation and Refinement Network (FAR Net) (Ugurlu, 2022) [22], and an Inception-based neural network layers [23].

In the upcoming chapter, we will conduct a thorough examination of the essential components of our research. This examination will comprehensively investigate the methodological framework that underpins our research. We will primarily concentrate on the specifics of our data gathering procedure, the methodology we have utilized, and the meticulous preparations undertaken for our training data.

IV. Materials

This chapter provides a comprehensive analysis of the complexities involved in our study technique. In the first stage of our study, we will provide a thorough examination of our data collection process, with a detailed explanation of the methods used and the sources of our data. The dataset is thoroughly documented, offering a strong foundation for our upcoming investigations.

After the comprehensive discussion on the process of data acquisition, we now delve into the intricate preparations that were meticulously carried out to enhance the quality of our dataset for the purpose of training. The methodology encompasses various essential components, such as preprocessing techniques, data cleansing methodologies, and necessary transformations implemented to guarantee the dataset's appropriateness for the intended research.

In the culmination of this chapter, we embark upon the fundamental essence of our investigation—the proposed methodology. In this article, we will explore the cutting-edge methodologies and techniques that underpin our research efforts. By the conclusion of this chapter, readers will have acquired a thorough comprehension of the meticulous procedures and approaches that form the foundation of our research methodology.

A. Data Acquisition

In a meticulous and all-encompassing investigation, a collection of lateral cephalograms was procured from a heterogeneous group consisting of 400 individuals. The subjects covered a wide age range, from 7 to 76 years, with an average age of 27.0 years. The sample comprised 235 females and 165 males, ensuring a balanced representation of both genders. The cutting-edge Soredex CRANEXr Excel Ceph machine, situated in Tuusula, Finland, was employed to capture all images in the TIFF format. These images were subsequently processed using the advanced Soredex SorCom software, specifically versions 3.1.5 and 2.0. The captured images exhibited an impressive resolution of 1935×2400 pixels, accompanied by a pixel spacing of 0.1mm, thereby guaranteeing an exceptional level of precision and meticulousness in capturing even the finest details [24]. The dataset utilized in this study, sourced from the ISBI 2015 challenge, consisted of distinct collections of data obtained from a total of 400 subjects. Each subject's data encompassed a lateral cephalogram, as well as two sets of landmark points that were meticulously plotted by skilled orthodontic specialists. Notably, both a junior and a senior specialist contributed to the manual plotting of these landmark points. Significantly, the average intra-observer variability for these specific landmarks was found to be 1.73 mm and 0.90 mm, respectively, indicating a high level of precision [19]. In the captured images, every individual pixel corresponded to a precise 0.1 mm square region. These pixels were characterized by grayscale values spanning from 0 to 255. In order to ensure a good training phase, a total of 150 images were subjected to augmentation techniques, the test1 set was merged to the training set, resulting in an increase to over 900 images. These augmented images were then carefully allocated for rigorous training purposes. Additionally, the remaining 100 images underwent meticulous testing. This comprehensive approach provided a robust assessment of the overall performance of the system. See the annotated image below in Fig. 1.

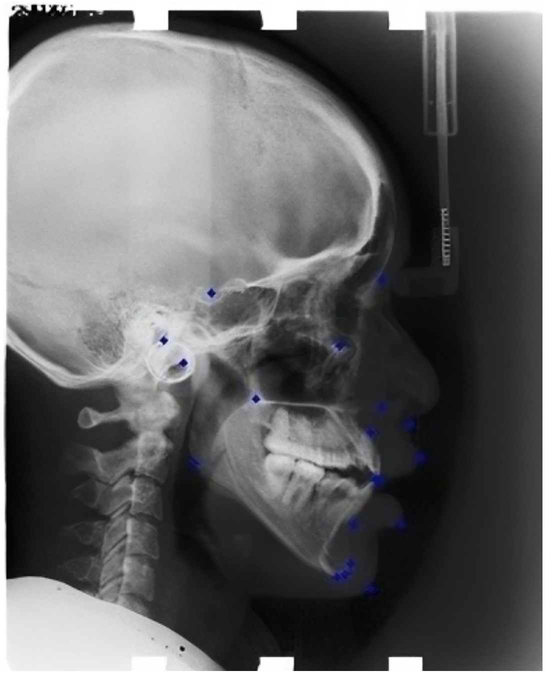

Fig. 1. Annotated image.

B. Data Preparation

In the pursuit of scientific inquiry, we diligently undertook a comprehensive analysis of the data preparation phase, breaking it down into various discrete stages. This approach diverged significantly from the methodologies employed in previous studies. In our study, we departed from traditional methodologies and instead, we embraced a simultaneous detecting approach across all data points.

The dataset being examined, as previously discussed, was burdened with limitations due to its size. In order to overcome these limitations, the incorporation of data augmentation techniques became crucial (Fig. 2). In our study, we have discovered that while mosaic augmentation possesses inherent advantages within the framework of YOLOv8, it unfortunately falls short in meeting our specific requirements. In pursuit of enhancing the dataset, our research endeavors prompted us to extract supplementary images from our preexisting repository of unprocessed visual data.

In the quest for enhancing data quality, we employed three pivotal techniques for augmentation. Color jittering has emerged as a powerful tool that is widely employed in the fields of computer vision and image processing. Through the intentional introduction of controlled randomness into the color attributes, our augmented dataset has successfully attained a heightened level of diversity, in term of saturation,contrast, brightness, and hue. The process of diversification has played a crucial role in enabling machine learning models to adapt and generalize effectively across a wide range of real-world situations. This adaptability is particularly evident in the models' ability to handle changes in lighting conditions and variations in color.

Furthermore, our study carefully utilized Gaussian noise, a fundamental augmentation technique deeply rooted in the fields of machine learning and computer vision. Through the careful manipulation of noise intensity and the introduction of stochastic perturbations into the input data, our augmentation methodology has successfully attained a remarkable level of precision. This includes the ability to accurately account for subtle differences in lighting conditions and address inaccuracies in sensor measurements.

Moreover, we used another technique on the experimental procedure, Random contrast, which involved the manipulation of image contrast through the expansion or compression of the range of pixel intensity values. The process of diversification played a crucial role in effectively addressing the challenge of analyzing images taken under different lighting conditions. By incorporating this approach, our model was able to successfully adapt to and manage the diverse levels of contrast encountered in various real-world situations. The implementation of random contrast adjustment has resulted in a notable improvement in the robustness of our model.

Another crucial aspect of our data preparation process was the transformation of labels. The recorded labels, originally in the form of coordinate dataframes, underwent a transformation to conform to the YOLO annotation format. The utilization of this particular format offers an additional advantage in the form of its inherent normalization feature. The successful outcome of this endeavor led to the smooth incorporation of our image data into the system, eliminating the necessity for additional adjustments such as resizing, scaling, or normalization procedures. The incorporation of this particular aspect has demonstrated itself to be a significant time-saving element within our data preparation procedure.

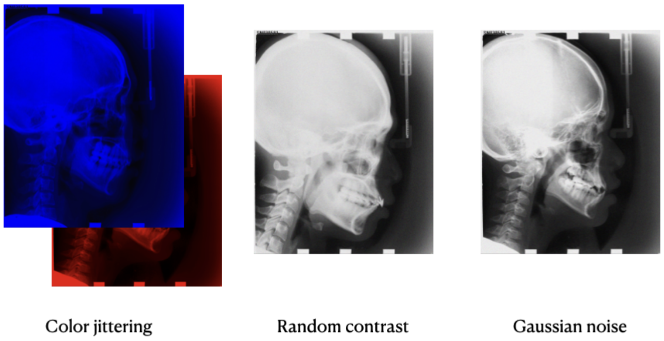

Fig. 2. Data augmentation.

V. Experimental Results

After establishing the underlying motivation behind our research and presenting a thorough summary of the existing literature in the field, we now proceed to explore the core aspects of our study. In this section, we introduce our proposed methodology that centers around leveraging the advanced functionalities of the most recent release of the state-of-the-art object detection algorithm, YOLOv8. Present the experiment's results, and conclude with a comparison with relevant findings from the previous studies.

A. The Proposed Approach

In our study, we adopted YOLOv8 as the base model, employing a meticulous approach to effectively tackle the complexities inherent in our research goals. The decision to utilize this particular choice was driven by its well-documented track record of high efficiency, exceptional accuracy, and remarkable adaptability. These qualities render it an optimal platform for conducting our scientific investigations. In the subsequent sections, we expound upon the intricate intricacies of our methodology, shedding light on the alterations, advancements, and refinements we incorporated to customize YOLOv8 for the precise challenges presented by our research inquiries.

Prior methods frequently employed sliding windows coupled with a classifier, necessitating hundreds or thousands of iterations per image, or employed more refined techniques that divided the task into two steps. The initial phase would identify prospective regions containing objects (referred to as "regions of interest"), and the subsequent phase would evaluate the presence of objects in these proposed regions using a classifier. Our model, only requires a single pass of the network to perform the detection task.

The structure of our model consists of multiple essential components, as illustrated in Fig. 3. The Conv block, also known as the beginning block, is composed of a conv2d layer, batch normalization, and a SiLu activation function. The parameters for this function include the input channels (c1), output channels (c2), kernel size (k), and stride (s). The following block, referred to as the c2f block, comprises Conv blocks in which the generated feature maps are distributed between the bottleneck block and the concat block. The parameters for this block consist of c1, c2, the quantity of shortcuts (n), and a boolean value indicating the utilization of shortcuts. The third block, known as the Spatial Pyramid Pooling Fast (SPPF) block, combines a Convolutional (Conv) block with three Max pooling layers. Significantly, every resultant feature map is merged together prior to the completion of the Spatial Pyramid Pooling Function (SPPF). The parameters accepted by this block include c1, c2, n, and a shortcut indicator. The last component, known as the Detect block, consists of many Conv blocks that have two separate tracks—one for bounding box data and another for class data. The combination of these blocks is detailed in Table I and visually depicted in Fig. 3.

In the field of deep learning research, much attention is typically given to the design of model architecture. However, it is imperative to recognize the significant impact that training procedures. The neural network model used in our study had 295 layers, with a total of 25,867,321 parameters and 25,867,305 gradients. We meticulously adjusted a set of hyperparameters in order to get optimal performance. Mosaic augmentation was activated, which introduced a dynamic element to the training data by merging numerous pictures. To optimize the process, we utilized the AdamW optimizer with a designated learning

rate of 0.000435, along with a momentum of 0.9. The training phase consisted of 60 epochs, with batches of size 20, which enhanced the overall resilience of the model.

After presenting a thorough clarification of the fundamental components of our methodology, our attention now shifts towards the results yielded by our endeavors. In the following sections, we shall now proceed to unveil the outcomes derived from the implementation of this particular methodology. The empirical evidence presented not only serves to confirm the strength and reliability of our methodology, but also provides valuable insights into the practical implications of our research in real-world scenarios. By conducting a meticulous examination and subsequent interpretation, we aim to elucidate the profound implications of these discoveries, effectively establishing a connection between theoretical knowledge and its real-world implementation.

B. Results

A distinctive feature of our research is the smooth integration of both unprocessed and meticulously enhanced data throughout the training stage of our YOLOv8 model. The combination of traditional imaging methods with augmented data has transformed the sector, presenting thrilling opportunities for enhanced precision and efficiency, ultimately resulting in notable progress in landmark detection. Our algorithm correctly recognized 19 anatomical landmarks on lateral cephalometric radiographs, proving its efficiency.

In order to assess the system's performance, we employed the Successful Detection Rate (SDR) score, a vital metric for quantifying its level of success. The SDR metric quantifies the accuracy of predicted landmarks by measuring the percentage of these landmarks that fall within a predetermined threshold distance from the ground truth.

Our system demonstrated exceptional performance in terms of average Successful Detection Rate (SDR) scores, operating within the specified range of 2 mm, 2.5 mm, and 3 mm. In the test set, the recorded scores were 86.31, 87.69, and 90.84, respectively. The findings show that the system's performance is consistently maintained throughout various settings, demonstrating its reliability and efficacy.

Through a rigorous examination of the data, a comprehensive analysis has unveiled captivating patterns that warrant further investigation. The 'S' point, scientifically referred to as Sella, the 'Po' point referring to the Pogonion, 'Gn' point and othres, has garnered significant attention due to the outstanding performance the model in prediction them in the threshold of 2mm.For other points, such as the lower lip, the precision of the model experienced a remarkable increase between the different thresholds, reaching a flawless 100.00 Successful Detection Rate within the specified thresholds of 2.5 mm and 3 mm, respectively. The Porion, A-point, and

Gonion point on the hand, have presented significant obstacles, according to the findings. The detection of these landmarks in lateral cephalometric radiographs has proven to be remarkably elusive, highlighting the complicated process of their identification (see Fig. 4 to 8).

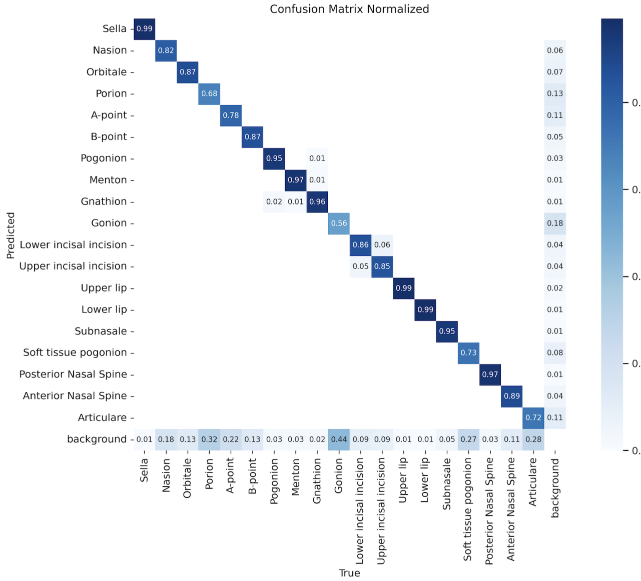

Fig. 4. Normalized confusion matrix for 2mm SDR.

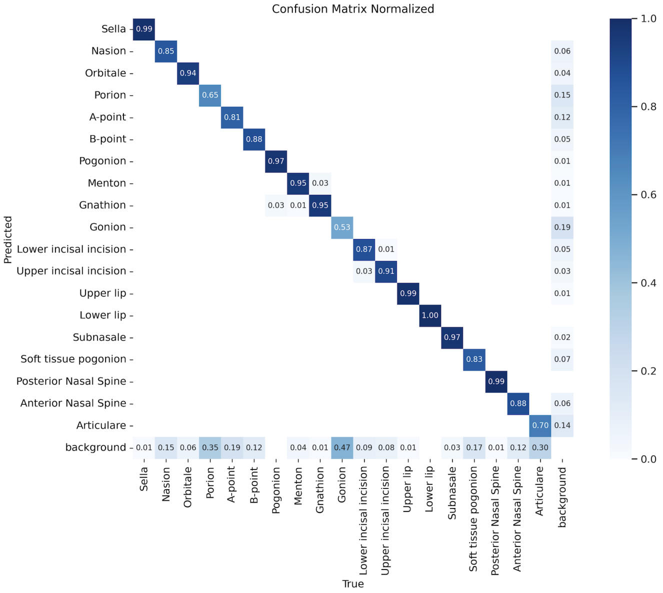

Fig. 5. Normalized confusion matrix for 2.5mm SDR.

To gain a comprehensive grasp of our findings and enhance our expertise, we did a meticulous study by meticulously comparing our results with those of previous studies that used the same dataset and followed the same data splitting techniques. The inclusion of a comparative analysis in our research has proven to be highly informative, as it has provided us with valuable context that allows us to assess the significance of our findings in relation to the existing body of knowledge (Table II, and Fig. 9).

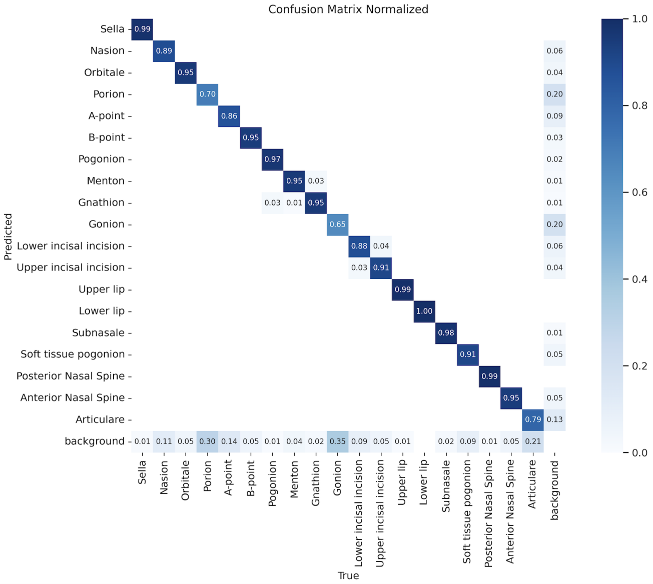

Fig. 6. Normalized confusion matrix for 3mm SDR.

TABLE II. COMPARISON OF RESULTS

	2mm	2.5mm	3mm
Ibragimov et al.[25]	62,74	70,47	76,53
Lindner et al. [26]	66,11	72,00	77,63
Arik et al.[19]	67,68	74,16	79,11
Qian et al. [27]	72,40	76,15	79,65
Oh et al. [28]	75,90	83,40	89,30
CephaX [29]	74,58	83,40	89,30
Our Model	86,31	87,69	90,84

After a thorough presentation of our findings and a meticulous examination of existing literature, our attention now turns towards a deeper exploration and analysis. In the forthcoming section, we embark on a more profound exploration of the complexities inherent in our discoveries. The primary objective of this discussion chapter is to provide a comprehensive context for our findings within the wider realm of established knowledge, elucidating the intricacies and ramifications of our research outcomes.

C. Discussion

The progressive assimilation of deep learning-driven artificial intelligence (AI) algorithms in the realm of medical image analysis has established a paradigm-shifting domain, particularly within the discipline of orthodontics. At the core of this metamorphosis lie cephalometric images, which serve as a crucial diagnostic instrument in assessing the complex interconnections among the mandible, maxilla, dentoalveolar structures, and in identifying dental and skeletal irregularities. The indisputable significance of cephalometric analysis in the field of orthodontics cannot be overstated. Nevertheless, it is imperative to acknowledge that this particular procedure is a complex and laborious undertaking, as its results are prone to fluctuations due to inherent variances in individual anatomical

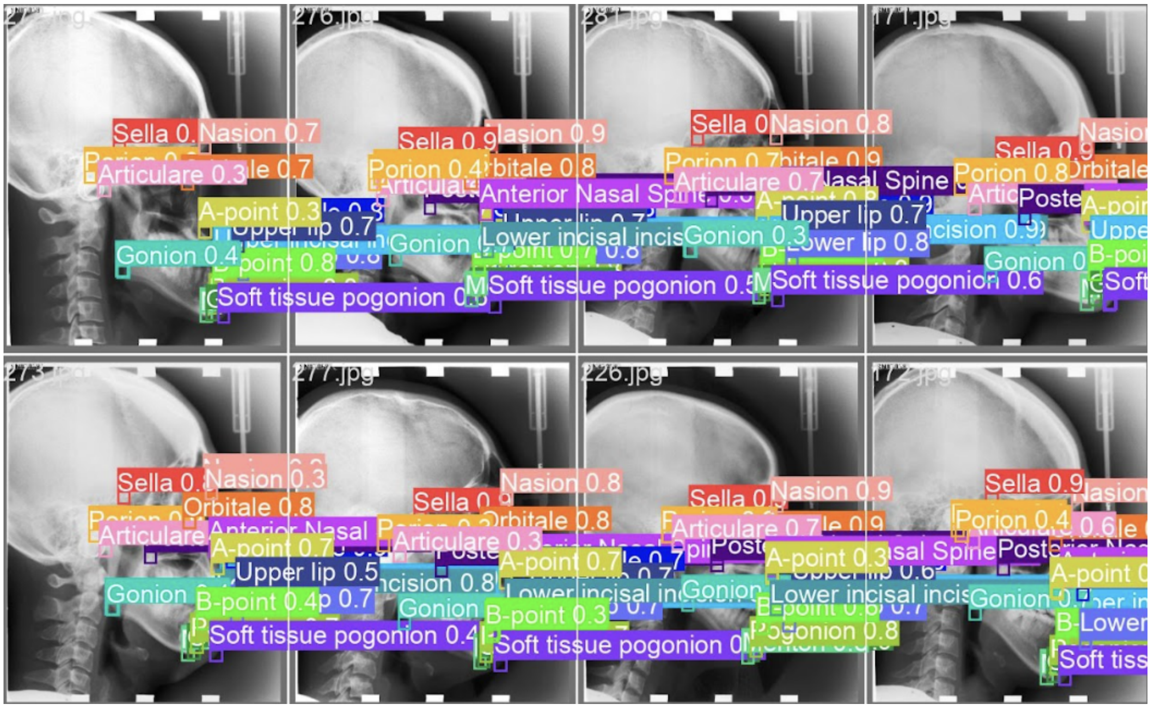

Fig. 7. Predicted batch sample.

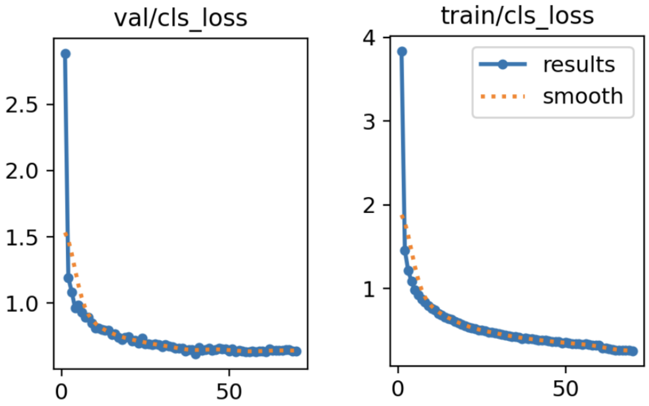

Fig. 8. Loss function.

structures.

The potential impact of AI algorithms in this particular context should not be underestimated. Numerous studies present in current scholarly literature provide substantial evidence supporting the effectiveness of diverse artificial intelligence (AI) techniques in facilitating and optimizing cephalometric analysis. The present study serves to augment the expanding reservoir of knowledge in this field. The YOLOv8 model exhibited varying levels of performance within the specified range of dimensions, specifically 2 mm, 2.5 mm, and 3 mm. Notably, the average SDR scores achieved were 86.31, 87.69, and 90.84, respectively. These results underscore the model's promising capabilities and aptitude in the given context.

Yet, a dive into literature and our observations indicate challenges in the automated detection of certain cephalometric landmarks. Specifically, points like A point, Go, Pg', and Or have traditionally posed challenges, often recording higher error rates or comparatively lower SDR scores. The Soft tissue pogonion point , as alluded to in [28], further exemplifies this challenge.

Notably, the A-point position being susceptible to variations based on head positioning, often complicates its precise tracing. This vulnerability of the A-point, corroborated by prior studies, underscores it as a landmark frequently marred by identification errors [5].

Notwithstanding the valuable insights provided by our research, it is imperative to duly recognize and address the limitations associated with our study. The images utilized in this study were obtained exclusively from a single source, ensuring consistency in terms of exposure parameters.

Furthermore, the labeling of these images was performed by an orthodontist, thereby ensuring accuracy and expertise in the categorization process. Moreover, it should be noted that the lack of external dataset validation and the restricted range of cephalometric landmarks examined could potentially impact the applicability of our results.

The story does not culminate at this juncture, as there exists an additional salient aspect necessitating a comprehensive examination. In the realm of orthodontics, the soft tissue paradigm [30] has ushered in a new era of comprehensive analysis, where the influence of facial soft tissue is taken into account in various jaw and tooth movements. Cephalometric studies encompass a range of soft tissue parameters, including but not limited to facial convexity, nasolabial angle, the positioning of the upper and lower lips, the mentolabial sulcus, as well as the positioning of the soft tissue chin and lower anterior face height [2].

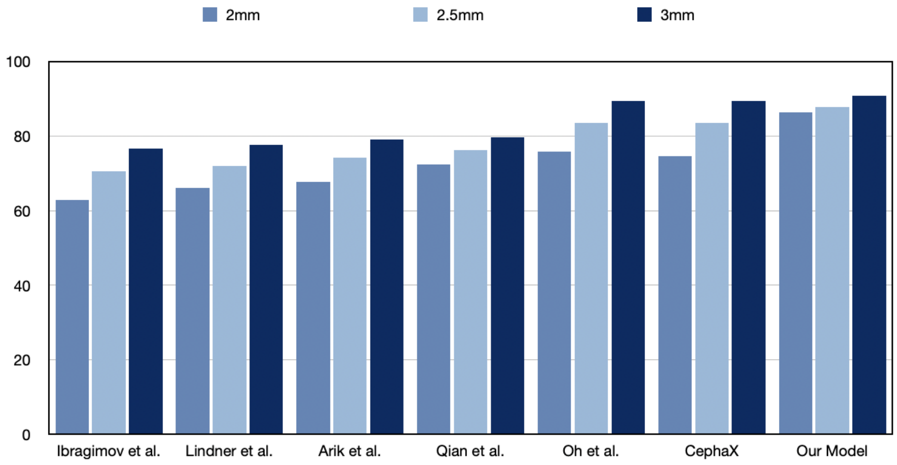

Fig. 9. Comparison of results.

The aforementioned characteristics are crucial in the field of orthodontics for making well-informed decisions on whether to pursue extraction or non-extraction treatment [31]. They play a crucial role in determining the degree of anterior teeth retraction, assessing growth changes, and evaluating surgical movements of the maxilla and mandible. In a recent investigation, it has come to light that the currently accessible datasets for soft tissue cephalometric analyses suffer from a notable limitation. These datasets only provide a small number of four soft tissue landmarks, making them insufficient for undertaking thorough analysis of soft tissue structures.

Soft tissue cephalometric analyses play a crucial role in various fields, including orthodontics, plastic surgery, and facial reconstruction. These analyses involve the examination and measurement of soft tissue landmarks to assess facial proportions, symmetry, and other relevant parameters. However, the limited number of soft tissue landmarks available in publicly accessible datasets severely hampers the accuracy and comprehensiveness of such analyses. The scarcity of soft tissue landmarks in these datasets poses a significant challenge for Furthermore, it is noteworthy that the existing datasets lack crucial occlusal landmarks, which play a pivotal role in the establishment of the occlusal plane. This plane holds significant implications in orthodontic diagnosis and treatment planning, as it has the potential to undergo alterations throughout the course of treatment. Consequently, a pressing demand arises for a novel dataset focused on cephalometric landmark detection. This dataset would efficiently address the current constraints and assist academics in developing sophisticated algorithms that might greatly improve cephalometric decision-making processes.

It is also worth noting that, Cephalometric analysis stands as a cornerstone in both orthodontics and orthopedics, relying on accurately identifying cephalometric landmarks. These landmarks are crucial reference points for a variety of measures and evaluations essential for diagnostic processes [32]. Steiner analysis and Tweed analysis are approaches that use several cephalometric landmarks to assess facial proportions, jaw connections, and dental inclinations. Dr. Tweed's research focused on the prognostic significance of landmark configurations [33]. Cephalometric study is useful not only for assessing dental parameters but also for evaluating upper airway dimensions and potential blockages. Precise recognition of landmarks is essential for assessing parameters like nasopharyngeal airway (NPA) depth and width, soft tissue thickness at various airway levels, and the relationship between the hyoid bone and the mandible, all of which impact airway openness and diagnostic precision.

VI. Conclusion

The integration of deep learning and artificial intelligence (AI) algorithms in medical image analysis, particularly in orthodontics, offers a promising approach to improve diagnostic precision and operational efficiency. The study examining the application of YOLOv8 for cephalometric landmark identification has strengthened the potential of these technical developments. The algorithm exhibited notable levels of accuracy within certain thresholds. However, it still faces persistent challenges, particularly in consistently detecting specific landmarks. Moreover, the variations in experimental procedures and inherent constraints of the study emphasize the need for wider and more varied testing environments.As the interaction between artificial intelligence (AI) and orthodontics becomes increasingly prominent, it is crucial for the technology and clinical sectors to work together to improve the effectiveness and usefulness of these technologies. Research such as ours is crucial in shaping the future of orthodontic diagnostics, which holds the potential for a harmonious integration of human expertise and technical proficiency.

A Robust License Plate Detection and Recognition Framework for Arabic Plates with Severe Tilt Angles

Khaled Hefnawy, Ahmed Lila, Elsayed Hemayed, Mohamed Elshenawy
Communication Department
Zewail City, Egypt

***Abstract*—This paper addresses the challenge of accurately detecting and recognizing Arabic license plates, particularly those subjected to severe tilt angles. It presents a robust license plate detection and recognition framework that consists three main steps: plate detection and segmentation, plate perspective correction, and vehicle number recognition. In the first step, a mask R-CNN model is used to detect the plate location, providing pixel-wise labels of identified plates' areas. Following this, a perspective correction technique is used to obtain a clear and rectangular image of each license plate in the image. Lastly, the framework employs a Bidirectional Long Short-Term Memory (Bi-LSTM) model for accurate vehicle number recognition. The framework's efficacy is demonstrated through its application to build a plate recognition system tailored for Egyptian license plates. The system was tested on a dataset collected from campus gate cameras at Zewail city of science and technology, achieving a character accuracy of 97%.**

Keywords*—*License plate detection; license plate recognition; feature extraction; Mask R-CNN; object detection

I. Introduction

The Automatic License Plate Recognition (ALPR) systems have become integral to modern transportation and smart city initiatives [1]. The rapid evolution of surveillance systems has increased the reliance on and demand for ALPR to analyze and process the extensive amounts of camera feeds generated daily. An efficient and reliable ALPR system is critical in many smart city applications including toll collection, safety monitoring, managing border crossings and parking management.

A typical ALPR system consists of three main stages: plate detection, character segmentation, and character recognition [2]. The process begins with plate detection, which locates the plate within the image. This is followed by character segmentation, which isolates each character or digit within the plate. Identified characters are then processed via a character recognition model that reads the plate number.

The incorporation of character segmentation and recognition in ALPR systems faces significant challenges when adapted to new environments [3]. Key challenges include different camera orientations, changes in illumination, and variations in image quality. For instance, models trained on license plates positioned directly in front struggle with footage from cameras mounted at high elevations or at acute angles to moving vehicles, significantly diminishing their recognition accuracy [4].

Furthermore, license plate designs vary across countries, with notable variations in size, language, color, and font. Accordingly, a one-size-fits-all system is impractical and there is a necessity for adaptable frameworks to guide the implementation and customization of these systems across diverse contexts [5].

Several recent research efforts have been proposed to address the above issues. Lin and Li [6] suggest the use of three-stage ALPR system that utilizes YOLOv2 for vehicle localization, in the first stage, and license plate localization, in the second stage. The final stage employs a mask R-CNN to detect each character in the plate. A similar approach is used in [5], where the authors suggest a three-stage system. The first stage employs Faster R-CNN to localize vehicles, followed by the use of morphological operations to localize license plates within the detected vehicles. The final stage utilizes a deep learning model for character recognition. Another approach [7], focused on license plate detection, uses a faster R-CNN for vehicle detection, morphological filtering for license plate detection. These efforts focus on recognition of non-Arabic plates.

Fewer research efforts have focused on Arabic plate recognition [8]. The nature of the Arabic characters, including its right-to-left writing system, complicate segmentation and recognition tasks. Additionally, model performance may be affected by environmental factors such as lighting conditions, plate obfuscation, and the presence of dust or damage on the plates. While using advanced deep learning techniques have shown promise in overcoming these challenges [9], most of the proposed techniques require extensive, diverse training datasets and careful tuning to build robust models. Further research is essential to enhance the robustness of Arabic license plate recognition systems.

This paper presents a robust framework for Arabic license plate detection and recognition. The framework is structured into three key steps. In the first step, the framework employs a Mask R-CNN model [10] for precise localization and segmentation of license plates. This is followed by a technique for perspective correction, ensuring each plate is presented in a clear and standardized rectangular format. Finally, the system incorporates a Bidirectional Long Short-Term Memory (Bi-LSTM) model, specifically employed to achieve accurate recognition of Arabic plate letters and numbers.

The system was trained using two datasets: the first dataset is a synthetic dataset, available on Kaggle [11], which consists of 5k of Arabic license plate images. The second dataset, which includes 2,712 real images from 300 unique cars, was gathered at a toll gate in Egypt. The dataset was originally created by Elnashar et al. [12]. We extended it by adding annotations of the license plate letters and numbers. The efficacy of the recognition was validated using a test dataset of real 140 images collected from cameras at the entrance of Zewail City of Science and Technology. The system achieved a character accuracy of 97%.

II. Related Work

As discussed earlier, the proposed framework has three main stages: license plate detection, perspective correction, and license plate recognition. This section reviews some prominent research efforts in license plate detection and recognition. In our review, we focus on Arabic license plate detection and recognition, as this is the scope of this work.

A. License Plate Detection

Traditional license plate detection methods have utilized image processing techniques, such as the Sobel edge detector [13] and the Hough transformation [14], to detect lines and edges in the given image, providing a way of identifying the license plate's boundaries. These methods, however, are prone to errors from noisy edges and complex images.

Plate texture is also used as a good detection indicator of the plate. Techniques such as Gabor filter [15] and Wavelet transform [16] have been used to detect the plate using its texture. Others used a decision tree with adaptive boosting on Haar-like characteristics [17]. This algorithm performed well in multiple camera orientations and lighting conditions. It achieved an accuracy of 94.5%.

Recently, deep learning techniques have been used extensively in license plate detection mechanisms. For instance, YOLOv3 was used to detect plates on multi-style Egyptian license plates [12]. This approach achieved 99.2% plated detection accuracy on the new standardized Egyptian license plates and 96.8% for the older versions of Egyptian plates. Another example is the detection algorithm in [18]. The algorithm uses a region-based convolutional neural network (R-CNN) to achieve dual objectives: plate detection and estimation of the four corners of the plates. Subsequently, the identified points were utilized to perform an affine transformation on the plates, correcting any tilt angles present.

B. License Plate Recognition

Automatic Arabic License Plate Recognition (AALPR) systems can be classified into two main approaches: segmentation-based approach [19] and segmentation-free approach [19] & [20]. The segmentation-based approach segments individual license plate characters and then detects each character using an OCR model. Elsaid, et al. [21] proposed a segmentation-based approach trained on Arabic and Indian numerals and Arabic alphabets on Saudi Arabian license plates. The proposed pipeline has five stages: license plate preprocessing, license plate localization, character segmentation, features extraction, and character recognition. It was tested on 470 license plates with different effects such as skewness and noise, achieving 96% segmentation accuracy and 94.7% recognition rate.

Antar et al. [22] proposed a method for detecting and recognizing vehicle license plates. A canny edge detector is used for the detection module, combined with other noise reduction techniques. The recognition module uses a masking technique to locate regions of interest in the license plate and applies a character recognition model to classify each region. The model achieved 96% accuracy for English and 92.4% accuracy for Arabic. Sarfraz et al. [13] performed character segmentation and normalization, then template matching with Arabic characters.

Shehata et al. [19] proposed four systems to recognize license plates. The first system is a segmentation-based approach and has three main modules: license plate extraction, character segmentation module, and character recognition module. The character recognition component employs a KNN classifier to assess the resemblance between the segmented characters and the reference characters stored as ground truth. The second system has the same modules as the first system but uses Deep CNN for feature extraction and Deep CNN for character recognition. The system was tested on 300 license plates and got 0.95 recall, 0.95 precision, and a character recognition accuracy of 0.99 which lead to license plate accuracy rate of 0.95.

The third system in Shehata et al.'s work is a segmentation-free approach. The model is based on two classical machine learning modules: license plate feature extraction and license plate recognition. The system was tested on 100 license plates and got 0.76 recall, 0.85 precision, and accuracy rate of 0.90. The fourth system is another free-segmentation approach with two deep learning modules: plate detection and plate recognition. The system was tested on 1000 license plates and got 0.89 recall, 0.91 precision, and accuracy rate of 0.93.

III. The License Plate Detection and Recognition Framework

As discussed earlier, the framework has three main stages: the plate detection and segmentation step, plate perspective correction, and plate recognition. A system implementing the proposed framework is shown in Fig. 1. The proposed system has four main components: the segmentation model, the corner estimation, the plate warping model, and the plate recognition model.

The first stage of the framework, plate detection and segmentation, is implemented via the license plate segmentation model shown in Fig. 1. The output of this model is pixel-wise segmentation of the detected plate, as indicated in the Figure. It should be noted that the model is trained to detect the plate directly without detecting the vehicle first.

The second stage, plate perspective correction, is implemented via the corner estimation and plate warping components. The segmented plate is passed through a series of operations to estimate the corner of the plate's rectangular area, namely edge detection, contour fitting, and contour fine-tuning. A homography transformation is then calculated and applied in the plate warping component to correct the plate perspective.

The corrected plate is passed to the recognition module in the last stage to get the recognized characters. The details

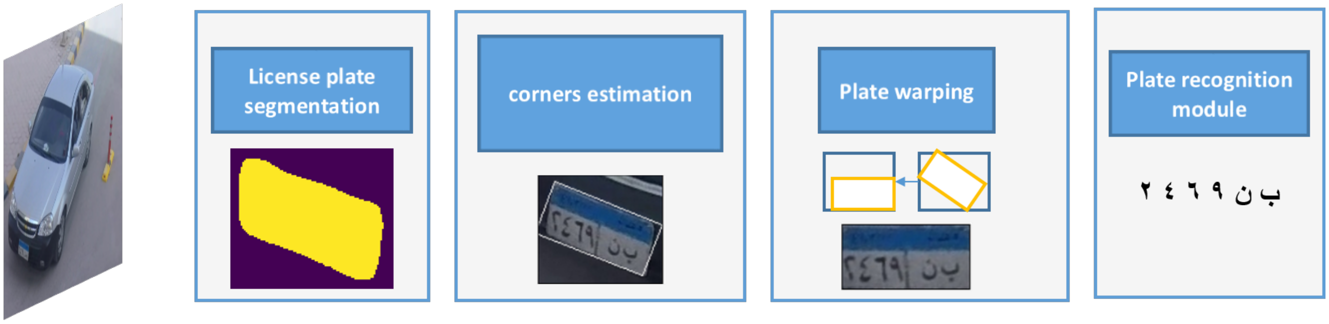

Fig. 1. System overview.

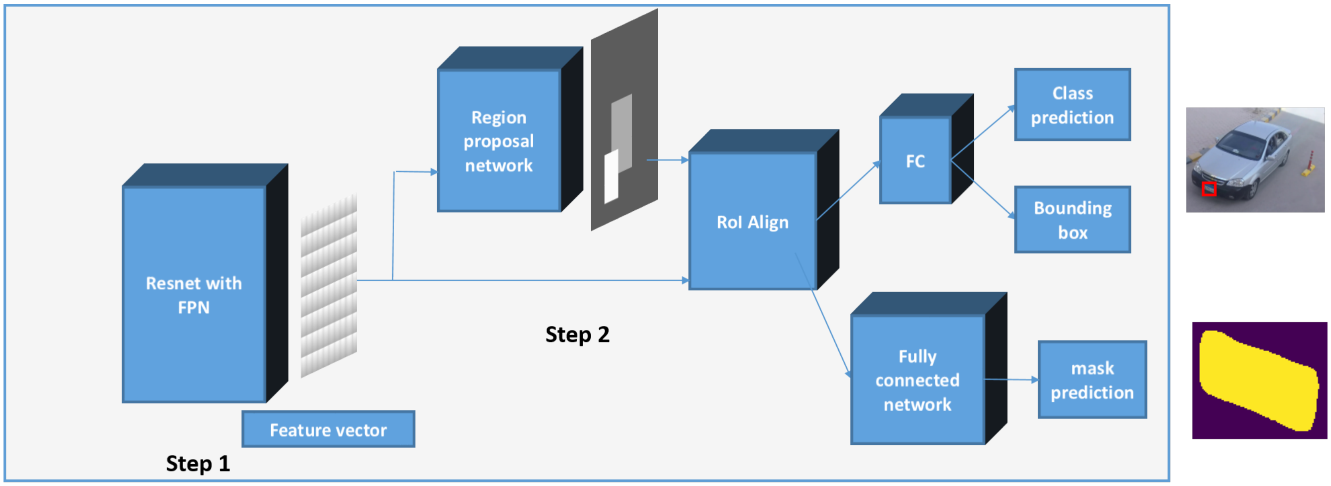

Fig. 2. Mask R-CNN.

about each model are discussed in the following subsections.

A. Plate Detection and Segmentation

We used Mask R-CNN [10] to detect the plate and its bounding box. Mask R-CNN is an extension for faster R-CNN [23] where a fully connected head is added to the faster R-CNN network to get additional output for the bounding boxes and classes. It gives a pixel-wise annotation for the image, which offers highly accurate labels. The segmentation enables us to get arbitrary shapes that describe precisely objects of interest. Mask R-CNN is shown in detail in Fig. 2.

Faster R-CNN is composed of two main parts. The first part proposes potential object bounding boxes using a region proposal network (RPN). In the second part, a region-of-interest (RoI) Pool layer extracts features for each potential bounding box, classifies it, and regresses its bounding box.

Feature extraction is done using ResNet [24] and Feature pyramid network (FPN) [25]. Features from ResNet are passed to RPN, which uses a sliding window to perform convolutions on different positions of the image using multiple anchors to detect the license plates. FPN passes different scales of the input image to the RPN. Using different scales of the input image makes the network more robust at detecting small license plates.

Mask R-CNN has the same structure as faster R-CNN, with the first part being the same (RPN). However, in the second part, a binary mask is formed parallel to class and bounding box predictions. This parallel computing simplified the training process greatly by combining multi-task loss and optimizing them concurrently on each potential object of interest. Multi-task loss is formed as shown in Eq. (1)

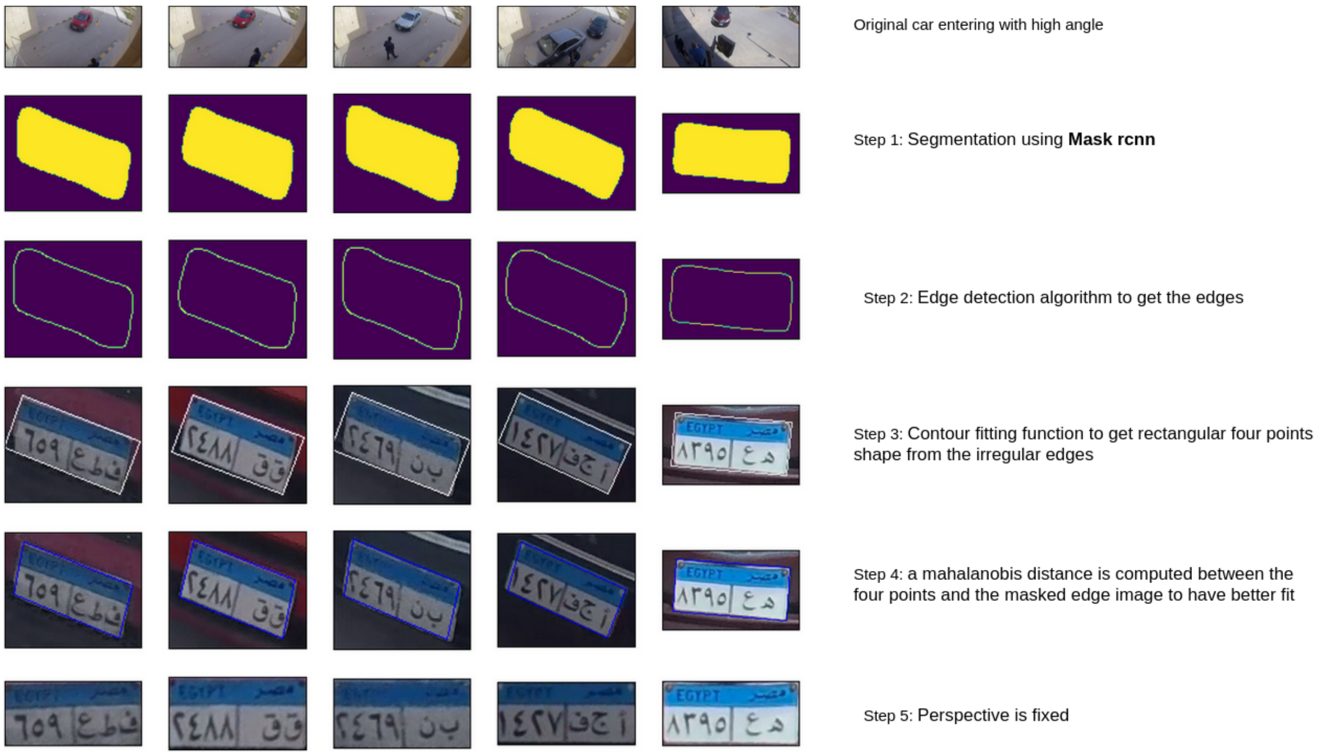
$$L = L_{cls} + L_{box} + L_{mask} \tag{1}$$

where L_{cls} & L_{box} are the classification and bounding-box loss, respectively, as defined in faster R-CNN. The mask network has dimensions of m^2 for each potential object of interest. For each pixel, a sigmoid activation function is computed. L_{mask} is computed by taking the mean of the cross entropy loss over all the pixels.

B. Corner Estimation

After the plate segmentation extraction step, we process the image to estimate the corners of the segmented plate image to be used in correcting the plate perspective as shown in Fig. 3. First, we apply edge detection to help get the minimum rotated bounding box. Then, we use a canny algorithm [26], which passes the images through multiple steps to find the edges.

To get the rotated bounding box coordinates, we use a rotating calipers algorithm [27] to find the minimum bounding box that fits the segmentation polygon output. The rotated



Original car entering with high angle
Step 1: Segmentation using **Mask rcnn**
Step 2: Edge detection algorithm to get the edges
Step 3: Contour fitting function to get rectangular four points shape from the irregular edges
Step 4: a mahalanobis distance is computed between the four points and the masked edge image to have better fit
Step 5: Perspective is fixed

Fig. 3. Perspective correction steps.

caliper algorithm starts with fitting a rectangle having one side aligned with the target polygon and a set of the polygon vertices. It updates the coincident edge and the vertices until it reaches the minimum fitting rotated bounding box efficiently in just O(n), where n is the number of polygon vertices.

C. Plate Warping

Due to the tilted angle of the camera, the detected plates do not have a rectangular shape, which affects the character recognition task. In this step, we fix the plate's perspective projection, improving the plate character recognition accuracy. The perspective transformation changes the viewpoint of the image, e.g., the angle, lengths, and geometry of the lines, but it keeps the collinearity of the points. Hence, we can correct the perspective of the plate by computing the transformation matrix needed to translate points from their actual view to the front-facing view. The transformation uses the actual viewpoints and the targeted points to get the matrix. This operation can be formulated using the transformation matrix in Eq. (2)

$$\begin{bmatrix} x^{'} \\ y^{'} \\ 1 \end{bmatrix} = \begin{bmatrix} a & b & e \\ c & d & f \\ g & h & 1 \end{bmatrix} \begin{bmatrix} x \\ y \\ 1 \end{bmatrix} \tag{2}$$

where constants a,b,c,d control rotation and scaling transformation, e,f control the translation vector, and g,h are the projection vectors.

We use the four input points (estimated corners) and their targeted location points (rectangular shape) to have eight equations that could be solved simultaneously to get the transformation constants.

D. Plate Character Recognition

Because of its excellent performance in different detection and recognition vision tasks, we initially trained and tested the YOLOv5 model for character recognition. However, the results could have been better after fine-tuning the model, as discussed in the experimental results section. Thus, we developed a new model for character recognition. The plate character recognition proposed module has two main steps: license plate feature extraction and character predictions. We will show the components of each module and how they are combined and trained at once to best solve the problem of limited datasets. We use a stack of CNN and RNN layers so that it can perform character-level inferences without the need for an explicit step for character segmentation.

License plate features extraction: Inspired by the VGG network [28], a CNN is used for character feature extraction. The ReLU activation function is used after each convolutional layer to add nonlinearity to the network. We used batch normalization for regularization. He initialization [29] was used to prevent the vanishing gradient problem and speed up the training process. The channel information was gradually reduced after each CNN layer using the maxPool layer to the required timesteps. Afterward, the feature extraction output is passed to the RNN layers using the Bi-directional LSTM.

Characters prediction: The developed model uses RNN to learn the sequential relations found in the license plates

combined with the CTC loss presented in Eq. (3).

$$\mathcal{L}_{CTC} = -\log p(\mathbf{y}|\mathbf{x}) = -\sum_{\mathbf{s}\in\mathcal{B}(\mathbf{y})} \log p(\mathbf{s}|\mathbf{x}) \tag{3}$$

where

- $\mathbf{y}$ is the target sequence, which is the ground truth license plate characters.
- $\mathcal{B}(\mathbf{y})$ is the set of all possible label sequences that can be derived. It includes all possible combinations of the target sequence with additional blank labels inserted between and after the characters, representing all possible alignments of the characters in the input sequence.
- $p(\mathbf{s}|\mathbf{x})$ is the probability of label sequence $\mathbf{s}$ given the input sequence $\mathbf{x}$, as computed by the CTC model. This probability is estimated by the neural network during training.
  The loss is computed as the negative log-likelihood of the target sequence, given the input sequence and the probabilities of all possible label sequences.

The whole network of the CNN and RNN is trained end to end using CTC loss. This takes care of extracting the implicit rules that are present in the license plates. For instance, the Egyptian license plate uses a structure in which, if the plate is read from left to right, the plate has four digits followed by three characters. By learning the sequence, the network can predict getting a digit in the first four values and characters in the last three.

Those learned rules direct the training of the feature extraction in the CNN layer. The whole network parameters are trained and optimized at once from the CTC loss. The loss is between labels, and targets are backpropagated to update all the parameters. Finally, a dense layer maps the output of the RNN network to the predicted category. We use the SoftMax function to obtain the probability of the correct character as shown in Fig. 4

The CTC loss function is used to decode sequential information to align plate characters in a segmentation-free way. This approach also has the advantage of not needing bounding box annotation for every character, simplifying the learning process. An annotator only needs to record the character of every license plate on a sheet.

CTC technique allows the training of sequence-to-sequence models, such as recurrent neural networks (RNNs), with variable-length inputs and outputs. It works by defining a set of possible alignments between the input and output sequences, called the “blank label” set, and computing the likelihood of each alignment given the input sequence.

In terms of time steps, CTC works as follows:

1) At each timestep, the RNN generates a probability distribution over all possible labels, including a special “blank” label.
2) For each possible label sequence, the CTC algorithm computes the probability of that sequence given the input sequence.
3) The CTC algorithm then sums the probabilities of all possible label sequences that can be derived from the target sequence by inserting, deleting, or repeating the blank label.
4) The CTC loss function is defined as the negative log-likelihood of the target sequence given the input sequence and the probabilities of all possible label sequences.

5) During training, the RNN's parameters are updated to minimize the CTC loss.
6) In the decoding stage, the probabilities generated by the RNN are used to find the most likely label sequence. In summary, CTC works by defining a set of possible alignments between the input and output sequences, computing the likelihood of each alignment given the input sequence and minimizing the negative log-likelihood of the target sequence.

The training dataset is fed to the model with a batch size of 256 images. We used the Adam optimizer for faster convergence and better performance using gradient descent and momentum optimization.

IV. Experimental Result

This section discusses the experimental results, starting with a description of the datasets used in the training and testing of the developed models.

A. Datasets

Accurate datasets are necessary for training ALPR deep learning models. There are different aspects to be considered in the ALPR datasets, including environment-related aspects such as illuminations and background; camera point-of-view-related aspects such as the pose of the camera (frontal or upper view), rotation and skew Coefficients; and plate-related aspects such as color distribution, location of the plate with respect to the car, language and font styles.

Multiple datasets have been used in this research to improve the system's overall accuracy. These datasets are 1) the Macathon competition dataset on kaggle [11], 2) the toll dataset [12] and 3) a proprietary dataset collected from CCTV cameras on campus. Table I summarizes the distributions of each dataset.

TABLE I. Datasets Summary

	Datasets		
	Synthetic	Toll	University
Year	2022	2022	2022
number of images	7k	2k	140
LP size	376 x 172	68 x 32	100 x 50
LP angle	Frontal	frontal	Oblique

1) Kaggle macathon competition dataset: The Machathon competition dataset comprises synthetically modified 5k images of Arabic license plates. This dataset has annotations for the plate's characters, including characters' bounding boxes. The images are generated with a high resolution that isn't realistic in real-life scenarios. Samples of the dataset are shown in Fig. 5, and the distribution of the characters is shown in Fig. 6. The distribution indicates that the classes are unbalanced and digits are more common than letters.

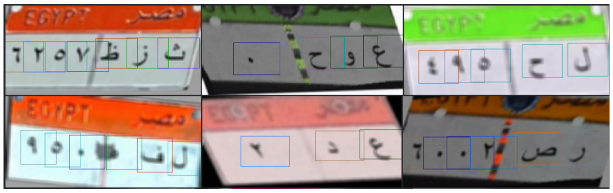

Fig. 5. Macathon competition dataset samples.

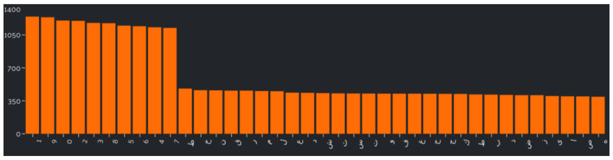

Fig. 6. Macathon competition dataset character distribution.

After inspection of the character bounding boxes, it was noticed that some bounding boxes may cover more than one character, which causes problems if used without correction. As such, we used a bounding box correction process, summarized visually in Fig. 7, to improve the dataset's quality. First, each bounding box is extracted from the image. A fixed constant, decided experimentally, is removed from each margin so the bounding box encloses only one character. Secondly, a K-means segmentation is used to extract three clusters in each bounding box. The bounding box around the largest cluster is considered the corrected bounding box. Finally, annotations are fixed manually to account for errors that could occur due to noise. Samples of the corrected annotations are shown in Fig. 8.

2) Toll dataset: The toll dataset [12], includes real images collected at a toll gate in Egypt. Fig. 9 displays samples from the toll dataset. An imbalance is observed in the toll dataset, as demonstrated in the character distribution in Fig. 10.

The car images are taken from a frontal view camera facing the entering cars, which means the dataset does not present the tilted angle challenge addressed in this paper. The dataset contains 2712 images, corresponding to 300 unique cars, with the license plate at varying proximities from the camera and in different qualities. For the purpose of character recognition, all images were manually labeled with the correct characters and digits shown on the license plate.

3) The Arabic License Plate Recognition (ALPR) Dataset: The Arabic License Plate Recognition (ALPR) dataset consists of two hours of videos captured from two gate cameras at the entry and exit gates of campus. This dataset consists of 140 images that the model has not seen. Samples of this dataset are shown in Fig. 11. As seen in the figure, the dataset is challenging. Due to the pose and height of the camera, all plates are tilted. Some plates have different illuminations, and others are distorted.

After automatic fix and manual correction of remaining mistakes

Fig. 8. Synthetic dataset before and after corrections.

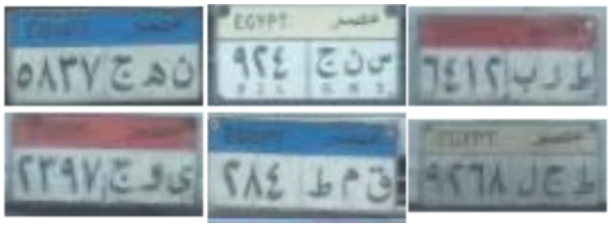

Fig. 9. Sample of the toll dataset.

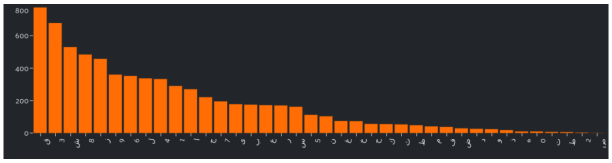

Fig. 10. Toll dataset character distribution.

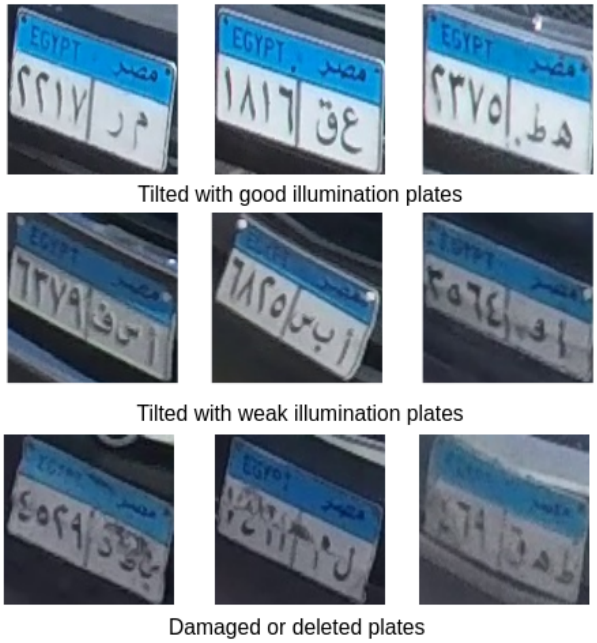
To enrich the dataset for the character recognition task, an augmentation process was used to increase the dataset 10 times. Plate images were resized to dimensions of 32 pixels in height and 128 pixels in width. Experiments were conducted with different kinds of augmentations, such as random brightness, contrast, image quality, and saturation. Additionally, the recommended YOLOv5 augmentations were used, which include HSV color space augmentation, Letterbox, Mixup, and Random perspective.

B. Results

The plate recognition mechanism was trained on the Kaggle Machathon competition dataset. The dataset was split into three sets for training, validation, and testing. The training dataset was used to extract the patterns of the letters. The validation dataset was used to choose the right parameters of the neural network. Finally, the testing dataset was used to provide unbiased accuracy results. The recognition is tested using two models YOLOv5 and the VGG network supported



Tilted with good illumination plates

Tilted with weak illumination plates

Damaged or deleted plates

Fig. 11. Samples of the ALPR testing dataset and its challenges.

by bidirectional LSTM layers. Table II shows the results when these models were applied to the validation dataset.

Three metrics are used to evaluate the plate recognition model:

1) character accuracy: This metric represents how many characters were recalled correctly
2) Identical 0: This metric represents how many plates were identified completely correctly
3) Identical 1: This metric represents how many plates were identified with a one-character error

TABLE II. Character Recognition Accuracy for the Validation Dataset

Model	Character Accuracy	I0	I0+I1
Yolov5	96.89%	86.43%	98.12%
VGG11 - BI LSTM	99.54%	97.9%	100%

Then, both models were tested on the Campus dataset. Table III shows the accuracy of both models.

TABLE III. Character Recognition Accuracy for the Testing Dataset from the Campus

Model	Character Accuracy	I0	I0+I1
VGG11 - BI LSTM using CTC loss	82.29%	27.9%	67.9%
VGG11 - BI LSTM more training data	94%	73.5%	92.1%
VGG11 - BI LSTM fine-tuned on annotated toll dataset	97%	86%	96.4%

As seen from the table, VGG using bidirectional LSTM surpasses YOLOv5. The list below discusses the performance of the two models.

1) VGG was more accurate than YOLOv5 in mapping the relationship between letters.
   a) There is some correlation between two letters that should appear together in a certain province or area
   b) There is some correlation between letters and digits, meaning that if two or a maximum of three letters appear, the coming characters are sure to be digits. VGG can map this very well, while YOLOv5 makes mistakes in this. For example, the number 4 in Arabic may be misrecognized by letter ع .
2) YOLOv5 requires a lot of data to generalize well on unseen data
3) These results are satisfactory considering the limited availability of training data. The accuracy is expected to increase as the model works and collects more data. For the time being, accuracy can be improved by using a voting mechanism for the recognition results of several images of the same plate. Three stages were shown in training VGG network; the last stage with most data showed the best results on the test set.

Fig. 12 shows a sample of the mistakes encountered when using YOLOv5 but were correctly handled by the VGG. In this case, the number 4 is misrecognized by غ or ع. Fig. 13 shows two plates that were recognized entirely by VGG, but only two letters were recognized when using YOLOv5.

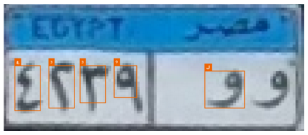


Fig. 12. Some samples not detected by YOLOv5 but were correctly detected by VGG.

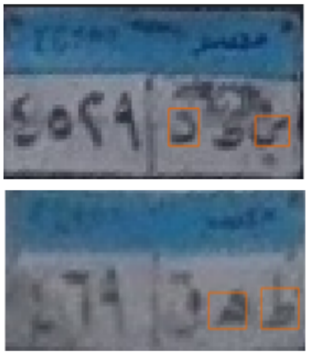

Fig. 13. Challenging samples that were correctly recognized by VGG but not YOLOv5.
Bounding boxes represents the detection of YOLOv5.

V. Conclusion

This study has demonstrated that algorithms with inherent automatic rules extraction, combined with effective preprocessing, outperform deep learning methods for license plate recognition when working with limitations in both the number of instances and the size of images. The results indicate the importance of preprocessing and the potential of automatic context-understanding approaches in applications where data are limited or expensive to obtain. By continuing to refine the methodology and expand the dataset, the aim is to further improve the accuracy and efficiency of license plate recognition systems.

VI. Future Work

In future work, the plan is to further enhance the license plate recognition system by increasing the dataset size, which is expected to improve the model's performance. Additionally, integrating an annotation tool into the system will facilitate the creation and management of annotated data, streamlining the training process for the models. These improvements will help better understand the impact of larger datasets and more sophisticated preprocessing techniques on license plate recognition accuracy. It will also provide the ability to train more deep models that can ingest large datasets.

VII. Acknowledgment

We would like to express our appreciation for the funding provided by the Science, Technology and Innovation Funding Authority (STDF) in Zewail City, which was crucial for the success of this project.

***Abstract*—Images captured under low lighting frequently exhibit low brightness, low contrast, and a small grayscale. These features can affect the individual's view and severely limit the performance of machine vision systems, particularly when data annotation is involved. Hence, the issues motivate this study to examine the effectiveness of advanced fuzzified histogram equalization for image enhancement. A comparative study was conducted based on the low lighting condition of iris images to evaluate three image enhancement methods: Advanced Fuzzified Histogram Equalization (AFHE), Contrast Limited Adaptive Histogram Equalization (CLAHE), and Fuzzy Contrast Enhancement (FCE) using the MIREIS dataset. The Gaussian membership functions (GMF) were modified accordingly to satisfy the suitable pixel intensity of the input iris images. The results were compared using the peak signal-to-noise ratio (PSNR) value, including the central processing unit (CPU) times. As a result, the AFHE showed a better PSNR value at 76.02db with faster CPU times at 4.04s compared to CLAHE and FCE. Although the PSNR value of HE is slightly lower than CLAHE (0.3%) and FCE (0.7%), AFHE improved the image's quality and brightness, which can help other researchers with the data annotation process. The performance of the proposed methods was validated by comparing them with state-of-the-art methods. The results demonstrated that AFHE, CLAHE, and FCE exceeded other HE, AHE, CLAHE, and hybrid HE using fuzzy approaches that employed PSNR metrics.**

***Keywords*—Image enhancement; fuzzy logic; histogram equalization; CLAHE; iris recognition**

I. Introduction

The quality of the images significantly influences the effectiveness of an iris recognition system. As such, it is crucial to enhance the image quality, especially when dealing with images captured in non-cooperative environments. The non-cooperative environment images provide low-quality data due to the rigidity condition during data acquisition [1]. The near-infrared illumination needed for iris recognition systems that allow for user identification additionally involves the users' cooperation to obtain a good-quality iris image, as these devices are not user-friendly [2]. These requirements impose an extra responsibility on the user to actively engage in the recognition process.

Current studies focus on detecting the iris when an iris image is acquired under varying lighting conditions and at a long distance. Poor quality images, mainly low lighting, reflection, occlusion, off-angle, and motion blur can further decrease iris pattern performance [3]. Nevertheless, when the distance between the iris and the device increases, the quality of the iris image decreases, and more illumination is necessary. Employing a visible light camera does not necessitate further illumination because the captured images present color data [4]. Iris recognition functionality can be integrated into an existing device or reduced to comply with these features.

A study has been conducted using a database comprising iris images captured at 4 to 8 meters with a high-resolution visible camera. The database includes low lighting, rotation, motion blur, and off-angle [5]. Another database contains an iris with face images captured with a visible light camera integrated into mobile devices [6]. The following processes must be followed to improve the quality of iris images: acquisition, enhancement, segmentation, feature extraction, and recognition. Image enhancement refers to converting the image intensity to create a new image and enhance the image quality. The key objectives of image enhancement are improving contrast, adjusting brightness, sharpening, color restoration, and noise reduction.

Various studies have proposed new enhancement methods based on histogram equalization (HE) [7], [8], [9], [10], [11]. By increasing the image's contrast through histogram stretching, HE can enhance the image's visual appeal [12]. The gray grouping approach underpins histogram stretching, which can be utilized for low-contrast and brightness images. It offers several benefits, including the fact that it is both simple and highly effective. While iris image enhancement technologies are generally efficient [13], they can lead to over-enhancing of the image if there is a prominent peak in the histogram [14]. In addition, HE tends to adjust the image's average brightness to the dynamic range's midpoint. This limitation renders the HE impractical in multiple technological applications.

This study is motivated by the crucial need for high-quality images in iris recognition systems, especially in challenging environments where image quality can be affected by factors like low lighting, reflections, occlusion, off-angle capture, and motion blur. Current methods frequently encounter challenges in retaining performance in these conditions, requiring the development of image enhancement methods to tackle these issues. While previous studies have investigated image enhancement methods such as HE, limitations such as over-enhancement and impractical brightness adjustments emphasize further investigation into more effective image enhancement methods for iris recognition systems.

The paper is structured as follows: Section II discusses the state-of-the-art image enhancement for iris recognition, and Section III presents a comprehensive explanation of the fuzzification process of advanced fuzzified histogram equalization (AFHE), contrast limited adaptive histogram equalization (CLAHE), and Fuzzy contrast enhancement (FCE). Section IV provides the experimental data and analysis, while Section V concludes this paper.

II. Related Works

Previous studies on iris image enhancement used images acquired from low lighting and NIR illumination to tackle image over-enhancing and brightness problems. A study in [12] employed HE to improve the visibility of iris images captured under low lighting conditions, aiming to determine the borders of the pupil area. This approach accomplished redistributing pixel intensities. Hence, the darkly pigmented iris reduced the HE outcome due to the low contrast ratio between the iris and pupil.

Maheshan et al. [15] employed HE and CLAHE methods for analyzing fuzzy sclera. In this study, HE aims to find the frequency of dark colors, which typically covers a range of zero to fifty pixels. Conversely, the CLAHE establishes a limit on contrast that provides a proportional adjustment of white balance for the image. Hassan et al. [1] conducted a comprehensive study on HE, CLAHE, and HE for iris images at varied distances and in visible wavelength illuminations. The study aims to improve iris segmentation and recognition performances.

A study in [16] introduced the CLAHE approach to enhance the performance of iris recognition in low contrast or low illumination conditions. It is an improved version of the adaptive histogram equalization (AHE) method initially developed by Zuiderveld [17]. This technique reduces potential noises in the image while enhancing contrast in grayscale images. A study in [18] presented an image enhancement method using HE to increase the quality of iris images for rubeosis iridis disease. The processes were divided into three image groups: low, medium, and high. The best results for the low contrast group enhanced by 50%; however, it can be reduced by 50% in the high contrast group.

An advanced recognition system in [19] proposed a Convolutional Neural Network (CNN) with HE and CLAHE to efficiently enhance and detect COVID-19 diseases in chest X-ray images. AlKhalid in [20] proposed the same model; CNN combined with HE and CLAHE using COVID-19 chest X-ray images for data expansion, transformation, and enhancement. Two layers of HE are applied to seven layers of data transformation; however, the study begins with a conceptual hashing algorithm to eliminate duplicate images. A study in [21] introduced CNN with HE and CLAHE to produce high-contrast tooth X-ray images. The proposed method created high-intensity data to visualize the tooth features, including the infection, inflammation, and nerve.

In study [22], Xiong et al. proposed a chaotic Pareto sparrow search algorithm (CPSSA) with CLAHE for iris augmentation. The CPSSA algorithm utilizes population-based iteration to search for specific clipping thresholds that meet the specified criteria, resulting in CLAHE generating a collection of iris images. A study in [23] applied HE and AHE to compare with Canny edge detection. The AHE aims to determine the iris patterns with high-contrast images. The Canny edge detection combined with HE produced a sharper, more structured image with less noise. On the other hand, the Canny edge detection method with AHE introduced more noise in the final images. However, these images exhibit more robust features than those obtained using conventional HE.

The enhancement method proposed by Chang et al. [24] eliminates the specular reflections from the iris image by applying the preprocessing method to the input image in three stages. The initial phase was applying the Gaussian filter method with a sigma value of 0.9. The second stage involved converting the ocular images from grayscale to binary using a threshold value of 0.18. Finally, the binary iris image was exposed to a Gaussian filter with a sigma value of 2, followed by a median filter to enhance the image's smoothness.

A study in [25] utilized fuzzy membership weighted functions to analyze image pixel values. With a triangle function, the fuzzy average and fuzzy median filters outperform the other four fuzzy filters in terms of filtering performance. Without using deep learning, these fuzzy techniques were employed to improve images. For instance, a one-pixel attack on an image can significantly change the prediction's outcome [26]. The resilience of neural networks can be enhanced by utilizing the fuzzified image enhancement in deep learning.

Orujov et al. [27] developed a contour detection algorithm using Mamdani (Type-2) fuzzy rules for blood vessel detection in retinal fundus images. It utilizes green channel data, Contrast-Limited Adaptive Histogram Equalization (CLAHE), and a median filter for background exclusion. The method achieved accuracies of 0.865, 0.939, and 0.950 on STARE, DRIVE, and ChaseDB datasets, respectively, demonstrating flexibility and comparable performance to existing methods, with potential for dynamic rule formulation in image processing systems.

Another study in [28] applied fuzzy average, fuzzy median, and Gaussian filters to preprocess iris images that had reflections on glasses and were occluded by eyelids and eyelashes. This preprocessing aimed to improve the out-of-bounds areas, enhance the noise ratios, and sharpen the edges of the iris images. However, the success rate remained poor, prompting the employment of morphological operations and other alternative preprocessing approaches.

This study proposed advanced fuzzified histogram equalization (AFHE) based on the modified Gaussian member functions to enhance the quality of low-lighting iris images, facilitating the data annotation process. The quality assessment of low-lighting iris images is evaluated based on the Peak Signal-to-Noise Ratio (PSNR) while optimizing the central processing unit (CPU) time. The proposed methods were compared with state-of-the-art methods to benchmark and validate the performance.

III. Materials and Method

This section discusses the materials used to implement the image enhancement methods. Fig. 1 illustrates the enhancement process that begins with data collection for iris images. The original image retains its dimensions without performing image resizing. The iris images are subjected to the image enhancement methods AFHE, CLAHE, and FCE, with equal distribution of intensities. Finally, the iris images are trained to achieve the PSNR values based on the implemented methods.

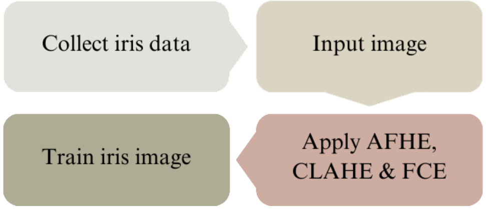

Fig. 1. Image enhancement system flow for AFHE, CLAHE, and FCE.

A. Dataset

This study employs 24 iris images from the Mobile Iris-Eye Computer Vision (MIREIS) dataset to test the image enhancement techniques for low lighting conditions as presented in Fig. 2. The iris images were captured using an iPhone 13 in early 2023 at the Universiti Teknologi Malaysia, Kuala Lumpur. The dataset focuses on the iris occlusions, motion blur, reflection, visible illuminations, and low-lighting conditions. Therefore, it is available for only several images in low-lighting conditions. The iris images are in standard exposure and RGB color space with the dimension of 2316 × 3088.

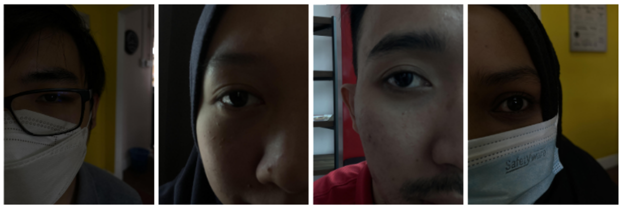

Fig. 2. Sample iris images from MIREIS dataset.

B. Fuzzification

Image enhancement with fuzzification involves the transformation of gray-level intensities of an image onto a fuzzy plane using membership functions. In addition to mapping the fuzzy plane back to the grayscale intensities of the images, the membership functions are changed to improve contrast. Increasing the weight of the gray levels closest to the image's mean gray level over those further from it aims to produce an image with higher contrast than the original.

Theoretically, fuzzy set theory provides a fresh perspective on image interpretation. An image with dimensions of size pixels and L distinct gray levels may be conceptualized as an array of fuzzy singletons. Each singleton represents a pixel, and its membership value indicates its brightness relative to a set of brightness levels, $I = 0, 1, 2, \dots L-1$ [29]. Eq. (1) presents the fuzzy theory utilized in image enhancement, where I_{xy} denotes the pixel intensity, (x, y), while μ_{xy} denotes its corresponding membership value.

$$FT = \bigcup_{x=1}^{X}\bigcup_{y=1}^{Y}\frac{\mu_{xy}}{I_{xy}} with \mu_{xy} \subseteq [0,1] \tag{1}$$

The three phases of fuzzy image processing are membership functions, fuzzification, fuzzy inference system, and defuzzification. Fuzzification involves providing an image with one or more membership values based on intriguing features, such as sharpening, edginess, brightness, and similarity. Following the image transformation into fuzzification, the membership values are modified using an appropriate fuzzy method.

Defuzzification signifies a retransformation of the membership values into the gray-level plane. The grayscale levels must be blurred for the image histogram's location to handle grayscale uncertainty. It indicates that each gray level is given a certain degree of membership based on where it falls on the histogram. High membership values are generally given to bright pixels, and low membership values are assigned to black pixels.

C. Defuzzification

Contrary to fuzzification, image defuzzification converts a fuzzy image back into crisp values. The inverse transformation in Eq. (2) is calculated to produce the enhanced image, $I'(x, y)$, where T' represents the original inverse transformation, T, while $I'(x, y)$, represents the gray-level of the enhanced image.

$$I'(x,y) = T'(I(x,y)) = (\bigcup_{x=1}^{X}\bigcup_{y=1}^{Y} I(x,y) \times (L-1) \tag{2}$$

D. Fuzzy Inference System

The fuzzy inference system comprises an expert's knowledge base, consisting of IF-THEN rules. The compositional rule establishes the mapping between fuzzy inputs and outputs, as presented in Fig. 3. The rules set in the proposed algorithms are as follows,

1) IF input is Very Dark THEN output is Extremely Dark
2) IF input is Dark THEN output is Very Dark
3) IF input is Slightly Dark THEN output is Dark
4) IF input is Slightly Bright THEN output is Bright
5) IF input is Bright THEN output is Very Bright
6) IF input is Very Bright THEN output is Extremely Bright

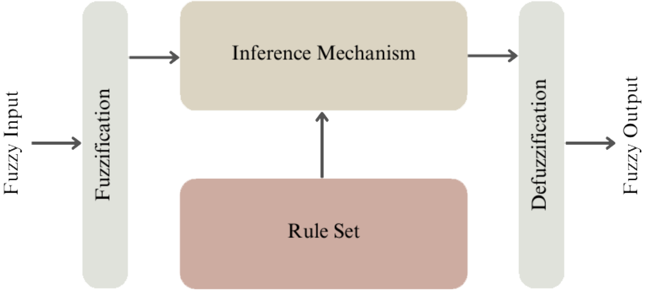

Fig. 3. The fuzzy inference system for this study.

This study involves eight rules for iris image enhancement, such as Extremely Dark (ED), Very Dark (VD), Dark (Da), Slightly Dark (SD), Slightly Bright (SB), Bright (Br), Very

Bright (VB), and Extremely Bright (EB). Fig. 4 illustrates the gray levels space derived from the membership functions for iris image enhancement. The rules are developed using the fuzzy sets specified in the gray levels ranging from [-50, 305] to [0, 255].

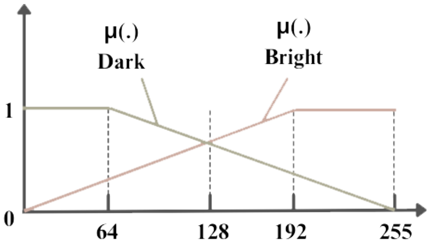

Fig. 4. The gray levels space based on the fuzzy sets.

E. Modified Gaussian Membership Functions

GMF comprises fuzzification, rule-based enhancement, and defuzzification. GMF quantifies the level to which pixel intensities belong to different iris regions. It transforms the initial data into a Gaussian distribution. The membership decreases as input values move further from the midpoint in positive and negative directions. The midpoint of the normal distribution, which is assigned to one, offers an optimal condition for the set.

Membership in the set decreases for input values, beginning at the midpoint and continuing until it diverges significantly from the optimal condition. At this point, it is deemed outside the set and is assigned zeros. The GMF can be computed in Eq. (3), where x is the input value of the GMF for set A, σ is the standard deviation, and c denotes the mean of the Gaussian function.

$$\mu_A(x;\sigma,c) = \exp\frac{-(x-c)^2}{2\sigma^2} \tag{3}$$

Following the fuzzification process, each intensity level, A, is assigned a corresponding fuzzy membership value $\mu(A)$ in the image. The attribute, such as bright or dark, is correlated with the intensity. The modification of GMF involves fine-tuning the fuzzy membership values assigned to each intensity level in the image. This modification enhances the image by increasing lighting on specific elements.

A function, $f(\mu(A))$, is selected to modify the membership values. This function varies according to the type of enhancement required. The modification function is applied to an individual's membership value. The modified value of intensity A, denoted as $f(\mu(A))$, is obtained by applying a function f on the original membership value $\mu(i)$. The function $f(\mu(A))$ affects membership values. An enhancement function can be:

$$f(\mu(A)) = \mu(A)^\gamma \tag{4}$$

The parameter γ determines the features of the enhancement:

- When γ is less than 1, the function extends the range of membership values, increasing contrast.
- When γ is greater than 1, the function compresses the membership values, reducing the contrast of specific intensity ranges.

Upon implementing this modification, the image's histogram receives a significant reshaping. The reshaping process is defined by fuzzy logic concepts and is characterized by a higher level of detail than conventional HE. The final stage in the procedure (distinct from the modification phase but essential for achieving the improvement) involves pairing these modified membership values with the corresponding pixel intensities.

F. Image Enhancement Methods

Image enhancement can be crucial due to poor image quality, including lighting, noise, high brightness or darkness levels, lack of sharpness, and blurriness. The image enhancement methods may reduce the analysis process that involves comprehensive image extraction. A low-quality image has distortions, such as an image that is not visible due to low lighting.

1) Advanced fuzzified histogram equalization: AFHE is an advanced approach used in image processing to boost brightness and improve the level of detail in images. The advanced version of the conventional HE method incorporates ideas of fuzzy logic. AFHE enables a more refined and situation-specific modification of image brightness in comparison to conventional HE. By transforming the original image into a uniform histogram, AFHE effectively improves the image's contrast. AFHE produces a significant global enhancement but may diminish the image's local details.

The AFHE provides the relationship in gray level and its corresponding frequency, which produces a gray image $G(i)$ as expressed in Eq. (5).

$$G(i) = \frac{n_i}{TN}, i = 0, 1, ..., L-1 \tag{5}$$

Let i represent the image's gray level, n_i be the number of pixels comprising gray level, and TN denotes the total number of pixels in the image. The histogram represents the probability distribution function of i. Eq. (6) expresses the HE, which can be accomplished based on $G(i)$.

$$h_k = Tf(r) = (L-1)\sum_{i=0}^{k} G(i) \tag{6}$$

Let the mapping function, $Tf(r)$, be denoted as h_k, and transform each pixel value k from the input image to h_k. L denotes the gray level of an output image. The histogram can receive a more even image intensity distribution with this modification. As a result, regions with lower local contrast can achieve higher contrast without compromising global contrast.

2) Contrast limited adaptive histogram equalization: CLAHE is a method for enhancing local contrast in an image. The image is acquired locally by forming some symmetrical grids, referred to as the region size. Three markers identify the image's regional structure: the corner region (CR) designates the areas in the image's corner, the border region (BR) designates the areas around the image that keeps the CR, and the inner region (IR) designates the remaining areas in the center.

CLAHE, which involves placing a boundary value on the histogram, can be used to solve the issue of excessive contrast enhancement. This limit value, which indicates a histogram's maximum height, is the clip limit. Eq. (7) defines how to compute a histogram's clip limit.

$$\beta = \frac{T}{L}(1 + \frac{\alpha}{100}S_{max}) \tag{7}$$

Let T denotes the pixel count of each block, and L indicates the block's gray level. While α is the clip factor and $Smax$ is the maximum slope.

3) Fuzzy contrast enhancement: The FCE aims to create dark pixels that are darker and bright pixels that are brighter to improve the image. Eq. (8) computes the FCE.

$$F \leftarrow h(x) + \sum_{x}\sum_{y}\mu_{F(x,y)'} \tag{8}$$

The FCE is an integer series, denoted as $h(x)$, where x ranges from 0 to $L-1$. In this context, $h(x)$ represents the frequency at which gray levels within x occur. The fuzzy histogram is constructed by viewing the gray value $f(x,y)$ as a fuzzy number $\mu_{F(x,y)'}$. While $\mu_{F(x,y)}$ represents the fuzzy membership function. Fuzzy logic is more adept at managing values' imprecision than traditional crisp values. Thus, it yields a smooth histogram.

G. Performance Measurement

PSNR is a quantitative indicator that reflects how much an image's quality was reduced throughout the compression or processing processes. It measures the ratio between the maximum signal value and the amount of noise in the image using decibels (dB). This study employed PSNR to compare the quality differences between the original and enhanced images. Image quality is evaluated based on the PSNR value, which a higher PSNR value indicates a high-quality image.

The mean-squared error (MSE) is initially computed in Eq. (9) to obtain the PSNR, where I_1 is the enhanced iris image, I_2 is the original iris image, and X and Y are the numbers of rows and column in the input iris image.

$$MSE = \frac{\sum_{X \times Y}[I'(x,y) - I(x,y)]^2}{X \times Y} \tag{9}$$

Eq. (10) calculates the PSNR value, where Z represents the maximum variation in the data type of the input iris image. Z equals one if the input image is a double-precision floating-point; otherwise, Z is 255.

$$PSNR = 10\log_{10}\frac{Z^2}{MSE} \tag{10}$$

IV. Result and Discussion

All experiments used Google Colaboratory to analyze the iris image enhancement methods: AFHE, CLAHE, and FCE. PSNR, a prevalent metric for assessing image quality, was employed to evaluate the efficacy of the iris image enhancement methods. This study also measures the total CPU times for each method to determine which image enhancement method works faster for 24 iris images. The relationship between the PSNR value and the CPU times shows the effectiveness of the image enhancement methods. Therefore, it can identify which image enhancement method works best for iris images.

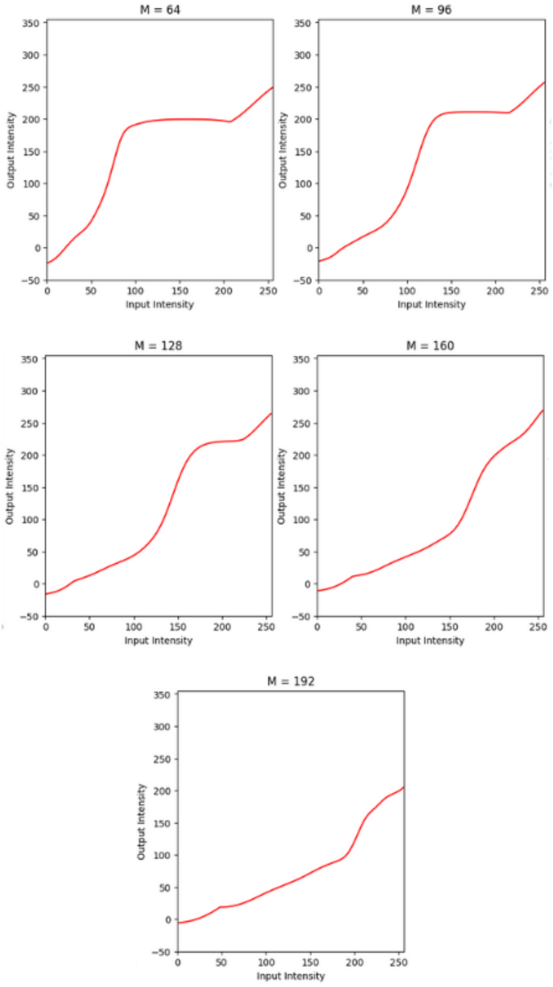

Fig. 5. The input and output intensity for $M = 64$, $M = 96$, $M = 128$, $M = 160$, and $M = 192$.

Fig. 5 shows the input and output intensities of 24 iris images to map the gray level. The range of the pixel intensity value is 64 for minimum input pixel intensity to 192 for maximum input pixel intensity. The gray level for the output pixel intensity increases for intensity values of 64, 96, and 128 at the middle of the block, while the intensity values of 160 and 192 slightly decrease but remain constant to enhance the image's brightness. The results highlight how the image enhancement methods improve the visibility and contrast of iris images, thereby rendering them more appropriate for iris recognition systems used in non-cooperative environments.

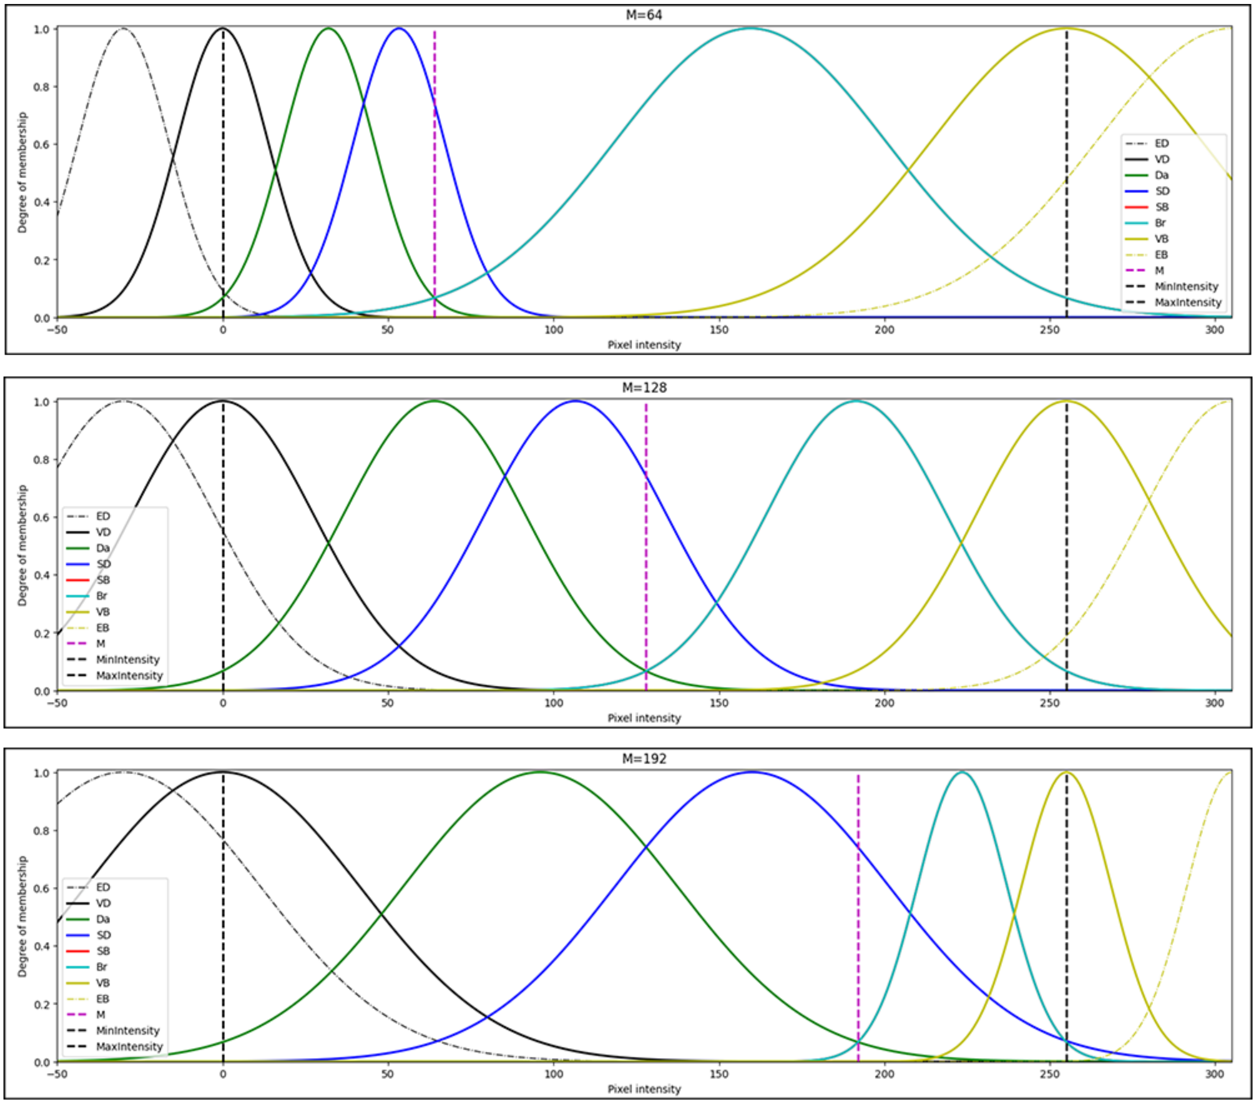

Fig. 6. The relationship between modified gaussian membership function, M and the pixel intensity based on the modified membership functions.

The fuzzy rule sets according to the IF-THEN rule were modified based on the input image. The maximum M used for iris images is six, while the minimum M is two. Fig. 6 demonstrates the relationship between the modified Gaussian membership functions and the pixel intensity based on the value in the selected membership functions, M. The image's brightness decreases and darkens when M equals 64. In addition, the pixel intensity also shows high contrast. The image becomes extremely bright when $M = 192$, with a maximum intensity between 192 and 255, respectively. Therefore, the image can contrast less to the $M = 64$. However, the high and low contrast is balanced when M is 128. The mid-range of the pixel intensity between 0 and 255 made the image not too dark and bright.

The analysis of the AFHE, CLAHE, and FCE depicted in Fig. 7 demonstrates that the image quality of AFHE outperforms those of CLAHE and FCE. The original images exhibit low lighting; hence, the enhanced images using AFHE preserves brightness better with low contrast. The AFHE could help the data annotation process for iris segmentation. CLAHE marginally brightens the image compared to AFHE; however, some areas continue to have high contrast, which makes the image slightly dark. Nevertheless, FCE demonstrates a significant difference in brightness levels, resulting in a darker appearance in some images. Some images merely enhance a low gray level, retaining the image in poor lighting.

Table I shows the experiment result of image enhancement methods (AFHE, CLAHE, and FCE) based on the PSNR. Enhanced image quality corresponds to a higher PSNR value. FCE has a higher PSNR value of 76.48db and longer CPU times at 13.9s. To be compared with AFHE, AFHE indicates the lowest PSNR value at 76.02db with faster CPU times at 4.04s. Although the PSNR value of HE is lower than CLAHE and FCE, it demonstrates better image quality, as depicted in Fig. 7, with faster CPU times.

AFHE enables more refined contrast enhancement, which is particularly beneficial in images with complex lighting settings or situations where simple histogram equalization can result in severe or insufficient enhancement. Fuzzy logic regulates

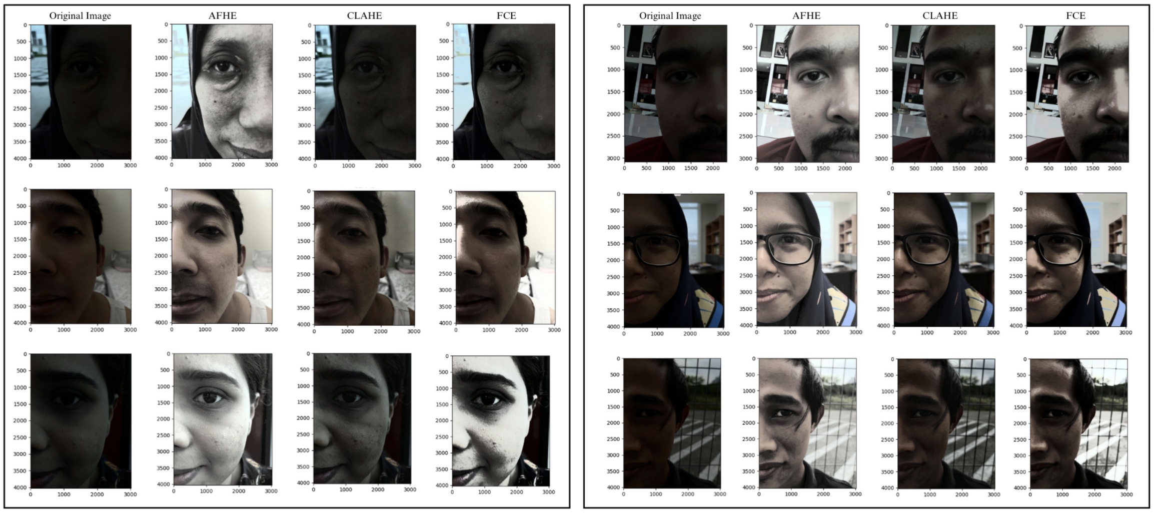

Fig. 7. Iris image enhancement results using AFHE, CLAHE, and FCE based on the low lighting conditions of original images.

TABLE I. Comparison of Iris Image Enhancement Methods with the PSNR Value

Enhancement Methods	PSNR (dB)	CPU Time (s)
AFHE	76.02	4.04
CLAHE	76.23	4.9
FCE	76.48	13.9

TABLE II. Comparison with State-of-the-art Methods

Author	Method	Evaluation Metric	Result
[15]	HE-FCM	Accuracy	0.86
	CLAHE-FCM		0.91
[1]	HE	PSNR	14.725
	AHE		14.148
	CLAHE		17.459
[18]	HE	MSE	18.25
		PSNR	28.87
[23]	HE	PSNR	16.76
	AHE		16.95
[28]	Gaussian	Accuracy	89.2
	Triangular fuzzy average		87.4
	Triangular fuzzy median		88.4
	HE		83.4
	CLAHE		84.8
This study	**AFHE**	**PSNR**	**76.02**
	CLAHE		**76.23**
	FCE		**76.48**

the enhancement, which helps retain details better and prevent errors frequently created by aggressive methods. Implementing fuzzy sets and rules enhances the method's adaptability to various image types and expected outcomes. Therefore, it can be concluded that AFHE is the best iris image enhancement method, followed by CLAHE and FCE, respectively, because AFHE preserves more brightness and provides a significant iris image quality.

The comparison with state-of-the-art methods is crucial for validating the effectiveness and benchmarking the performance of the proposed image enhancement techniques, namely AFHE, CLAHE, and FCE. Using PSNR as a measure evaluates the accuracy of the image enhancement in terms of pixel-level fidelity. The proposed approaches achieved higher PSNR values than existing state-of-the-art methods [1], [18], [23], as shown in Table II, indicating that AFHE, CLAHE, and FCE preserve image quality and reduce distortion throughout the enhancement process. PSNR is commonly employed to evaluate methods such as HE, CLAHE, and FCE that modify image brightness; however, it may not adequately measure perceptual quality or task performance. This limitation is highlighted by the accuracy results of previous studies in [15], [28], which demonstrate superior performance compared to AFHE, CLAHE, AHE, and FCE in terms of accuracy.

As different metrics may capture various aspects of image quality and utility, this inconsistency highlights the significance of employing multiple evaluation metrics to comprehensively evaluate the performance of image enhancement methods. Hence, while PSNR can indicate better pixel-level accuracy, accuracy metrics further explain enhanced images' perceptual quality and efficiency for specific applications. Further research could explore the development of comprehensive evaluation frameworks that consider a range of metrics to provide a more holistic assessment of image enhancement methods. Additionally, investigating the factors contributing to inconsistency between PSNR and accuracy metrics could yield valuable information for further improving the performance of image enhancement methods, ultimately enhancing their utility in practical applications.

V. Conclusion

This study presented fuzzified image enhancement methods, AFHE, CLAHE, and FCE, to enhance the quality of iris images, specifically for data annotation. The iris images in the MIREIS dataset provide some images with low lighting conditions, creating a challenging process during data annotation. Based on the input iris images, the Gaussian membership functions were modified to the suitable intensity value. The GMF followed the rule set in the fuzzy inference system for the fuzzification and defuzzification process. The AFHE is the best fuzzified image enhancement method compared to CLAHE and FCE based on the PSNR value and CPU times. The findings of this study can assist other researchers in data annotation, particularly in non-cooperative environments when iris images contain low lighting conditions. This study only employed image enhancement methods to modify the iris image's contrast and lighting. However, these approaches cannot reduce the presence of reflections in the iris image.

VI. Future Work

Further work can be focused on extending the study to include reflections in iris images, which were not adequately reduced by the image enhancement methods. Studies could focus on developing methods to precisely reduce or eliminate reflections in iris images captured in non-cooperative environments with low lighting. Further improving the effectiveness of the AFHE, CLAHE, and FCE approaches in data annotation tasks might be examining their ability to work with iris images at different distances and angles. This could offer significant data concerning the methods' robustness and efficacy in various conditions.

Moreover, combining several image enhancement methods or employing machine learning for modifying parameters adaptively might improve the effectiveness and flexibility of image enhancement methods. The effectiveness and application of AFHE, CLAHE, and FCE in iris image enhancement would be further advanced by addressing these issues and investigating these potentials for enhancement. It can support the improvement of iris recognition systems in non-cooperative environments.

***Abstract*—In the Internet of Things (IoT) security, anomalies due to attacks or device malfunctions can have serious consequences in our daily lives. Previous solutions have been struggling with high rates of false alarms and missing many actual anomalies. They also take a long time to detect anomalies even if they successfully detect anomalies. To overcome the limitations, this paper proposes a novel anomaly detection system, named IoT Malfunction Extraction Observer (IMEO), that utilizes semantics and correlation information for smart homes. Given IoT devices installed at home, IMEO creates virtual correlations based on semantic information such as applications, device types, relationships, and installation locations. The generated correlations are validated and improved using event logs extracted from smart home applications. The finally extracted correlations are then used to simulate the normal behaviors of the smart home. Any discrepancy between the actual state of a device and the simulated state is reported as abnormal while comparing correlations and event logs. IMEO also utilizes the observation that malfunctions of IoT devices occur repeatedly. An anomaly database is created and used so that repetitive malfunctions are quickly detected, which eventually reduces processing time. This paper builds a smart home testbed on a real-world residential house and deploys IoT devices. Six different types of anomalies are analyzed, synthesized, and injected to the testbed, with which IMEO's detection performance is evaluated and compared with the state-of-the-art correlation-only detection method. Experimental results demonstrate that the proposed method achieves higher performance of detection accuracy with faster processing time.**

***Keywords*—Security; anomaly detection; semantics; Internet of Things; attack**

I. Introduction

The rapid growth of Internet of Things (IoT) has enjoyed a wide variety of applications. According to a market report, the global number of connected IoT devices is expected to grow to up to 16.7 billion endpoints by the end of 2023 [1]. It also reports that this number will grow by 16% annually to reach 29.7 billion by 2027. IoT devices are increasingly being integrated through IoT platforms such as SmartThings [2] and Homekit [3]. This allows users to connect to IoT devices from different vendors using smart applications, thus providing great convenience for IoT heterogeneity.

With the development of IoT applications (this paper is specifically focused on smart homes), there are also growing security and safety concerns [4]. Various causes, including attacks, device errors, malfunctions, and misconfigurations, can cause anomalies in IoT and eventually lead to unexpected (and often unfavorable) outcomes. IoT anomalies have intrinsic properties, and followings show some examples of anomalies and consequences in smart homes. First, IoT devices can extend cyberspace attacks to the physical world. For instance, a "close the water valve" command can be blocked by an attacker, resulting in flooding of the room. Second, it is very often that the malfunction of the device is rarely noticed until a specific result occurs. An electronic heater that has received a "too cold" command from a smart home application can cause a fire due to the relay switch not being able to turn off the heater. Third, when IoT devices are connected to each other via automation, abnormal behaviors of one device can cause unwanted behaviors of other devices, which exacerbates the effects of the anomaly. For instance, a smart door lock that is automatically unlocked only when there are residents, is released due to false events by a human presence sensor.

To address these concerns, many previous research on anomaly detection utilize data mining techniques that profile normal behaviors of a system and report off-profile events as anomalies. These works generally accept event logs as inputs without fully considering semantics of each event that can actually be obtained from smart apps, device types, and device functions. There are three limitations to be considered in this approach. First, the logic in some smart apps is too complex to be accurately extracted, which may cause incorrect normal operations and malfunctions. Say, a smart app logic generates an event pattern, "If two motion sensors in a living room both do not detect movement, turn off the smart plug after 30 minutes". It is difficult to mind this when considering the 30-minute delay and the "AND" logic between two sensors. Therefore, it may not be possilbe to detect the anomaly, "a smart plug fails to turn off". Second, it is often difficult to interpret the learning results, making it difficult to explain them and thus confusing to users. Third, when configurations are changed, learning results are not updated quickly. A long retraining process is required to adapt to the changes, and a lot of false alarms occur before retraining is finished.

An intuitive approach to improve the accuracy of anomaly detection is to incorporate semantic information such as device types, installation locations, relationships, and automation logic. However, there are many technical challenges to be resolved to realize the approach. 1) Typical mining techniques accept event logs as inputs; however, representing a variety of semantic information in the form of event logs has not been studied. 2) Patterns extracted from event logs may conflict with those of system behavior derived from smart home applications; identifying and resolving these conflicts are not easy. 3) It is unknown how to update a system profiling effectively when a smart home application changes.

To overcome the challenges, this paper proposes IoT Mal-

*Corresponding authors

function Extraction Observer (IMEO), a new anomaly detection system for smart home applications. Technically, it constructs correlations by using semantic information, explaining how a device's states and events correlate with those in another device, and verifies them by using event logs as evidence. Given the correlations, IMEO simulates normal behaviors and compares the simulated states to those in a real world via contextual and consequential checkings. It then reports anomalies if finding inconsistencies in comparison. Because the correlations become explainable along with the semantics in IMEO, they can help resolve conflicts with smart home applications. Thanks to the explainability, the correlations can be updated with the changes of the smart home application. This paper implements a prototype of IMEO and builds a real-world smart home testbed consisting of three rooms. Then, experiments are conducted, and the results show that IMEO can reach a high precision of 99.33% and a recall of 95.35%, demostrating better performance than a prior method.

The rest of the paper is organized as follows. Section II summarizes possible anomalies that can occur in IoT environment. Section III reviews research works on anomaly detection for IoT. Section IV introduces a reference architecture for an IoT system and defines a threat model in the architecture. In Section V, three correlation channels and the representation of correlations are described. We present the proposed system in Section VI. Our testbed is implemented and experimented in Section VII, which is followed by evaluation in Section VIII. Finally, Section IX concludes the paper.

II. Anomalies in IoT

Previous works have reported that IoT devices are often unreliable and vulnerable to malicious attacks [5], [6], [7]. This section discusses anomalies in IoT caused by devices' malfunctions and attacks.

A. Malfunctions in IoT Devices

In general, IoT devices communicate with an IoT platform; they report any *event* records and receive *command* messages to/from the platform. This subsection categorizes malfunctions in terms of them.

1) Events: There are two types of causes related to event records. (i) *Faulty event* refers to devices' reporting incorrect values. This is mainly attributed to a device defect or physical inteference. For instance, a door knocking sensor goes active and then inactive without reason [8], and a motion detector sees motions in an empty room and turns on lights [9]. (ii) *Event loss or delay* represents that event records are not reported to the platform (or any server) in a timely manner. For instance, status updates from presence sensors have been reported to suffer from long delays [10]. This may cause significant delays in executing related automation when after a resident leaves home. If the update is lost, an automation rule may fail to lock a door while away.

2) Commands: There are cases inducing malfuntions on devices. (iii) *Bogus command* refers to a phenomenon called "poltergeist" frequently reported on a user forum [11]. For instance, users reported that lights or sensors turned on in the middle of the night. It is said that this phenomenon occurred in an office where no one was present or in the hallway of a house where everyone was sleeping. They also reported that a heater connected to an air conditioner suddenly reacted and turned on. (iv) *Command failure* represents that the IoT platform issues a command that is not executed on an IoT device. A physical problem or cyber problem may cause this. The physical problem is mainly attributed to a malfunction of an IoT device. For instance, if an electrical relay inside a smart plug is broken, it may prevent the plug from cutting off the power supply. The platform recognizes that the plug is turned off, though. The cyber problem includes unstable network connections and system crashes that prevent commands from being executed.

B. Attacks on IoT Devices

This subsection identifies potential vulnerabilities on IoT devices and discovers five different types of IoT attacks.

(i) *Fake event* is an event maliciously generated by an attacker. This can trigger an IoT device to behave unexpectedly, which can lead to unfavorable consequences [12]. For example, when the attacker injects an event indicating the presence of a fake person, a door lock is unlocked. (ii) *Event interception* by an attack can intercept and discard event records. For instance, the attack blocks the wireless connections of window and door sensors so that they stop sending event records, which can lead to a home security system fails to alarm [13]. (iii) *Fake command* is injected by by an attacker into an IoT device [14]. Say, smart speakers and smart switches may accept fake commands from a local network without authenticating sources [15], [16]. (iv) *Command interception*. An attacker can also intercept commands and prevent them from being delivered to IoT devices [17]. (v) *Compromised device*. An attack can gain access to an IoT device and perform the following attacks. In a "stealthy command", the attacker takes control of a device to execute commands and prevents corresponding feedback events from being sent in order to remain covert [18]. This is similar to the fake command, except that no feedback events are sent. "Denial of Execution" means that when a valid command is sent to the device, it does not execute the command and sends back a feedback event reporting that the command was executed.

C. Repeated Malfunctions of IoT Device

A user forum notes that users are frequently having trouble with malfunctions of specific IoT devices; devices that malfunctioned once malfunction repeatedly after that or cause other problems. For instance, a sensor once disconnected from a network once experienced multiple network disconnections over several days. As such, repeated malfunctions of the device can cause difficulties in operating the automation involved or problems that incorrectly trigger other actuators.

III. Related Works

With the advancement of IoT devices and the advent of home automation applications, security and privacy issues are attracting great attention. However, most research has focused on detecting threats, attacks, and malicious codes rather than IoT malfunctions. For example, HomeGuard [19] presents the first systematic classification of threats caused by interference between different automated applications, such as automation collisions, serial execution, and loop triggering. The authors propose a method to detect these threats using SMT (Satisfiability Modulo Theories) Solver, where it performs symbol execution to extract automation rules from an application. PFirewall [20] is a study that recognizes the continuous inflow of excessive IoT device data into an IoT automation platform. It protects users' personal information from the platform by minimizing data without changing the IoT device or platform. HoMonit [21] focuses on detecting smart home applications that are malfunctioning, unlike this work on detecting anomalies of IoT devices. Given a physical event, Orpheus [22] automates system call tracking and then checks for attacks via comparison. However, it is not possible to detect anomalies such as fake events and event intercepts.

Many previous studies allow anomaly detection systems to learn the normal behavior of smart homes from historical data. For example, SMART [23] trains activity classifiers for multiple users based on different subsets of sensor readings, and further trains another classifier that takes a vector of activity classification results as input to detect sensor failures. DICE [24] checks contexts in smart homes to detect anomalies during state transition.

Traditional mining-based solutions are not clear how they can accurately learn complex behaviors in smart homes. The main difference between these conventional anomaly detection systems and this work is that IMEO extracts various semantic information such as device types, device relationships, and smart home applications and injects the information into mining processes. IMEO is not only more accurate in detection, but each detected anomaly can be interpreted as violating the correlation, so it can be explained by itself.

IV. Threat Model

A. IoT System Architecture for Smart Homes

IoT devices in smart homes are increasingly integrated through IoT platforms for seamless automation. IoT integration platforms such as SmartThings, OpenHAB, and Amazon Alexa support automation programs. Although these platforms can handle numerous IoT devices, they are summarized as a small number of abstract devices. For instance, smart lights, regardless of their brands, shapes, sizes, or wireless technologies, are equally abstracted as light. Each abstract device has events and commands associated with it.

This paper considers SmartThings, one of the leading IoT integration platforms, for a system architecture for smart homes as it supports rich automation logic. A typical SmartThings deployment, as shown in Fig. 1, has a cloud-centric architecture consisting of four layers. At the top is SmartThings Cloud. It is a cloud where smart apps run and interact with abstracted functions. The cloud uses various communication techniques such as Wi-Fi, Zigbee, and ZWave to communicate with IoT devices through the network connection layer. IoT devices can be divided into cyber and physical parts. The cyber part manages the interface for humans and connects communication between the cloud and the physical part, while the physical part performs its functions in the physical world. For instance, the Philips' Hue smart bulb consists of a physical part of an LED bulb and a cyber part of a microcontroller with a built-in wireless component.

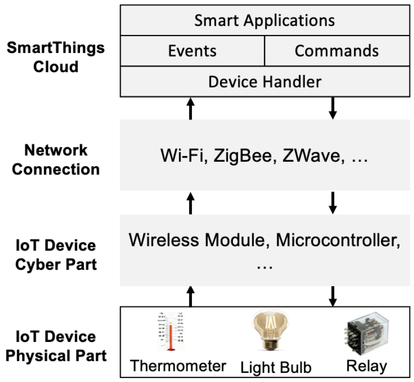

Fig. 1. IoT System architecture for smart homes; SmartThings.

Terms used in the SmartThings are briefly described in the following. An IoT device has one or more instrumental capabilities that are classified as actuators or sensors. Each capability defines one or more attributes. For instance, a smart plug device has a "switch" attribute and optionally a "power" attribute. The state (value) of each attribute is stored in the cloud and updated by events transmitted from the IoT device. For instance, a multi-purpose sensor has a capability of "contact sensor", and the cloud changes the state of its attribute "contact" from "open" to "closed" when it receives an event "contact closed" from the sensor. In the case of an actuator, SmartThings ensures that the state of the its attribute is udpated by a feedback event transmitted by the IoT device after a command is executed by the actuator.

B. Threat Model

This paper focuses on detecting malfunctions and attacks in IoT devices described in the previous section and on reporting repeated malfunctions immediately. It is also noted that IMEO is able to detect attacks that violate correlations. Attackers who know the correlations can avoid our detection by constructing an attack that does not violate the correlations.

Our threat model assumes that the IoT platform is not compromised. As with other anomaly detection tasks, we assume that there is no or few anomalies during training. No malicious or conflicting rules in installed smart home applications are also assumed. It is predicted that the average household could have more than 500 IoT devices in the near future [25]. Therefore, considering dense deployments, we propose to leverage scenarios where IoT devices have one or more other devices nearby to interact with and leverage this to detect abnormal physical behavior of the devices.

V. Correlations

IoT devices instrumented in the same home may be interrelated in the form of simultaneous or temporally related events [26], [27], [28], [29]. These correlations can occur due to the execution of application, physical interactions, or user activities. This section investigates causes of these correlations and classifies them into three channels as shown in Fig. 2. It also defines their representations.

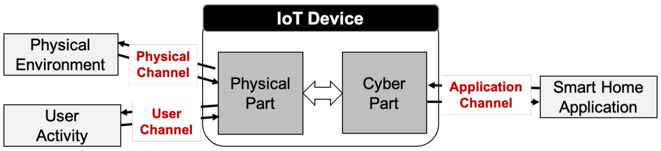

Fig. 2. Three correlation channels for IoT devices.

A. Correlation Channels

1) Application channel: Smart home applications directly cause correlations between triggers and actions as programmed. But, it also induces some additional correlations implicitly. For instance, in the SmartThings application, each automation rule implies a correlation worth verifying.

2) Physical channel: Two devices can be interrelated via certain physical properties. First, when an actuator takes an action it changes a physical property, which can be detected by a nearby sensor. For instance, an illuminance sensor can be affected by a nearby smart light turning on or off. Second, different sensors can be affected by the same physical event, creating temporally correlated IoT events. For instance, a door opening inevitably involves movement of the door, which captures an acceleration sensor and a contact sensor installed on the door, causing corresponding events to occur sequentially. As IoT device types increase, physical channel correlations can be widely observed across a variety of physical characteristics such as lighting, power, sound, and temperature.

3) User activity channel: A user activity gives rise to changes on a device, and the states of devices also reflects user activities. Thus, the user activity channel can lead to correlations between devices. For instance, when a TV is turned on it means that a user is nearby, and the motion sensor must detect it. When a user returns home, there must be continuity in events such as “person presence” showing the user’s movements and “contact sensor open” showing a front door opening.

B. Representation of Correlations

This paper represents an *event* and a *state*. Let denote $E_a^{\alpha(A)}$ an event reporting that the attribute α of device A should change to value a and $S_b^{\beta(B)}$ a state indicating that the attribute β of device B has value b. Based on them, it defines two types of correlations as below.

1) Event-to-Event (E2E) correlation: represents that an event should be followed by another. For instance, E2E correlation $\langle E_{active}^{motion(A)} \rightarrow E_{on}^{switch(B)} \rangle$, given motion sensors A and light B, indicates that an active event $E_{active}^{motion(A)}$ should be followed by another event $E_{on}^{switch(B)}$.

2) Event-to-State (E2S) correlation: represents that an event occurring means that a state is true. For instance, E2S correlation $\langle E_{high}^{power(Plug)} \rightarrow S_{on}^{switch(heater)} \rangle$ indicates that the state $S_{on}^{switch(heater)}$ should be true, when an event $E_{high}^{power(Plug)}$ occurs.

3) State-to-Event (S2E) correlation: represents that an event occurs only when a state satisfies a true condition. For instance, S2E correlation $\langle S_{>60}^{illuminance} \rightarrow E_{off}^{smartplug} \rangle$ indicates that the event $E_{off}^{smartplug}$ occurs only when the state $S_{>60}^{illuminance}$ becomes true.

4) Coditional (AND) correlation: represents that events and states are combined with conditions using the $\wedge$ symbol. For instance, a correlatin $\langle E_{active}^{Motion} \wedge S_{present}^{Presence} \rightarrow E_{on}^{Switch(Light)} \rangle$ represents that an event E_{active}^{Motion}, only when a state $S_{present}^{Presence}$ is true, should be followed by another event $E_{on}^{Switch(Light)}$.

VI. Proposed System: IMEO

This section proposes a novel anomaly detection system, named IoT Malfunction Extraction Observer. Fig. 3 demonstrates an overall architecture of the proposed system, and the followings describe operation steps. IMEO first generates correlations regarding three channels hypothetically by using a smart home application and Natural Language Process (NLP) techniques. We note that SmartThing is used for our application. It also receives event logs from the application that are then used to verify the correlations. Only correlations that have passed verification are used to detect anomalies. Upon receiving event logs in real time, it checks them through verified correlations. When an event log does not match correlations, it reports the event as an anomaly. IMEO reuses the detection results for better performance. It saves details of identified anomalies and maintains an anomaly history. Upon reoccurring the same malfunction, it can detect the anomaly directly from the history, instead of performing the correlation matching process.

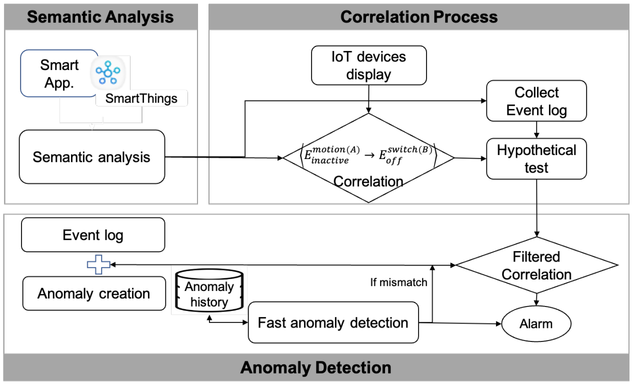

Fig. 3. System architecture of the proposed IMEO system.

A. Analyzing Semantics

The semantic analysis module first extracts semantics from the smart home application and then converts them to correlations (of application channels). To capture semantics, it investigates automation logics and related configurations, such as a temperature threshold in an air conditioner, in the application. For instance, given a semantic telling “Turn off the smart plug when illuminance is greater than 60,” an E2E correlation $\langle E_{>60}^{illuminance} \rightarrow E_{off}^{smartplug} \rangle$ is generated. This can also be represented by an S2E correlation $\langle S_{>60}^{illuminance} \rightarrow$

$E_{off}^{smartplug}\rangle$. It is noted, however, that the S2E correlation does not guarantee to be true necessarily and has to be verified in the following step.

B. Mining Correlations

There are many pattern mining methods, but few achieve both good usability and high accuracy in the context of smart home applications. Supervised mining methods are more accurate, but often require well-annotated data sets or user interventions. Unsupervised mining methods can be applied to unannotated data, but they are less accurate.

To overcome limitations of existing methods, this paper proposes a semantic-based mining method. Semantic information includes device type and installation location, which can be obtained from a smart home application. Based on this semantic information, IMEO generates virtual correlations corresponding to physical channels and user activity channels. Each virtual correlation is then independently verified. This paper assumes that there will be no or very few anomalies in the training phase, as with other anomaly detection tasks.

1) Processing event logs: It is necessary to preprocess event logs for two reasons as follows. First, repetitive sensor readings introduce noise into raw event log data. For instance, some power meters periodically report similar but slightly fluctuating measurements. Second, numerical readings of a device cannot be incorporated into logical calculations. Therefore, our preprocessing module eliminates duplicated records and transforms numerical data to binary information. To this end, the module applies the Jenks natural breaks algorithm [30] to the remaining readings and classify them as *low* or *high*. Then, it looks at the events for a given attribute on each device and removes events that do not continuously change state. Finally, two temporally adjacent events for the same attribute of the device have opposite values. However, our measurement observed that there were values whose differences were too small to be binarized using the Jenks natural breaks algorithm. So, these values were all added up to find the average value. Based on this, a value was classified into *low* if it was lower than the average value, and classified into *high* if it was greater than the average value .

2) Generating virtual correlation: In addition to E2S correlations generated from the application channels, correlations can be generated with other semantic information such as device attributes and relationships between attributes in the physical and user activity channels. To this end, semantic information is utilized to construct a table displaying correlated attribute pairs, and then each pair is filled with devices with matching attributes to create a correlation.

For physical channel correlations, IMEO sets up seven physical properties (illuminance, sound, temperature, humidity, vibration, power, and air quality) related to IoT devices in smart home environment. An NLP technique is used to determine whether the attributes of two IoT devices can be associated through physical properties. To obtain IoT abstract attributes, we refer to the description from the SmartThings developer site [31]. In order to objectively evaluate the relevance between attributes and physical properties, Google's word2vec model [32] is used to calculate the semantic similarity score between each word in the list and the physical properties. Then, this score is used as the *correlation score* between the physical property and attribute. The top 10 attributes with the highest scores for each physical property are considered to be interrelated through the corresponding physical properties.

Attributes that represent users' characteristics can be expressed as *presence* and *motion*. Since IoT devices are always influenced by users, it is natually assumed that all attributes related to each physical properties in the physical channel are related to users. User activity channel correlations are formed by considering that each physical property has a correlation with *presence* and *motion*.

Eventually, IMEO can find attribute pairs considered to be correlated with each other, from which it is possible to identify all the attributes of IoT devices installed in a smart home environment. Given a pair of two correlated attributes α and β on device A and B, respectively, IMEO generates four E2E correlations $\langle E_a^{\alpha(A)} \rightarrow E_b^{\beta(B)}\rangle$, $\langle E_{a'}^{\alpha(A)} \rightarrow E_b^{\beta(B)}\rangle$, $\langle E_a^{\alpha(A)} \rightarrow E_{b'}^{\beta(B)}\rangle$, $\langle E_{a'}^{\alpha(A)} \rightarrow E_{b'}^{\beta(B)}\rangle$, and four E2S correlations $\langle E_a^{\alpha(A)} \rightarrow S_b^{\beta(B)}\rangle$, $\langle E_{a'}^{\alpha(A)} \rightarrow S_b^{\beta(B)}\rangle$, $\langle E_a^{\alpha(A)} \rightarrow S_{b'}^{\beta(B)}\rangle$, $\langle E_{a'}^{\alpha(A)} \rightarrow S_{b'}^{\beta(B)}\rangle$. Symmetrically, eight correleations can also be generated with events on $\beta(B)$ leading the correlations.

Fig. 4. Anomaly detection process with three examples.

C. Detecting Anomalies

IMEO detects anomalies via two checking processes; *contextual check* and *consequential check*. The contextual check determines anomalies with E2S correlations. Suppose there is a correlation that a switch is *on* only when a motion sensor is *active* as shown in Fig. 4(b). Upon detecting the switch is *off* when the sensor is *active*, IMEO finds that this violates the correlation and determines to be an anomaly. The consequential check sees whether the next event occurs within 60 seconds when the preceding event of an E2E correlation occurs. If the next event occurs within the time boundary, the correlation is judged to be correct. For instance, Fig. 4(a) shows a correlation telling that an event "a contact sensor is *on*" should be followed by another event "a motion sensor is *on*". IMEO considers it normal if the motion sensor changes to on within 60 seconds after the contact sensor is turned on. It determines it to be abnormal if the motion sensor does not turn on within 60 seconds.

IMEO also performs a fast anomaly detection process. This is based on the feature, which has been frequently reported in user forums, that IoT devices malfunction repeatedly once malfunctioned. IMEO makes use of the feature to speed up the detection process while not sacrificing detection accuracy performance. Upon detecting an anomaly (i.e., a mismatch between an event log and correlation(s)), the anomaly detection module records a pair of event log, correlation(s) in a database of anomaly history. When the same malfunction occurs later, the module searches for the database and immediately determines if the event is abnormal before going through the checking processes. Once identified as anomaly this time, the resulting pair data is also recorded in the database. The number of repeated occurrence for each record is also saved in the database. Once sorted efficiently, this information can help accelerate the search process. Considering the repetition property of IoT devices, the fast anomaly detection process is expected to reduce detection time meaningfully.

VII. Experimental Setup

In order to evaluate the proposed IMEO system, we have built a real-world testbed as shown Fig. 5. Data was collected for three weeks to obtain event logs of IoT devices required for training and for one week for testing. We have applied correlations verified through the collected data to every events, from which the performance of IMEO is evaluated.

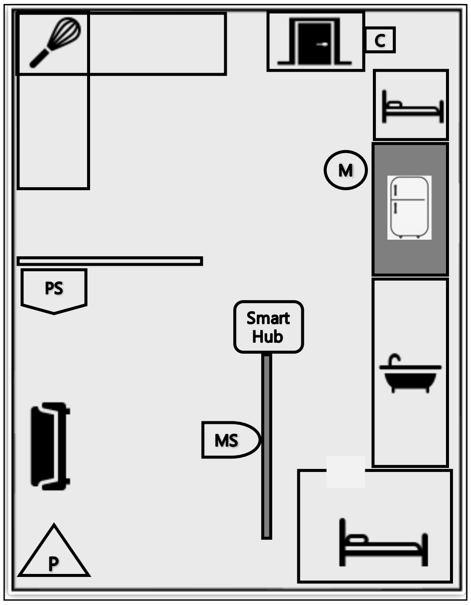

Fig. 5. Deployment layout of IoT devices.

A. Preliminary

1) Testbed: We have deployed IoT devices in a testbed of a private house consisting of three rooms and used Samsung SmartThings as an application. There are four residents in the testbed; one undergraduate student and three ordinary family members (two women and one man) who go to work during the day and returns home at night. None of them had any experience of using a smart home automation system. Residents are allowed to set automation of their interests that is fulfilled by IoT devices compatible with our smart home application. They are also given enough time to get used to the installed automation system before collecting data.

TABLE I. A List of IoT Devices Deployed in the Testbed

Device name	Attributes	Deployment	Abbr.
Motion Sensor (SmartThings)	motion	on wall	M
Multi Sensor (SiHAS)	motion, illuminance, humidity, temperature	on wall	MS
Contact Sensor (SmartThings)	contact, acceleration	on doors	C
Smart Button (SmartThings)	room control unit	on wall	PS
Smart Plug (SmartThings)	switch, power	as light lamp	P

2) IoT devices: Our testbed are deployed with five different types of IoT devices. Fig. 5 illustrates a deployment layout of devices, and Table I describes details of the devices including abbreviations. The motion sensor (denoted as M) is placed in the living room to detect the presence and motion of residents. The multi-function sensor (denoted as MS) is an IoT device that can detect human movements and perform a variety of roles, including detection of illumination, humidity, and temperature. The contact sensor (denoted as C) is able to detect the opening and closing of the front door. It can be used as a factor to determine whether residents are inside the house. The smart button (denoted as PS) is able to control the operation of smart devices in the testbed by unit. It can also check the temperature of the testbed. The smart plug (denoted as P) is a power plug used to control electrical devices.

TABLE II. Automation Rules Extracted from the Application

Index	Automation rules
R1	If (illuminance <30), then smart plug (on).
R2	If (illuminance >400), then smart plug (off).
R3	If C (opened) and MS (detected) for 15 minutes, then TV (on).
R4	If C (opened) and MS (undetected) for 20 minutes, then TV (off).
R5	If C (opened) and M (undetected) for 15 minutes, then P (off).
R6	If PS (pressed), then toggle TV
R7	If PS (double pressed), then toggle P.
R8	If PS (held), then turn off TV, air conditioner and P.
R9	If (illuminance <5), then TV (off).

3) Automation rules: We have extracted nine automation rules from the installed smart home application in the form of “automation operation if conditions arise”. The extracted rules of the test bed are listed in Table II.

4) Ethical concerns: All participants are fully aware of installed devices and the application. Experiments did not use sensitive devices such as cameras or microphones. All the data collected was considered as sensitive personal identification information and thus was removed immediately after experiments. For testing purposes, anomalies are generated intentionally and injected into the event log (see Section VII-C). To avoid safety issues, the injected anomalies did not target safety-sensitive devices. We notified participants that there might be some deviation from existing automated rules, but did not disclose the details of the anomalies (e.g. device and time). In addition, participants were advised to maintain a normal lifestyle and not panic if abnormalities were found. The purpose of maintaining their lifestyle habits is to avoid biasing their behavioral during experiments. Details of injected anomalies were presented to participants after testing.

TABLE III. A Partial List of Verified Correlations Obtained from the Testbed

ID	Correlation
$\mathcal{C}1$	$\langle E^{illuminance(\mathsf{MS})}_{<30} \rightarrow E^{power(\mathsf{P})}_{on}\rangle$
$\mathcal{C}2$	$\langle E^{illuminance(\mathsf{MS})}_{>400} \rightarrow E^{power(\mathsf{P})}_{off}\rangle$
$\mathcal{C}3$	$\langle E^{contact(\mathsf{C})}_{open} \wedge E^{motion(\mathsf{M})}_{detect} \rightarrow E^{TV}_{on}\rangle$
$\mathcal{C}4$	$\langle E^{contact(\mathsf{C})}_{open} \wedge E^{motion(\mathsf{M})}_{undetect} \rightarrow E^{TV}_{off}\rangle$
$\mathcal{C}5$	$\langle E^{contact(\mathsf{C})}_{open} \wedge E^{motion(\mathsf{M})}_{detect} \rightarrow E^{switch(P)}_{off}\rangle$
$\mathcal{C}6$	$\langle E^{humidity(\mathsf{MS})}_{<40} \rightarrow S^{contact(\mathsf{C})}_{close}\rangle$
$\mathcal{C}7$	$\langle E^{humidity(\mathsf{MS})}_{>60} \rightarrow S^{contact(\mathsf{C})}_{close}\rangle$

$\mathcal{C}22$	$\langle E^{motion(\mathsf{MS})}_{detect} \rightarrow S^{switch(\mathsf{P})}_{on}\rangle$
$\mathcal{C}23$	$\langle E^{motion(\mathsf{MS})}_{undetect} \rightarrow S^{switch(\mathsf{P})}_{off}\rangle$
$\mathcal{C}24$	$\langle E^{motion(\mathsf{MS})}_{detect} \rightarrow S^{contact(\mathsf{P})}_{closed}\rangle$

B. Training for Testing

1) Training IMEO: In the testbed, 14 E2E correlations are generated from the automation rules. Additionally, it generates 10 E2S correlations in the application channel, 749 correlations in the physical channel, and 417 correlations in the user activity channel, for a total of 1,176 correlations. Then, they are verified using 20,002 event logs collected during the three-week training phase. A total of 96 correlations passed the verfication test. Table III lists portions of the verfied correlations.

2) Findings: Belows share some interesting obervations from the testbed.

O1. While C is a contact sensor, it has an additional correlation, $\mathcal{C}12$= $\langle E^{accelation(\mathsf{C})}_{acitve} \rightarrow E^{contact(C)}_{closed}\rangle$. This implies that an event $E^{accelation(C)}_{acitve}$ is followed by another event $E^{contact(C)}_{closed}$, explaining that a front door (C) usually closes immediately after it opens.

O2. The E2S correlation $\mathcal{C}18$ indicates that the power of P is high only when P is on.

O3. The smart plug P turns a light on and off. Each time P is turned on, the power usage increases (see $\mathcal{C}19$ in the table).

O4. Physical and user activity channel correlations cannot be obtained without mining because they are not included in the application. On the other hand, there are correlations that can be easily extracted from the application but are difficult to mine. For instance, it is difficult to mine correlations that involve delays accurately, but their relations can be derived from rules like R3, R4, and R5.

3) Baseline: This research selects a correlation-only detection method [33], [34], [35] as a baseline approach, because it has been widely used for anomaly detection and is a well-established for mining correlations and rules. It is noted that IMEO is also based on correlation mining. For comparison, the correlation-only method is performed on the same data collected from our testbed.

TABLE IV. A List of Anomalies Selected and Simulated

Index	Anomaly type	Anomaly Creation Method
A1	Faulty/Fake events	To insert events into the data set
A2	Event loss/Interception	To remove events from the data set
A3	Bogus/Fake commands	To toggle from a bogus application
A4	Command failures(cyber)/ Command interception	To cut off devices' power supply
A5	Command failures(physical)	To cover bulbs with a paper
A6	Command failures(physical)	To unplug connected appliances

C. Generating Anomalies

To evaluate IMEO, six anomalies are simulated on the testbed as listed in Table IV. Because the same anomaly often occurs in IoT devices when malfunctions occur, six representative abnormalities are selected. To this end, we refer to the attacks from the literatures investigating IoT attacks and malfunctions frequently discussed in the Samsung SmartThings community. In order to simulate IoT devices as abnormal cases, event logs collected during the three-week training phase are arbitrarily modified. We also disrupt the automation rules, and resulting event logs are used to detect malfunctions. Tests are conducted multiple times for each malfunction. If an IoT attack has the same impact as a malfunction on event logs, we group and simulate it as one case. For instance, since faulty events due to sensor malfunctions and fake events due to attacks have the same impact, a total of 100 MS motion events are grouped and simulated by randomly injecting them into the test event log (see A1 in Table IV).

1) Faulty / Fake events: Events of devices such as motion sensors, presence sensors, and contact sensors are known to be unreliable, so we insert them to simulate the faulty/fake events.

2) Event loss / Interception: To simulate this, we randomly remove events on some devices from the test event log. We primarily select devices for which users have reported discomfort with event loss, such as multi-function sensors, contact sensors, and motion sensors.

3) Bogus / Fake commands: Users have frequently reported inconvenience that both smart lights and plugs have been unexpectedly turned on or off. To simulate these, a bogus application has been developed, that IMEO does not know about, and arbitrary commands to the appplication turn the smart plug on and off randomly.

4) Command failures (cyber) and Command interception: Our experiments simulate command errors and command interceptions in the cyber part of the smart plug. To this end, we make the power of target devices disconnected so that they are unable to respond to any commands. Experiments are conducted several times a day on each target device.

5) Command failures (physical): Command failures in the physical part are simulated in the multi-function sensor (illuminance) and the smart plug. The multi-function sensor is covered by blackout curtains, and appliances are physically unplugged from smart plugs. Two deivces still respond to commands with feedback events, but these commands have no physical effect. For each device, experiments are conducted several times a day.

VIII. Performance Evaluation

This section evaluates the performance of IMEO, the proposed anomaly detection system for IoT devices. First, it shows how correctly the proposed method can detect anomalies. Then, IMEO's performance is compared with the baseline approach (correlation-only detection method, COD) described in Section VII-B, which is followed by demonstration of overall performance in both methods. The last part evaluates the processing time of IMEO.

A. Evaluation Metrics

For evaulation, this paper uses the following metrics. Given the context of anomaly detection, *accuracy* is the ratio of event logs reported correctly (true anomalies and true normal events) to the entire events. *Precision* indicates the ratio of correctly detected anomalies to those reported to be abnormal (i.e., percentage of anomaly detection that is correct), and *recall* indicates the ratio of correctly detected anomalies to all the anomalies (i.e., percentage of anomalies that can be detected). *F1 score* is the harmonic mean of the precision and recall and represents the detection accuracy considering an imbalanced event situation where there are a relatively small number of anomaly events or vice versa.

$$
\begin{aligned}
Accuracy &= \frac{True\,Positive + True\,Negative}{All\,Events} \\
Precision &= \frac{True\,Positive}{True\;\,Positive + False\,Positive} \\
Recall &= \frac{True\,Positive}{True\,Positive + False\,Negative} \\
F1\,Score &= 2 \times \frac{Precision \times Recall}{Precision + Recall}
\end{aligned}
$$

B. Results of Anomaly Detection

Table V summarizes detection results of IMEO across six different anomaly types described in Section VII-C. For three out of six types, IMEO successfully detects all events. The following detection examples illustrate how IMEO detects anomalies.

TABLE V. Detection Results of IMEO Across 6 Different Types of Anomaly Events

Anomaly Index	# of instances	Precision	Recall	Correlation(s) violated
A1	100	98.97%	94.12%	$\mathcal{C}22$
A2	100	100%	100%	$\mathcal{C}12$
A3	100	97.02%	98%	$\mathcal{C}12$, $\mathcal{C}19$
A4	100	100%	100%	$\mathcal{C}11$, $\mathcal{C}12$
A5	30	100%	80%	$\mathcal{C}1$, $\mathcal{C}2$
A6	100	100%	100%	$\mathcal{C}17$, $\mathcal{C}18$

Detection 1. When entering the house, a resident is detected by the contact sensor C attached to the front door, which should be followed by a motion-active event of M in the living room. However, as the motion-active event of M becomes an faulty/fake event, the user activity E2E correlation $\langle E_{open}^{contact(\mathsf{C})} \rightarrow E_{detect}^{motion(\mathsf{M})}\rangle$ is violated and an anomaly is detected.

Detection 2. When a resident leaves home, the motion sensor M in the living room is detected, and the contact sensor M attached to the front door must be detected immediately. Then, the front door is expected to be closed. However, as a malfunction occurs in which the event is lost or intercepted, it violates the correlation $\langle E_{detect}^{motion(M)} \wedge E_{open}^{contact(C)} \rightarrow E_{closed}^{contact(C)}\rangle$, and an anomaly is detected.

Detection 3. The smart plug P shall be off when the illumination sensor in MS exceeds a certain threshold by automation rules R1 and R2. Conversely, if the illuminance is lower than a certain criterion, the plug P should be on. However, the smart home application changes its behavior by ghost/fake commands. An anomaly is detected in violation of the E2S correlation $\langle E_{low}^{illuminance(\mathsf{MS})} \rightarrow S_{off}^{switch(\mathsf{P})}\rangle$ generated by the automation rule.

Detection 4. The smart plug P should behave appropriately according to automation rules related to the illuminance sensor MS. Due to command failure (cyber)/command interception, power supply to the smart plug is temporarily cut off. Consequently, the E2S correlation $\langle E_{low}^{illuminance(\mathsf{MS})} \rightarrow S_{off}^{switch(\mathsf{P})}\rangle$ is violated, resulting in the omission of all instances in this case.

Detection 5. Due to the blackout curtain, the illuminance value in the multi-function sensor MS is detected as low or zero. Thus, E2S correlations related to the illuminance events are detected as violation (anomalies A5). But, 6 instances are missing because the living room is brightened by natural light when anomalies occurr. In additon, as appliances connected to the smart plug P are broken (simulated by physically unplugging power cables), there is no operation at all on the plug. Therefore, events associated with A6 are detected as malfunction.

For Detection 1, 3, and 5, some instances are missing, which should be attributed to the incompleteness of the simulations injecting malfunctions. For example, six instances in Detection 1 are missing because fake motion-active events of M are injected during the time when real motion sensors (M) are logged as event logs. Similarly, two missed instances of Detection 3 are resulted from manipulating the smart plug P with a bogus application that is not allowed for the smart home application. Although malfunction is detected, there is a delay time until it is recorded in the event log because they are randomly manipulated operation states. For example, IoT devices turn on or off themselves by random bogus commands. However, there were cases in which the immediately preceding state of off is recorded although a device is on. In Detection 5, six instances are missing because the living room is brightened by natural light when anomalies occur.

TABLE VI. Anomaly Detection Results of Two Methods

Anomaly Index	Correlation-only (COD)		IMEO	
	Precision	Recall	Precision	Recall
A1	98.36 %	95.6 %	98.97 %	94.12 %
A2	91.11 %	82.79 %	100 %	100 %
A3	100 %	100 %	97.02 %	98 %
A4	100 %	100 %	100 %	100 %
A5	100 %	66.67 %	100 %	80 %
A6	100 %	100 %	100 %	100 %

TABLE VII. Comparison of Overall Performance

Method	Precision	Recall	F1 score	Accuracy
IMEO	99.33%	95.35%	0.97	99.98%
COD	97.83%	94.12%	0.95	99.32%

C. Performance Comparison

As summarized in Table VI, IMEO achieves better performance in 5 types. In A2 (faulty and fake events), especially, precision and recall increase from 91.11% and 82.79% to 100% in both. And recall in A5 (physical command failures) increases from 66.67% to 80%. COD can detect E2E, E2S correlation violations in smart home applications, but 17.22% events are lost for anomalies with event interception. In A3 (bogus and fake commands), however, there are small performance degradation.

Table VII compares overall performance of anomaly detection with two methods. IMEO has an average detection precision of 99.33% and a recall of 95.35% across 6 different types of anomaly events, while COD has 97.83% and 94.12%, respectively. It is noted that two methods show similar results in accuracy: 99.98% with IMEO and 99.32% with COD. However, IMEO performs better than COD with respect to the F1 score. This implies that IMEO is able to detect anomalies well even in a real-world smart home environment where malfunctions and/or attacks could occur rarely.

D. Fast Anomaly Detection

We believe that it is critical to reduce anomaly detection time using correlation data for increasing the security of smart home automation. Once detecting an anomaly, in this sense, IMEO memorizes a detection record as described in Section VI-C. When the same malfunction occurs later, it can immediately determine if the event is abnormal by searching for the record history. On the other hand, if the future malfunction is not the same as the history, additional comparisons are made in IMEO, which is likely to take more time. Thus, our experimentation study also measures how long it takes to detect anomalies when using the baseline method and the proposed method. As compared in Table VIII, IMEO takes 1,666 seconds while COD takes 2,647 seconds on average. This shows that the fast anomaly detection process in IMEO can improve performance by 58.9%.

TABLE VIII. Processing Time to Detect Anomalies

	Correlation only (COD)	IMEO
Processing time	44m 07s	27m 46s

IX. Conclusion and Discussion

As IoT devices are integrated and combined with the physical environment, anomalies in them can have serious consequences in our daily lives. Previous solutions that only used a data mining technology to detect anomalies have been struggling with high rates of false alarms and missing many actual anomalies. It also takes a long time to detect anomalies even if they correctly detect anomalies. To overcome the limitations, this paper proposed an anomaly detection system, named IoT Malfunction Extraction Observer, that made use of semantic information at smart homes such as smart home applications, configurations, device types, and installation locations. IMEO used event logs to detect malfunctions to take advantage of semantic information from different channels (smart home applications, physical activities, and user activities). It also provided an easier and faster way to detect frequently repeated malfunctions. These allowed for more reliable malfunction detection. We developed and deloyed the proposed method in a real-world testbed. Experiments were conducted with various abnormal instances, and the results demonstrated that the proposed method achieved higher performance of detection accuracy with faster processing time.

A. Discussion

The evaluation results are very promising, but we consider IMEO as the first step in the anomaly detection using semantic information in smart homes. IMEO has some limitations that we are trying to address in the future.

First, correlations due to user activity channels are useful for detecting anomalies, but false events can occur if there is a deviation in user activity. Such cases rarely occur, but we found them during evaluation. Some events generated events that were irrelevant to the correlation when a user encountered an abnormal situation (e.g., a state with an open front door). One day, for instance, a person wants to read in his or her living room, so he or she turns on the extra light, not the living room light, to increase the illumination. If this rarely happens during the experiments, malfunctions can occur. The key question is how to constantly update correlations to adapt to changes in IoT devices and user activities.

Next, IMEO can only compare and experiment with correlations that result in forward and backward events within a short interval. Correlations that require long intervals, such as the relationship between turning on the air conditioner and temperature events, cannot be detected yet.

Third, the physical constraints of IoT devices are problems to be solved. For example, some IoT devices may be placed relatively far away, and physical channel correlations between them may be very small. One way to solve this problem is to explore the correlations across the entire home rather than separate rooms, which will lead to more correlations between IoT devices. The opposite can also be considered. Recently, the size of houses has decreased, and more and more IoT devices are being installed in the houses. In this case, the redundancy of the correlations can be strong and this information needs to be interpreted differently.

Last, an attacker who knows correlation, that is, semantic-based detection, can construct an attack that does not violate correlation to avoid detection. The study of robustness to this type of attack will be an interesting topic. The key to IMEO execution is that it imposes additional constraints on the attacker. In the correlation channel, each attribute is included in at least four correlations. Attacking the device without violating the correlation is a barrier for the attacker.

***Abstract*—Multimodal sentiment analysis is a traditional text-based sentiment analysis technique. However, the field of multi-modal sentiment analysis still faces challenges such as inconsistent cross-modal feature information, poor interaction capabilities, and insufficient feature fusion. To address these issues, this paper proposes a cross-modal sentiment model based on CLIP image-text attention interaction. The model utilizes pre-trained ResNet50 and RoBERTa to extract primary image-text features. After contrastive learning with the CLIP model, it employs a multi-head attention mechanism for cross-modal feature interaction to enhance information exchange between different modalities. Subsequently, a cross-modal gating module is used to fuse feature networks, combining features at different levels while controlling feature weights. The final output is fed into a fully connected layer for sentiment recognition. Comparative experiments are conducted on the publicly available datasets MSVA-Single and MSVA-Multiple. The experimental results demonstrate that our model achieved accuracy rates of 75.38% and 73.95% , and F1-scores of 75.21% and 73.83% on the mentioned datasets, respectively. This indicates that the proposed approach exhibits higher generalization and robustness compared to existing sentiment analysis models.**

I. Introduction

2023 Global Digital Report [1] indicates that there are currently 5.16 billion internet users and 4.76 billion social media users worldwide, accounting for 59.4% of the global population. The global social media user base has grown by 3.0% year-on-year, equivalent to 137 million people. With the continuous flourishing development of social networks and internet-enabled mobile devices, there is a growing diversity of expressions for emotions or opinions on various topics posted on social media and various website platforms. This evolution has transitioned from initial text information to gradually include multimodal information such as images, audio, and videos. Consequently, utilizing multimodal feature information for sentiment analysis has become one of the research hotspots in recent years [2], and it has been successfully applied in various potential applications, including decision-making [3], personalized advertising [4], emotion retrieval [5][6], and other domains.

Early sentiment analysis (SA) models mainly focused on text, and manual features were usually designed using limited human knowledge. Text features can quickly summarize subjective emotions, but cannot fully describe the highly abstract nature of emotions. For single-modal approaches, extreme cases such as irony often posed challenges in meeting sentiment analysis needs. In recent years, the rise of deep learning has provided powerful tools for Multimodal Sentiment Analysis (MSA). MSA leverages massive multimodal data generated on social media for integrated analysis, combining various multimodal features. This approach not only enables a more comprehensive understanding of user emotional expressions but also effectively addresses limitations of single-modal methods in handling complex emotions, ambiguity, or extreme cases like irony [7].

However, there are still some shortcomings in multimodal feature fusion methods. In early multimodal fusion methods, they either simply concatenate the extracted multimodal features [8] or roughly integrate relationships between images and text on a horizontal feature level [9] to obtain concatenated or linearly fused feature representations. These methods lack in-depth exploration of the complex relationships between multiple modal features. On the other hand, information loss, redundancy, and noise among different modal features can affect sentiment judgments. Effectively utilizing the complex correlations between high-level abstract features and low-level abstract features across modalities and improving method fusion effectiveness pose significant challenges in the field of multimodal analysis [10].

In order to solve the problem of multi-modal model fusion, this paper proposes a Multimodal Sentiment Analysis model, named CLIP-CA-CG, based on Contrastive Language-Image Pretraining (CLIP) [11], cross-attention, and cross-modal gating.The CLIP model maps text and images into a shared embedding space, making related text descriptions and image representations in this space closer, modeling at fine-grained features, and the model uses contrastive learning and pre-training. This method can learn feature representations with good generalization capabilities and reduce computational pressure and speed. Additionally, considering the complementary role of the contextual information of image text in sentiment analysis, where the same word may cause different emotions in different contexts, so this model integrates the original cross-modal feature information through the self-attention mechanism. This can extract high-level abstract features while maximizing the fusion of environmental features, which helps the model learn the correlation between different modalities to more comprehensively explore multi-modal emotions.

The remainder of the paper is structured as follows: Section II will review related research on sentiment analysis of unimodal and multimodal models, Section III will provide the methods proposed in this study, Section IV will introduce the experimental analysis and discussion, and finally, conclusion and future works are provided on Section V.

II. Related Work

A. Single-modal Sentiment Analysis

1) Text sentiment analysis: In the past, conventional techniques for text sentiment analysis primarily utilized dictionary methods [12]. In this approach, the sentiment scores of individual words within the text are combined based on predefined values. Text sentiment classification methods can be roughly divided into two categories, namely dictionary based models and machine learning models. Hu et al. [13] predicted the semantic analysis orientation of opinion sentences by using adjectives as prior positive or negative polarity. Taboada et al. [14] introduce a dictionary-based method called the Semantic Orientation Calculator (SO-CAL), which not only utilizes word dictionaries annotated with semantic orientations but also incorporates reinforcement and negation factors. Barbosa et al. [15] proposed a two-step sentiment classification method for Twitter messages using online tags as training data.

With the evolution of machine learning, Pang et al. [16] are the first to introduce machine learning methods into text sentiment classification, including Naive Bayes (NB) [17], Support Vector Machine (SVM) [18], and Maximum Entropy Classifier. However, machine learning performance heavily relies on the quality and quantity of the training set. Inspired by the success in the field of Natural Language Processing (NLP), Kim et al. [19] first apply Convolutional Neural Networks (CNN) in text sentiment classification. Tai et al. [20] considered the complex structure of text features and introduced Tree LSTM for sentence sentiment classification. Tang et al. [17] first combined CNN and LSTM to obtain text sentence representations, and then used recursive neural networks to encode their intrinsic connections [21]. Researchers also adopt various neural network models for sentiment analysis, such as hierarchical attention network model (HAN) to select important feature information [22] and facial expression recognition network based on enhanced attention [23].

As large models gain prominence, word embeddings and pre-trained models have seen significant success in sentiment analysis. Word2Vec [24] maps semantically similar words to similar vector spaces, while GloVe [25] derives semantic relationships between words based on global co-occurrence. ELMo [26] introduces context-aware embeddings, allowing word representations to vary based on their specific contexts within sentences. The emergence of BERT [27] further propels the development of sentiment analysis. Built on self-attention mechanisms, BERT captures long-range dependencies and contextual information more effectively. This context-sensitive representation enables BERT to achieve outstanding performance in sentiment analysis tasks, particularly excelling in handling complex sentence structures and context-dependent sentiment expressions.

2) Visual sentiment analysis: Visual sentiment analysis has undergone significant development. In the early stages, image sentiment analysis involved inferring emotions from low-level features. For example, Machajdik et al. [28] predict emotions by extracting features such as texture and color. Borth et al. [29] used the SentiBank model to identify adjective noun pairs (ANP) and extract visual semantic information.Yuan et al. [30] proposed an image sentiment method that utilizes 102 intermediate visual attributes to make the classification results more interpretable.

In recent years, with the continuous advancement of deep learning, researchers have explored the coordination of image color and content in relation to emotional expression. Yang et al. [31] developed a multi task framework to optimize visual emotion models by considering mixed images of multiple emotions. Ruan et al. [32], for instance, employ CNN networks to extract both content and color features from images. By introducing attention mechanisms and sequence convolution, they adeptly model the correlations between content and color features. To delve deeper into the semantic associations among visual emotion regions, Zhang et al. [33] utilize a fully convolutional neural network for image saliency detection. The CNN selection strategy is employed for filtering, and ultimately, Transformer encoders [34] are used to analyze the correlations between different emotion regions, thereby obtaining a comprehensive emotional output.

B. Multimodal Sentiment Analysis

In the field of multimodal research, psychologists have confirmed that emotions are primarily influenced by the joint effects of multimodal data, with visual-text emotional features being particularly prominent. The same piece of text pairs with different images may elicit completely opposite emotions. In early multimodal sentiment analysis, researchers concatenate, added, or weighted shallow features. Cao et al. [35], for example, analyze cross-media sentiment analysis through visual and textual methods. Yu et al. [36] use a pre-trained CNN model to extract feature representations and ultimately fused textual features for sentiment classification.Zhao et al. [37] proposed an image text consistency driven method that utilizes text features, social features, low-level and intermediate visual features, and image text similarity.

As deep learning continues to evolve, mid-term model fusion and late-stage decision fusion methods are showing remarkable success. Yang et al. [38] achieve good results by stacking and gradually pairing different feature vectors on datasets like CMU-MOSI. Poria et al. [39] detail an approach using Long Short-Term Memory (LSTM) networks to capture interdependencies and relationships between utterances in multimodal sentiment prediction. Huang et al. [40] proposed a Deep Multimodal Attention Fusion (DMAF) method, which utilizes both intermediate and post fusion, combining unimodal features and internal cross modal correlations to improve accuracy. Liu et al. [41] introduce a shared memory attention mechanism, capturing interactions between two modalities and their impact on sentiment using similar features.

In recent years, multimodal tasks have made significant progress, benefiting from the latest developments in visual language models. Cheema et al. [42] apply CLIP in multimodal sentiment analysis, demonstrating its potential as a powerful baseline for emotion prediction tasks in tweets. Arevalo et al. [43] propose the Gated Multimodal Unit (GMU) model, which controls the influence of input modalities on unit activation levels for data fusion. Gupta et al. [44] introduce a Collaborative Attention Model based on RoBERTa and FiLMed ResNet, addressing the issue of visual-text inconsistency through joint attention mechanisms.

Although multi-modality has made certain progress in emotional tasks, there is still much room for improvement in image-text feature interaction. Most existing methods simply connect features extracted from different modalities, or simply learn The relationship between images and text leads to bias in complex tasks. Considering the complex relationship between the two modalities and the efficiency of the model, we use a pre-trained model to extract feature networks while capturing the potential alignment between image regions and text words, and finally consider the complementary role of individual modalities in emotion prediction. , situational features are also integrated into our network.

III. Methods

This paper proposes a cross-modal sentiment model, CLIP-CA-CG, based on CLIP image-text attention interaction, as illustrated in Fig. 1. The model architecture consists mainly of a feature extraction layer, an interaction attention layer, a gating fusion layer, and a regression layer. The feature extraction module utilizes existing methods for extracting features from images and text, producing feature vectors for each and a fused feature vector. The interaction attention module enhances the feature representation of images and text based on a multi-head attention mechanism, further exploring consistent emotional features in the image-text pairs. The gating fusion module aligns high-level abstract image-text features, fuses global concrete features, and introduces an adaptive cross-selective block to determine how much interaction information each component should transmit. Finally, sentiment is comprehensively predicted through a multi-layer perceptron and a Softmax regression layer.

A. Image-Text Feature Extraction

The original input of the model consists of two modalities: text and image. For the raw textual data, a set of textual data T can be represented as n words forming $T = [T_1, T_2, ..., T_n]$, where n represents the maximum length of the sequence. Considering the need for a more comprehensive understanding of context and capturing bidirectional language relationships, this paper utilizes the pre-trained RoBERTa (Robustly optimized BERT approach) model to encode the text sequence T. The advantage of the RoBERTa model lies in further optimizing the BERT model by adjusting training tasks, datasets, learning rates, etc. Additionally, unlike BERT, RoBERTa does not add special token embeddings at the beginning and end of the input text, enhancing the generalization of text feature extraction. The textual data is embedded into vectors $F_{T-RoBERTa}$ by the RoBERTa model, where each word is represented in the vector space.

$$F_{T-RoBERTa} = [f_1, f_2, ..., f_x, ..., f_N] \subseteq R^{d \times N} \tag{1}$$

In the equation: f_x represents the contextual semantic feature of the x-th word, d is the output dimension of the RoBERTa model (768), and N is the maximum length of the RoBERTa model's word encoding.

Then, to summarize the contextual information in the sentence, a Bidirectional Gated Recurrent Unit (Bi-GRU) [45] is employed. The combination of RoBERTa and Bi-GRU ensures the learning of text semantics while preserving multi-granular, multi-level information extraction from the text. The vector $F_{T-RoBERTa}$ is passed through the Bi-GRU gated units to further extract and generate the feature h_x.

$$h_x = [\overrightarrow{GRU}(f_x) \oplus \overleftarrow{GRU}(f_x)] \subseteq R^d \tag{2}$$

In the equation: h_x is the feature extracted from f_x through Bi-GRU, $\overrightarrow{GRU}(f_x)$ denotes obtaining the forward hidden state information, and $\overleftarrow{GRU}(f_x)$ represents acquiring the backward hidden state information. Finally, the average of the bidirectional hidden state information, h_x, is obtained, yielding the ultimate textual semantic feature F_T.

$$F_T = [h_1, h_2, ..., h_N] \in R^{d \times N} \tag{3}$$

For image features, ResNet introduces a residual network structure, addressing the issue of gradient vanishing that arises with increasing network depth. Moreover, deeper network structures can handle images under different sizes, angles, and lighting conditions. In this paper, pre-trained ResNet50 is used for feature extraction. Simultaneously, each original image is cropped to 224×224×3 as input for ResNet50. After convolution and pooling, the image feature F_{In} is obtained. Finally, aligning visual feature F_{In} and textual feature FT through a perceptron results in the ultimate image feature F_I.

$$F_I = Linear(F_{In}) \tag{4}$$

After obtaining the original visual and textual features, this paper further utilizes Contrastive Language-Image Pre-training (CLIP) to integrate image and text features, thereby establishing a close connection between them. The core idea of CLIP involves using contrastive learning to represent images and text in a shared embedding space. It maximizes the cosine similarity of paired image and text embeddings while minimizing the cosine similarity of unpaired image and text embeddings. This ultimately brings related images and text closer in this shared space. The original visual-text features, after passing through the CLIP model, result in the fused feature F_{IT}.

$$F_{IT} = CLIP(F_I) \odot CLIP(F_T) \tag{5}$$

B. Multi-Head Attention Mechanism

Multi-Head Attention (MHA) is an extended form of the self-attention mechanism initially introduced in the Transformer model. The core idea is to use multiple distinct attention heads, allowing the model to learn various attention patterns in parallel, with each head focusing on different parts of the sequence. Subsequently, by concatenating the outputs of these heads and projecting them through a linear layer, the final output of multi-head attention is generated. The input to the self-attention mechanism consists of key vectors, query vectors, and value vectors. The mechanism calculates the similarity between query and key vectors, applies a Softmax operation to obtain attention weights for weighted summation, resulting in the final self-attention output as expressed in Formula (6).

$$Attention(Q, K, V) = Softmax(\frac{QK^T}{\sqrt{d_k}})V \tag{6}$$

Fig. 1. Overall architecture diagram of the model.

In the equation: Q represents the query matrix, K represents the key matrix, V represents the value matrix, and dk is the dimensionality of the query vectors. Multi-Head Attention is an operation that stacks multiple self-attention mechanisms to focus on different representations of information at different positions.

$$MHA(Q, K, V) = Concat(head_1, ..., head_h)W^O \tag{7}$$

$$head_i = Attention(QW_i^Q, KW_i^K, VW_i^V) \tag{8}$$

In the equation: $head_i$ represents the calculation of the i-th attention head, W_i^Q, W_i^K,W_i^V are the weight matrices for linear mappings, and W^O is the weight matrix for the linear mapping of the output. Multi-Head Attention typically includes h attention heads, each with independent weights. The schematic diagram of the multi-head attention mechanism used in this paper is shown in Fig. 2.

By utilizing the image-text features from CLIP, we can obtain more comprehensive global information. In this study, we choose the fusion feature F_{IT} as the main modality for multi-head attention, while visual feature F_I and text feature F_T serve as secondary modality inputs. The main modality learns the sequential information of the secondary modality and ultimately improves the convergence speed and expressive capability of the model through forward propagation. The final output yields feature vectors $F_{image-IT}$ and $F_{text-IT}$.

$$F_{image-IT} = LayerNorm(F_I + MHA(Q_I, K, V)) \tag{9}$$

$$F_{text-IT} = LayerNorm(F_T + MHA(Q_T, K, V)) \tag{10}$$

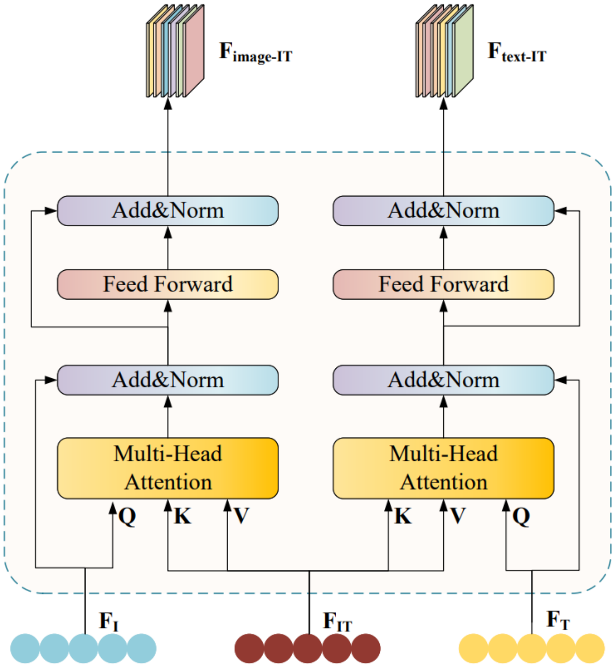

Fig. 2. Principle diagram of multi-head attention mechanism.

C. Cross-modal Gating Fusion

The cross-modal joint feature vector is generated through the interaction and fusion of features from two modalities. It allows vector features to pass fragmentary messages across both modalities for cross-modal interaction. However, in practice, there are still issues such as information redundancy, loss, noise, and region misalignment. To overcome these drawbacks and fully utilize the complementary information of modality correlations contained in the joint features, this paper further proposes a cross-modal gating fusion module. This module adaptively controls the fusion strength through model training to obtain multi-modal fusion features by concatenating them. Considering the significant role of environmental information in sentiment analysis, where the same object may evoke different emotions in various text or visual contexts, it is essential to supplement the fusion with the original image and text features. The structure of the cross-modal gating fusion is illustrated in Fig. 3.

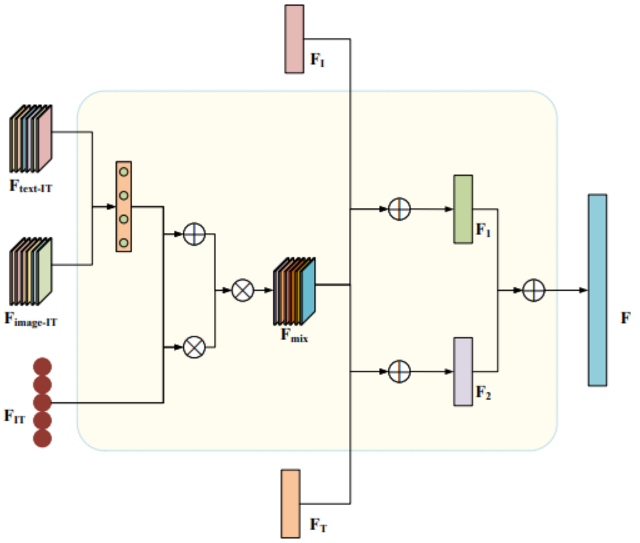

Fig. 3. Cross-modal gated fusion structure diagram.

Firstly, the feature vectors $F_{image-IT}$ and $F_{text-IT}$ obtained through multi-head attention are concatenated to achieve the weight adjustment of joint features. This preserves effectively correlated information in the features, ultimately obtaining the complementary information feature FVT from both, as shown in Formula (11).

$$F_{VT} = [F_{image-IT}, F_{text-IT}] \quad (11)$$

To balance obtaining superior global feature information and the output from higher layers, the output obtained from the features F_{VT} and the globally extracted features F_{IT} by CLIP are used as inputs for fusion. After concatenation and non-linear transformation, the final mixed visual-textual feature information F_{mix} is obtained.

$$F_{mix} = \sigma(Concat(F_{IT}, F_{VT}), Norm(F_{IT}, F_{VT})) \quad (12)$$

In the equation, the σ function represents the fusion of concatenated visual-textual features and non-linearly transformed visual-textual features through trainable parameters. Finally, considering the complementary role of contextual information, we combine the single-modal contextual information feature with the mixed feature F_{mix}, and ultimately generate the final feature F through an MLP.

$$F_1 = MLP(F_I \oplus F_{mix}) \quad (13)$$

$$F_2 = MLP(F_T \oplus F_{mix}) \quad (14)$$

$$F = \lambda F_1 + (1 - \lambda) F_2 \quad (15)$$

In the equation, λ represents the concatenation operation, which is used to control the balance between aggregating visual and textual features.

D. Multimodal Sentiment Classification

The ultimate goal of sentiment analysis is to accurately classify the emotions expressed in multimodal data, such as Positive, Neutral, Negative, etc. To achieve this, the multimodal fusion feature F obtained through the multi-head attention and fusion module is fed into a fully connected layer and a Softmax layer, ultimately producing a probability distribution y for possible sentiment labels.

$$y = Softmax(Linear(F)) \quad (16)$$

In the equation: The Linear network represents the fully connected layer, and the classification results are obtained through Softmax. For model training, this paper utilizes the Adam optimizer to train the model, minimizing the cross-entropy loss.

IV. Experimental Analysis

A. Datasets

In this study, to validate the sentiment analysis performance of the CLIP-CA-CG model, we utilize two publicly available datasets, MVSA-Single and MVSA-Multi, established by Niu et al. [46]. These datasets are collected from the popular social media platform Twitter. The MVSA-Single dataset comprises 5129 pairs of images and text, while the MVSA-Multi dataset includes 196,000 pairs of images and text. The MVSA project provides standardized benchmarks, representing a significant development in the multimodal domain. The data is labeled with sentiment polarity, including positive, neutral, and negative emotions.

For a fair comparative study, we conduct preprocessing on both datasets. During this process, we remove cases where there is emotional inconsistency between the image and text labels, such as one label being positive (or negative) while the other is neutral. Such cases are considered as having a positive (or negative) sentiment label. The resulting new datasets are denoted as the revised MVSA-Single dataset and revised MVSA-Multi dataset, as shown in Table I.

TABLE I. MVSA-Single and MVSA-Multi Datasets

Dataset	Positive	Neutral	Negative	Total
MSVA-Single	2683	470	1358	4511
MSVA-Multiple	11318	4408	1298	17024

B. Implementation Details

In the experiments, we randomly divide the new datasets into training, validation, and test sets, with a data split ratio of 8:1:1. Regarding the experimental environment and parameters, the proposed model is implemented using Python 3.7, developed in the PyTorch 1.9.0 framework, and executed on CUDA 12.0. To eliminate external influences, all experiments are conducted on a server with 64GB of memory and an NVIDIA GeForce RTX 4090 GPU.

In terms of hyperparameter configuration for the model, this experiment employs the cross-entropy loss function and mean squared error loss function for computing the loss of classification and regression tasks, respectively. Adam is utilized as the optimizer for the CLIP-CA-CG model, initialized with a learning rate of 0.0001, executed over 100 epochs, with a 10-fold reduction in learning rate every 10 epochs, and a weight decay of 1e-5. For visual encoding,we utilize the pre-trained ResNet50 to extract image features, taking as input pre-processed image information in the form of a 224×224×3 matrix. In text encoding, we employ pre-trained RoBERTa for extracting text features, where the dimensionality of the extracted word vectors is 768, and subsequently align them for input into the model network. Given the disparate sample sizes in the two datasets, the batch size is set to 64 for the MVSA-Single dataset and 128 for the MVSA-Multi dataset. The initial hyperparameter settings are configured as shown in Table II.

TABLE II. Experimental Parameter Environment

Parameter	Value
Batch_size	64 / 128
Learning_rate	0.0001
Optimizer	Adam
Dropout	0.3
Epochs	100
Text_dimension	768

Finally, to validate the model's effectiveness, comparative experiments are conducted, wherein the proposed model is compared with other mainstream single-modal and multi-modal fusion experiments. Performance evaluation metrics include accuracy and $F_{1-score}$ (F1), calculated as follows.

$$P = \frac{T_P}{T_P + F_P} \tag{17}$$

$$R = \frac{T_P}{T_P + F_N} \tag{18}$$

$$F_1 = \frac{2 \times P \times R}{P + R} \tag{19}$$

$$Acc = \frac{T_P + T_N}{T_P + T_N + F_P + F_N} \tag{20}$$

In the equation: T_P represents true positive, T_N represents true negative, F_P represents false positive, F_N represents false negative, P represents precision, and R represents recall.

C. Model Comparison Experiment

In this study, we compare the proposed model with the following benchmark models in terms of accuracy and F1 score. SentiBank and SentiStrength [47] models rely solely on traditional statistical features and are unable to effectively extract key intrinsic features from both images and text, resulting in lower accuracy. Compared to other models, CNN-Multi [48] extracts text and image features separately using two individual CNNs. Benefiting from the powerful feature extraction capability of deep neural networks, this enhances the expressiveness of emotions, and the final prediction is made by connecting these features. The DNN-LR model [49] adopts transfer learning by using pretrained models and utilizes logistic regression for decision analysis. The Co-Memory model [9], introducing a fusion module in sentiment analysis, promotes feature connections between modalities. The MVAN model [38] enhances the semantic image-text features by employing a memory network module on the basis of a multi-view attention network, further improving dataset accuracy. The CLMLF model [50] utilizes contrastive learning to enhance the representation capability of image-text features, fostering relationships between images and text, thus improving model accuracy. The ITIN model [51] introduces cross-modal alignment operations and an adaptive cross-modal gate fusion module, significantly improving accuracy in sentiment analysis tasks.

TABLE III. Comparative Experiments of Several Models

Model	MVSA-S		MVSA-M	
	Accuracy (%)	F1 (%)	Accuracy (%)	F1 (%)
SentiBank&SentiStrength	52.05	50.08	65.62	55.36
CNN-Multi	61.20	58.35	66.39	64.19
DNN-LR	61.42	61.03	67.86	66.33
Co-Memory	70.51	70.01	69.92	69.83
MVAN	72.98	72.98	72.36	72.30
CLMLF	75.33	73.46	72.00	69.83
ITIN	75.19	74.97	73.52	73.49
CLIP-CA-CG (Ours)	**75.38**	**75.21**	**73.95**	**73.83**

As indicated in Table III, the proposed CLIP-CA-CG model achieves the best performance compared to other benchmark models on both the MVSA-S and MVSA-M datasets. This suggests that our model can effectively exploit the correlations between different modalities. Additionally, by preprocessing the model, we can effectively reduce the difficulty of model training. Finally, the model considers the adjustment of weights based on joint features between modalities and environmental features, thus achieving more accurate sentiment classification.

Compared to the SentiBank and SentiStrength models, both SentiBank and SentiStrength models exhibit inferior overall performance. This is attributed to the conventional feature statistics often failing to comprehensively encapsulate the intrinsic features of multimodal information, leading to missing or erroneous feature information inputted into the model, consequently resulting in inaccurate model predictions.

The CNN-Multi, DNN-LR, and Co-Memory models all utilize deep learning for feature extraction, which facilitates the extraction of data features. It is noteworthy that the Co-Memory model introduces a fusion module into sentiment analysis, resulting in a significant improvement in model accuracy. This suggests that effectively integrating image and text features is a viable approach for enhancing the accuracy of multimodal sentiment analysis. Although this approach can learn invariant or specific representations across multiple modalities, it also brings about issues such as excessively redundant feature representations, thereby affecting the effectiveness of fused features.

The MVAN, CLMLF, and ITIN models all incorporate attention mechanisms, which, as observed from the results, further enhance model performance. This indicates that attention mechanisms can focus on more valuable and contributory features. Additionally, considering issues such as feature fusion across modalities and feature redundancy, methods such as contrastive learning and adaptive cross-modal gating fusion have also, to some extent, improved model performance.

Building upon the strengths and weaknesses of baseline models, the proposed CLIP-CA-CG model first enhances the representation capability of image-text data by leveraging pre-trained vision and language models along with contrastive learning techniques. Concurrently, it incorporates a multi-head attention mechanism to capture and express image-text features at a finer granularity. Finally, by exploiting the interaction between images and text, the model utilizes a fusion interaction module to extract both global and focal features of image-text features. These features are complemented with environmental features for more accurate sentiment prediction. Experimental results demonstrate superior performance across public datasets.

D. Ablation Experiment

To validate the performance improvement of each module in multimodal sentiment analysis, we conduct a series of experiments focusing on image and text feature extraction methods, feature fusion methods, etc., to verify the effectiveness of the CLIP-CA-CG model. The details of the model ablation experiments are explained below.

- V_{only} and T_{only}: Represent the evaluation of sentiment analysis using only the visual modality and only the text modality, respectively.
- CLIP-CA-CG w/o Clip: Remove the Clip image-text contrastive model from the complete model, eliminate further feature extraction and fusion, and directly input the preliminary extracted image features and text features into the multi-head attention module.
- CLIP-CA-CG w/o CA: Remove the multi-head attention mechanism from the complete model, and directly input the obtained joint features along with the image and text features into the fusion module.
- CLIP-CA-CG w/o CG: Remove the cross-modal interaction fusion module from the complete model. Instead, use a simple concatenation method to combine multimodal data and process the fused features with an encoder.

TABLE IV. Ablation Experiments on MSVA-Single Dataset

Model	**Accuracy (%)**	**F1 (%)**
V_only	63.04	62.76
T_only	71.87	71.19
CLIP-CA-CG w/o Clip	73.65	73.36
CLIP-CA-CG w/o CA	72.15	71.56
CLIP-CA-CG w/o CG	72.41	71.98
CLIP-CA-CG (Ours)	**75.38**	**75.21**

According to the experimental settings, we conduct ablation experiments on the MSVA-Single dataset. As shown in Table IV, proposed CLIP-CA-CG model performs the best, and the absence of any modality or module results in a decrease in model performance. The V_{only} and T_{only} models, which extract features and make sentiment judgments using only a single modality, have the lowest accuracy compared to other experiments. The accuracy of the text model is 71.87, while the accuracy of the image model is only 63.04. This indicates that in the field of sentiment analysis, text has a stronger expressive capability than images. Additionally, incorporating multimodal features can complement information, improving the performance of sentiment analysis models. This provides a solid foundation for subsequent multimodal fusion experiments.

CLIP-CA-CG w/o Clip, CLIP-CA-CG w/o CA, and CLIP-CA-CG w/o CG models respectively remove the Clip contrastive learning module, the multi-head interaction attention module, and the gate fusion module. The experimental results show that the removal of these three modules led to varying degrees of performance degradation in all evaluation metrics. This indicates that these three modules have a promoting effect on the proposed CLIP-CA-CG model.

Specifically, the CLIP-CA-CG w/o Clip model, lacking the utilization of the CLIP pre-trained model, suffers from partial information interaction loss in the early feature extraction, affecting the model's feature fusion to some extent. The CLIP-CA-CG w/o CA model, due to the removal of the attention mechanism, hinders the effective capture of complex relationships between images and text. It fails to extract information components between modalities, making it challenging to ensure the model's robustness at a fine-grained level. The CLIP-CA-CG w/o CG model, obtaining fusion features through direct concatenation, often experiences information loss, redundancy, and noise, leading to a reduction in model accuracy.

V. Conclusion

Addressing the challenges of insufficient inter-modal information, information redundancy, and low effectiveness of fused features in existing multi-modal sentiment analysis, this paper proposes a cross-modal sentiment model, CLIP-CA-CG. The paper first elaborates on the overall architecture of the CLIP-CA-CG model. This model utilizes pre-trained RoBERTa and ResNet50 models to extract textual and visual features. Subsequently, the obtained features are further processed through CLIP contrastive learning to acquire deeper-level features. The model then employs multi-head attention mechanisms and cross-modal fusion modules for global feature, fine-grained feature, and contextual feature extraction, ultimately the control feature weights are input to the fully connected layer for sentiment analysis. In the experimental setup, this paper conducts comparative experiments and ablation experiments with several commonly used multi-modal sentiment analysis models on the public datasets MSVA-Single and MSVA-Multiple. The experimental results show that the accuracy of the CLIP-CA-CG model reaches 75.38% and 73.95%, and the F1 score reaches 75.21% and 73.83%, respectively, validating the generalization and robustness of the CLIP-CA-CG model.

The paper also has some limitations. Due to constraints on data resources, we did not further validate the robustness of the model using other publicly available datasets. Additionally, only two modalities, namely image features and text features, were utilized for experimentation, which might lead to misjudgment in complex scenarios. In future research, we intend to incorporate more modalities to form a more sophisticated multi-modal sentiment analysis model, aiming to further improve the accuracy and generalization of sentiment analysis.

Acknowledgment

***Abstract*—This paper presents a comprehensive study on the evaluation of algorithms for automating learning outcome predictions, with a focus on the application of machine learning techniques. We investigate various predictive models (logistic regression, random forest, gaussian naive bayes, k-nearest neighbors and support vector regression) to assess their efficacy in forecasting student performance in educational settings. Our experimental approach involves the application of these models to predict the outcomes of a specific course, analyzing their accuracy and reliability. We also highlight the significance of an automation process in facilitating the practical application of these predictive models. This study highlights the promise of machine learning in advancing educational assessment and paves the way for further investigations into enhancing the adaptability and inclusivity of algorithms in various educational settings.**

Keywords*—Machine learning; predictive learning outcomes; education; logistic regression; k-nearest neighbors; Gaussian Naive Bayes; Random Forest; support vector regression

I. Introduction

In the evolving landscape of educational technology, machine learning (ML) emerges as a pivotal tool, revolutionizing decision-making processes across various domains, particularly in education [1]. The integration of ML in educational settings has led to significant advances, such as personalized learning paths based on student data analysis, automated grading systems, and predictive models for student performance and learning outcomes [2]. These innovations underscore the transformative potential of ML in enhancing educational effectiveness and efficiency.

Despite these advances, the field faces several challenges. The complexity of educational data, characterized by its multidimensionality and the dynamic nature of learning processes, presents a significant hurdle [3]. Traditional ML algorithms often struggle to capture the nuanced patterns of learning, leading to inaccuracies in outcome predictions. Furthermore, the ethical considerations surrounding data privacy and the potential biases in algorithmic decisions add layers of complexity to the deployment of ML in education.

A critical overview of ML algorithms reveals their potential in predicting learning outcomes. These algorithms range from traditional statistical models to advanced deep learning networks, each offering unique perspectives in understanding student performance [2]. The importance of automation in this context cannot be overstated. Automation, in its essence, transforms the labor-intensive and often subjective process of outcome prediction into an objective, efficient, and scalable task [4].

An unsolved problem in this domain is the comprehensive automation of learning outcome predictions. While some progress has been made, existing systems either require significant manual intervention or fail to adapt to the evolving educational landscapes [1]. This gap not only hinders the scalability of ML solutions in education but also limits the potential for real-time, adaptive learning interventions.

The importance of this study lies in its focus on addressing these challenges by proposing an innovative approach to automate learning outcome predictions. By leveraging the latest advancements in deep learning and data analytics, this paper aims to develop a model that can accurately predict learning outcomes across diverse educational settings, thereby facilitating more personalized and effective learning experiences.

The novelty of our work is twofold. First, it introduces a novel algorithmic framework that combines the strengths of deep learning with the insights gained from educational psychology, aiming to better understand and predict learning behaviors. Second, it proposes a scalable automation process that can adapt to different learning environments and student profiles, significantly reducing the need for manual data processing and intervention.

This paper is structured into five sections, each designed to build upon the last in addressing the identified research gap. Following this introduction, we delve into a detailed review of the advances and challenges in ML applications in education, setting the stage for our novel contributions. We then present our methodology, focusing on the design and implementation of our predictive model. This is followed by an analysis of the results, demonstrating the effectiveness and adaptability of our approach. The paper concludes with a discussion of the implications of our findings for the future of ML in education, highlighting potential directions for further research.

II. Predicting Algorithms

A. Logistic Regression

Logistic Regression, a cornerstone in the realm of predictive analytics, offers a robust mathematical framework particularly suited for educational data [5]. Its essence lies in modeling the probability of a binary outcome, making it an ideal candidate for deciphering the dichotomous nature of learning outcomes: success or failure, pass or fail [6].

The application of Logistic Regression in predicting learning outcomes involves a meticulous process of mapping input variables — typically, the learning outcomes of certain subjects

— to a binary output, representing the predicted success or failure in other subjects. In the context of predicting learning outcomes, Logistic Regression is applied by modeling the probability of a student achieving a certain outcome (e.g., passing a subject) based on their performance in other subjects. The model's prowess stems from its ability to handle categorical data, a common characteristic of educational datasets. Logistic Regression shines in its simplicity and interpretability, a crucial aspect when educators and policymakers are at the helm, making decisions based on its predictions [7].

Several studies have illuminated the efficacy of Logistic Regression in educational settings. Singh and Jaiswal explored various machine learning classifiers, including Logistic Regression, in analyzing student performance in virtual learning environments [6]. Similarly, Lin et al. employed Logistic Regression, among other algorithms, to predict student submission timeliness in programming courses, highlighting the algorithm's versatility [8]. In conclusion, Logistic Regression stands out as a versatile and easily interpretable tool, essential for enhancing educational strategies through data analysis.

B. Random Forest

Random Forest, an ensemble learning method renowned for its robustness and accuracy, stands as a paragon in the domain of predictive analytics, particularly in educational settings [9]. At its core, Random Forest builds multiple decision trees and merges them to obtain a more accurate and stable prediction, a method especially effective in handling the multifaceted nature of educational data.

The Random Forest model can be conceptualized [10] as an aggregation of predictions from multiple decision trees, each contributing to the final decision. This ensemble approach significantly reduces the risk of over-fitting, a common pitfall in complex datasets such as educational data. The mechanics of Random Forest are particularly suited for educational data, which often encompasses a mix of categorical and continuous variables. By constructing a 'forest' of decision trees, each analyzing a subset of the data, Random Forest captures complex, non-linear relationships that might elude simpler models [11].

Several studies underscore the efficacy of Random Forest in this realm. Petkovic et al. demonstrated the algorithm's capability in predicting student learning effectiveness in software engineering teamwork with over 70% accuracy [9]. Su et al. applied Random Forest, among other algorithms, to predict student submission timeliness, showcasing its versatility in different educational scenarios [10]. Random Forest proves to be a vital and comprehensive tool for predicting educational outcomes, adept at managing complex datasets and offering interpretable insights for advanced learning strategies.

C. Gaussian Naive Bayes

Gaussian Naive Bayes, a probabilistic classifier underpinned by Bayes' Theorem, is a pivotal tool in the predictive analytics arsenal, particularly in the educational sector [12]. This algorithm stands out for its application of Gaussian probability distribution to handle continuous data, a common characteristic in educational datasets.

The application of Gaussian Naive Bayes in predicting learning outcomes involves a nuanced approach. It models the likelihood of outcomes based on input features, which in this context are the learning outcomes of selected subjects. The algorithm assumes that the features follow a Gaussian (normal) distribution, an assumption that simplifies the computation of probabilities. The strength of Gaussian Naive Bayes in educational settings lies in its ability to handle large datasets efficiently and its robustness in dealing with uncertainty in data. Its simplicity and the probabilistic basis provide a clear understanding of how predictions are made, which is crucial in educational contexts where interpretability is as important as accuracy.

Several studies have demonstrated the effectiveness of Gaussian Naive Bayes in educational data analysis. Wijaya et al. [12] applied the Naive Bayes algorithm to predict student success rates in learning, achieving high accuracy. Ouissal Sadouni and Abdelhafid Zitouni [13] discusses the implementation of dynamic optimization of learning indicators using Naive Bayes Classifier, which is relevant to understanding the application of Gaussian Naive Bayes in educational settings. Gaussian Naive Bayes stands out for its simplicity, efficiency, and effectiveness in analyzing complex educational datasets, making it a crucial tool for educational data analytics.

D. K-Nearest Neighbors

The K-Nearest Neighbors (KNN) algorithm, a cornerstone in the realm of machine learning, is renowned for its simplicity and effectiveness in classification and regression tasks. This non-parametric method operates on the principle that similar instances are likely to be found in close proximity [14].

In the context of predicting learning outcomes, KNN's application involves using the learning outcomes of certain subjects as input to predict the outcomes of others. The algorithm identifies the 'k' nearest data points to a query point and predicts the outcome based on the majority vote of these neighbors. The choice of 'k' and the distance metric, typically Euclidean, are crucial in this process. KNN's applicability in predicting learning outcomes is attributed to its ability to adapt to the intrinsic structure of educational data, which often exhibits complex, non-linear relationships. Its model-free nature allows for a flexible approach to understanding and predicting educational outcomes [15].

Several studies have underscored the utility of KNN in educational settings. Hendrianto et al. utilized KNN, among other algorithms, to predict student performance in compulsory subjects, demonstrating its predictive power in academic environments [14]. Tribhuvan and Bhaskar explored machine learning techniques, including KNN, to enhance student learning experiences, further highlighting the algorithm's relevance in educational data analysis [15]. KNN excels in educational data analysis with its simple implementation and local data-based predictions, showing promise as a tool for learning outcome predictions despite challenges like data scale sensitivity.

E. Support Vector Regression

Support Vector Regression (SVR), an extension of the Support Vector Machine (SVM) algorithm, is a powerful tool in the domain of machine learning, particularly for regression tasks. SVR is designed to find a function that approximates the relationship between input and output variables in a high-dimensional space, making it suitable for complex prediction tasks [16].

In educational data analysis, SVR can be employed to predict learning outcomes. The algorithm takes as input the learning outcomes of selected subjects and predicts the outcomes of other subjects. The core of SVR lies in constructing a hyperplane in a multidimensional space that best fits the data points. The efficacy of SVR in predicting learning outcomes is attributed to its robustness against overfitting and its capacity to handle high-dimensional data.

Studies such as those by Pimentel et al. have demonstrated the application of SVR in educational settings, showcasing its potential in efficiently predicting student performance based on large datasets [16]. Another study by Huan Xu [17] introduces an innovative method for forecasting students' academic performance, which involves utilizing support vector regression (SVR) and enhancing it through the application of an improved dual algorithm.

III. Automation Process

The process of forecasting based on learner data is a multifaceted and intricate endeavor, requiring a harmonious integration of various stages including data collection, meticulous analysis, and the strategic application of advanced analytical techniques. In pursuit of optimizing this process, we propose a comprehensive and automated approach, encompassing a series of well-defined and interconnected steps. This automation process is not just a linear progression of tasks but a dynamic framework designed to adapt and evolve in response to the changing educational landscape and the diverse needs of learners. The automation process includes of following steps is illustrated in Fig. 1

1) Data collection: Learner data is amassed from various sources since their enrollment in university programs. This includes enrollment data like high school grades, English proficiency certificates, SAT scores, and aptitude assessments; and ongoing academic data such as grades, class attendance frequency, study hours, extracurricular activities, and more. This phase also involves identifying the most significant variables for forecasting purposes. The Student Information System (SIS) is a key data repository, storing demographic information (age, gender, nationality) and academic performance. However, socio-economic characteristics are not typically available in SIS, as they are often gathered through data collection methods like questionnaires. Additionally, learner information can be collected through Learning Management Systems (LMS) usage, including course data, grades, participation in discussions, and online exams and assignments.

2) Data preparation / preprocessing: Preparing data is crucial in data mining and involves making raw data suitable for mining techniques. Educational databases are often large, and the stored data frequently encounters quality issues. Hence, data cleansing methods are essential to handle missing, inconsistent, and outlier data to ensure data quality. Essential preprocessing methods include data cleaning, integration, reduction, and transformation.

- Data Cleaning involves removing noise and handling missing values to improve data quality.

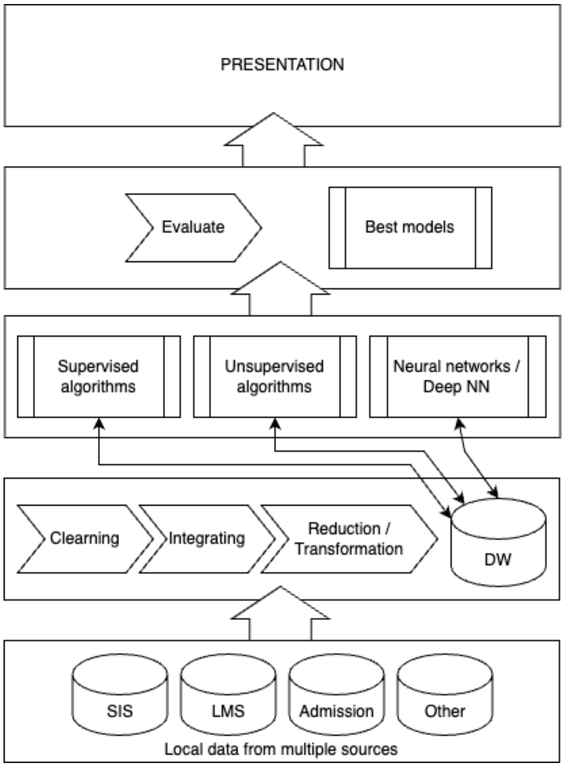

Fig. 1. Automation process.

- Data Integration combines data from multiple sources into a single source, addressing redundancy and inconsistency.
- Data Reduction transforms large datasets into smaller, information-rich datasets.
- Data Transformation modifies data into a form suitable for mining, including normalization and discretization.

Data after these steps are stored in a Data Warehouse (DW) which can be easily accessed for applying ML models in the next step.

3) Training ML models: This step involves using ML algorithms to analyze large data sets and identify patterns or trends. Both supervised and unsupervised learning models are employed to uncover interesting patterns in the data. Supervised learning uses labeled datasets to train models, which can then make predictions or classifications on new, unlabeled data. Unsupervised learning, on the other hand, involves analyzing data without any labels, aiming to identify patterns or clusters that can provide insights or aid decision-making. Classification and regression are two primary supervised learning techniques used for forecasting. Many more models/algorithms can be implemented and integrated into the system to provide flexibility in evaluating and selecting the best model for forecasting.

4) Model evaluation: Evaluating the performance of a classification model is a crucial step in developing and refining machine learning models. It allows for assessing the model's accuracy on test data. The original dataset is typically divided into two or three independent parts: a training set (validation/testing set) and a test set. The training set is used to build the model, the test set to evaluate its performance, and in the case of large data, a validation set to optimize hyper parameters. Common methods for dividing the dataset include holdout, random sampling, and cross-validation. The results of running models / algorithms in the previous steps are evaluated to select the best model for each specific task.

5) Presentation: The final step in the automation process involves meaningfully and understandably presenting the results and findings from the selected models. The presentation step aims to convey the insights gained from the data mining process to stakeholders like educators, administrators, policy-makers, and researchers in a format that supports decision-making and action.

IV. Experiment on Automation Process

We implement the automation process on a BI system described in our last paper [18]. The architecture of the BI system is shown in Fig. 2.

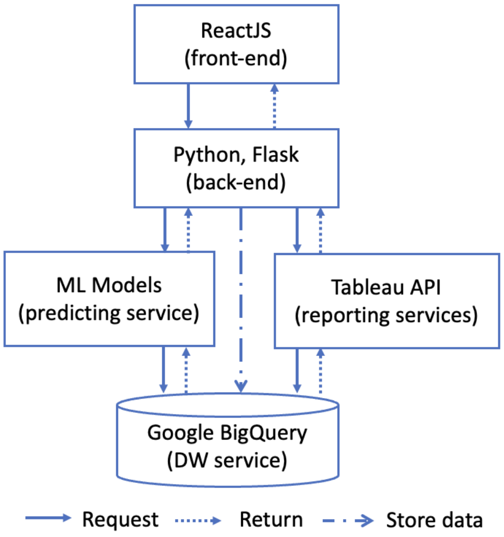

Fig. 2. The BI system.

In the back-end component, the steps of Data Collection and Data Preparation are executed seamlessly. This is followed by the Training ML models and the Model Evaluation steps, which are integral parts of the ML Models component. Subsequently, the Presentation step takes place in the front-end component. This component is a sophisticated web interface, designed to facilitate interaction with users through a web browser, ensuring a smooth and engaging user experience.

Using Data Collection and Data Preparation steps in the BI system, the authors have been updated the dataset to include data from years of 2022 and 2023, encompassing over 113,000 records. This dataset includes grades of students from three departments: Computing, Business Administration, and Graphic Design. In this experiment, the authors focused on the grades of Computing department.

A. Problem

Forecasting the academic performance in a subject based on the grades of previous subjects is a common and useful problem in the field of education. This not only helps students understand their abilities and developmental directions more clearly but also assists teachers and administrators in identifying and improving teaching methods as well as managing educational quality.

In the preceding discussion, this research will employ a dataset comprising grades from the Computing major to conduct experimental analyses. Specifically, a second-year course, designated as Advanced Programming (course code 1651), has been chosen as the focus for predicting academic outcomes namely, whether students pass or fail. This prediction will be based on the performance in a suite of first-year courses, which include Procedural Programming (1618), Programming (1619), Database Design & Development (1622), Website Design & Development (1633), Security (1623), and Managing a Successful Computing Project (1625). This approach allows for a detailed examination of the correlation between early academic performance and subsequent success in advanced coursework.

Following the data preparation phase, a selected subset of the requisite courses, encompassing the grades of 654 students, will be utilized for training and testing the predictive models. Within this subset, it is observed that approximately 80.6% of the students successfully passed the focal course 1651. Regarding the other courses integral to the prediction process, the average grades fluctuate, with the lowest mean grade being approximately 5.17 for course 1633 and the highest at around 5.93 for course 1619. Notably, course 1633 also exhibits the lowest pass rate at 68.81%, whereas course 1619 demonstrates the highest pass rate at 82.57%. These variations in pass rates and mean grades across different courses provide a comprehensive framework for analyzing and predicting academic performance in the Computing major.

B. Methods

To select the most effective model for prediction, the authors implemented the algorithms discussed in Section II and ran them on the same dataset to evaluate their outcomes. The model demonstrating the most optimal results was then chosen for integration into the automated forecasting process.

To assess the models' performance, the authors employed the k-folds verification technique with k = 10. Each model was trained and evaluated on each fold, calculating metrics such as Mean Squared Error (MSE), true positives (TP), false positives (FP), true negatives (TN), and false negatives (FN) and finally their average values on all the folds are returned. The correctness of the models was then determined based on the aggregation of true positives and true negatives across the data of each fold.

For all models, the authors trained and tested them on the same sub dataset of all grades from Computing Department. The sub dataset extracted from the main dataset had to ensure the inclusion of grades from all the relevant input and output courses, with at least one assessment per course. The total size of this qualified dataset comprised 654 students, making it suitable for running the predictive models.

All models uses the same inputs and output as described below:

- Input $X_1, X_2, X_3, X_4, X_5, X_6$: The average grades of assessments in first-year courses with codes 1618, 1619, 1622, 1633, 1623, and 1625.
- Output Y: Pass or fail outcome of a second-year course with the code 1651.

Next, we will see the result of training and testing on each model.

C. Experimental Result

1) Logistic regression result: To predict the binary outcome (pass/fail) of a second-year course (code 1651) using logistic regression we define the dependent variable, Y, represents the outcome of the course, coded as 1 for pass and 0 for fail. The independent variables, $X_1, X_2, X_3, X_4, X_5, X_6$, correspond to the average grades in six first-year courses with codes 1618, 1619, 1622, 1633, 1623, and 1625.

The logistic regression model is formulated as follows:

$$P(Y = 1|X) = \frac{1}{1 + e^{-(w_0 + w_1 X_1 + w_2 X_2 + \ldots + w_6 X_6)}} \quad (1)$$

where, $w_0, w_1, \ldots, w_6$ are the model parameters that need to be learned.

The model is trained by minimizing the logistic loss function defined as:

$$J(w) = -\frac{1}{6} \sum_{i=1}^{6} \Big[y_{(i)} \log\big(\sigma(w \cdot X_{(i)} + b)\big) + (1 - y_{(i)}) \log\big(1 - \sigma(w \cdot X_{(i)} + b)\big) \Big] \quad (2)$$

where, σ denotes the logistic (sigmoid) function.

For prediction, the model estimates the probability of a student passing the 1651 course. A student is predicted to pass (Y=1) if $P(Y = 1|X) > 0.5$; otherwise, the student is predicted to fail (Y=0).

The performance of the Logistic Regression model was evaluated using the k-fold cross-validation technique with $k = 10$ as described above. The results of k-folds verification, all values are average values of k-fold, are shown in Table I.

TABLE I. Performance Metrics of the Logistic Regression Model

MSE	TN	FP	FN	TP	Correctness
0.17	4.2	3.0	2.0	20.8	83.33%

2) Random forest: To predict the binary outcome (pass/fail) of a second-year course (code 1651) using a Random Forest algorithm, the dependent variable, Y, is defined as the outcome of the course, coded as 1 for pass and 0 for fail. The independent variables, $X_1, X_2, X_3, X_4, X_5, X_6$, correspond to the average grades in six first-year courses with codes 1618, 1619, 1622, 1633, 1623, and 1625.

Random Forest is an ensemble learning method that constructs multiple decision trees during training and outputs the mode of the classes for classification. The final prediction, $H(x)$, is the majority vote of the predictions made by individual trees, $h_1(x), h_2(x), \ldots, h_N(x)$, for N trees. In mathematical terms:

$$H(x) = mode\{h_1(x), h_2(x), \ldots, h_N(x)\} \quad (3)$$

Each tree is constructed using a random subset of the data, known as bootstrap sampling, and at each split in the tree, a random subset of the features is considered for splitting.

The Random Forest also uses out-of-bag (OOB) samples to estimate the error. The OOB error is the average error for each training sample, calculated using only the trees that did not have this sample in their bootstrap sample.

The effectiveness of the model was assessed through the application of the k-fold cross-validation method, wherein k was set to 10. The outcomes of this cross-validation, represented as mean values computed over all k-folds, are presented in Table II

TABLE II. Performance Metrics of the Random Forest Model

MSE	TN	FP	FN	TP	Correctness
0.11	5.4	1.8	1.4	21.4	89.33%

3) Support Vector Regression (SVR): SVR is a type of Support Vector Machine (SVM) that is used for regression challenges. While traditional SVM is used for classification tasks, SVR can be used to predict continuous outcomes. The main idea behind SVR in our problem is to find a function $f(x) = w_1X_1 + w_2X_2 + w_3X_3 + w_4X_4 + w_5X_5 + w_6X_6 + b$ that has at most ϵ deviation from the actual target values Y for all the training data, and at the same time is as flat as possible.

Mathematically, SVR solves the following optimization problem:

$$\min_{w,b} \frac{1}{2}\|w\|^2 + C \sum_{i=1}^{n} (\xi_i + \xi_i^*) \quad (4)$$

subject to

$$Y_i - (w_1 X_{1i} + w_2 X_{2i} + \ldots + w_6 X_{6i} + b) \leq \epsilon + \xi_i, \quad (5)$$

$$(w_1 X_{1i} + w_2 X_{2i} + \ldots + w_6 X_{6i} + b) - Y_i \leq \epsilon + \xi_i^*, \quad (6)$$

$$\xi_i, \xi_i^* \geq 0 \quad (7)$$

where, w is the weight vector, b is the bias, C is the regularization parameter, ξ and ξ^* are slack variables that allow for violations of the ϵ margin.

The efficacy of the SVR model was gauged utilizing the k-fold cross-validation approach, setting k at 10. The outcomes from the k-folds assessment, which are the mean values calculated across all k-folds, are outlined in the Table III.

TABLE III. Performance Metrics of the SVR Model

MSE	TN	FP	FN	TP	Correctness
0.133	4.6	2.6	1.4	21.4	86.67%

4) K-Nearest neighbors: The KNN algorithm operates by identifying the ‘K’ nearest neighbors of a given data point in the feature space. The Euclidean distance is commonly used as the distance metric, calculated as $d(X_i, X_j) = \sqrt{\sum_{n=1}^{N}(X_{in} - X_{jn})^2}$, where X_i and X_j are two points in an N-dimensional space.

In this application of the KNN algorithm, each student’s likelihood of passing or failing the second-year course (code 1651) is predicted based on the outcomes of the nearest neighbors in the dataset. These neighbors are identified by comparing the average grades in six other courses (codes 1618, 1619, 1622, 1633, 1623, and 1625) of each student. For a given student, the algorithm locates the ‘K’ students most similar in terms of their first-year grades and predicts the student as likely to pass (Y=1) or fail (Y=0) the 1651 course based on the most common outcome among these ‘K’ nearest neighbors. This can be represented as $Y = mode\{c_1, c_2, ..., c_K\}$, where c_i is the pass/fail outcome of each neighbor. Furthermore, a weighted voting approach can be employed where the influence of each of the ‘K’ neighbors on the prediction is inversely proportional to their grade distance from the student being classified, giving closer students (more similar in terms of grades) a higher influence in the prediction.

The KNN model’s effectiveness in forecasting the outcome of course 1651 was appraised through the k-fold cross-validation method, employing $k = 10$. Table IV shows the ensuing results represent the average values derived from the k-folds:

TABLE IV. Performance Metrics of the KNN Model

MSE	TN	FP	FN	TP	Correctness
0.18	3.0	4.2	1.2	21.6	82.00%

5) Gaussian Naive Bayes (GNB): In the context of the Gaussian Naive Bayes (GNB) model, we aim to predict the probability $P(Y = 1|X)$, which represents the probability of a student passing the course 1651 (coded as 1 for pass) given a set of relevant grades of other courses represented by the feature vector X.

- Y: A binary variable representing the result of 1651 course (pass or fail)
- X: A feature vector representing the grades $X_1, X_2, \ldots, X_6$, where X_i represents the grade in the respective course i.

The GNB model calculates the probability $P(Y = 1|X)$ using Bayes’ theorem, which relates the conditional probability $P(Y = 1|X)$ to the joint probability $P(X, Y)$ and the marginal probability $P(X)$:

$$P(Y = 1|X) = \frac{P(X|Y = 1) \cdot P(Y = 1)}{P(X)} \tag{8}$$

In this equation:

- $P(Y = 1|X)$: The probability of passing the course given the feature vector X
- $P(X|Y = 1)$ The probability distribution of the feature vector X when the student passes the course
- $P(Y = 1)$ The prior probability of passing the course
- $P(X)$ The marginal probability of observing the feature vector X

The GNB model assumes that each feature X_i follows a Gaussian distribution for each class (pass or fail). It calculates these probabilities based on training data and assumes that features are conditionally independent given the class label. In summary, the GNB model uses Bayes’ theorem and Gaussian distributions to estimate the probability of a student passing the course based on grades in other courses. It’s trained on labeled data to estimate Gaussian distribution parameters, including mean and variance, for each feature in both pass and fail classes.

The effectiveness of the GNB model in predicting the results of course 1651 was assessed using the k-fold cross-validation approach, with k set to 10. Presented in the Table V are the aggregated average results from these k-folds.

TABLE V. Performance Metrics of the GNB Model

MSE	TN	FP	FN	TP	Correctness
0.18	6.0	1.2	4.1	18.7	82.33%

D. Experiment Result Analysis

In this section, we present and analyze the results obtained from the k-fold cross-validation (with $k = 10$) for various predictive models: Logistic Regression, Random Forest, SVR, KNN, and GNB.

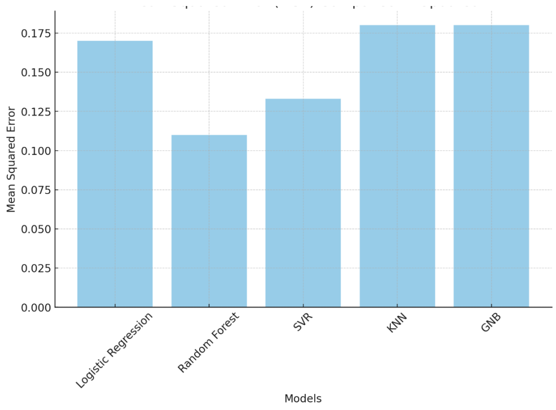

Fig. 3. Mean Squared Error (MSE) comparison.

1) Mean squared error comparison: As shown in Fig. 3, the Random Forest model demonstrated the lowest MSE (0.11), suggesting it as the most accurate among the evaluated models. Conversely, both KNN and GNB models exhibited the highest MSE (0.18), indicating relatively higher prediction errors.

2) Classification results: Classification results, including True Negatives (TN), False Positives (FP), False Negatives (FN), and True Positives (TP) counts, are essential for understanding a model’s capability in correctly classifying different

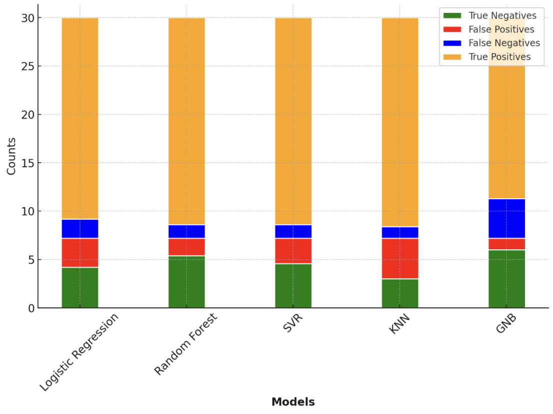

Fig. 4. Classification comparison.

outcomes. Fig. 4 illustrates a comparative analysis of these metrics. Notably, the Gaussian Naive Bayes (GNB) model excelled in identifying negative cases (TN), while the K-Nearest Neighbors (KNN) model slightly led in identifying positive cases (TP). However, the Random Forest model balanced false positives and false negatives effectively, indicating robust classification capabilities.

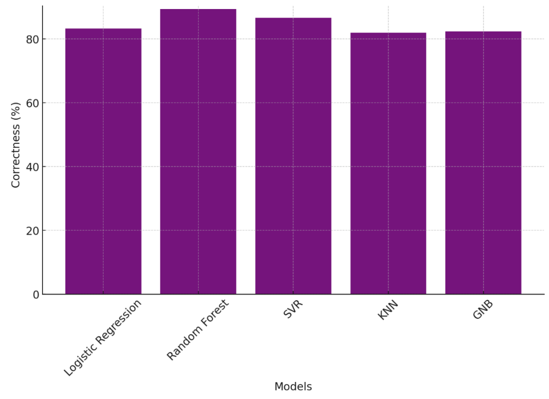

Fig. 5. Correctness comparison.

3) Correctness of models: The correctness percentage provides an overall effectiveness measure of the models. As depicted in Fig. 5, the Random Forest model outperformed others with the highest correctness percentage (89.33%). Despite high TP and TN rates in KNN and GNB models, respectively, their overall correctness percentages were lower, suggesting a trade-off between different types of classification errors.

4) Integration of predictive model: The analysis reveals that the Random Forest model exhibits a balanced and superior performance across various metrics, making it the most effective model among those tested. The GNB model, despite its high rate of TN, struggles in overall performance, indicating a potential issue in classifying positive cases. The KNN model, while showing a high TP rate, suffers from high MSE and lower correctness, pointing towards possible overfitting or poor generalization.

These insights suggest that further refinement and tuning of the Random Forest model could yield even better results.

Select Course to Predict

1651

Prediction: Pass

Fig. 6. Predict 1651 course result.

Additionally, a deeper investigation into the feature selection and parameter optimization for the GNB and KNN models might improve their performance.

Based on the analysis, we integrate the Random Forest model into the Automation process. With a simple Web interface in the Presentation step, it allows user to predict the result of a course according to the grades of other selected courses as in Fig. 6.

We also did another experiment in which we select fewer courses. Since 1651 is a programming course (name: Advanced Programming), we select only programming related courses which are 1618 (Programming), 1622 (Database Design & Development) and 1633 (Website Design & Development). The result is shown in the Table VI.

TABLE VI. Performance Metrics of Various Models

Model	MSE	TN	FP	FN	TP	Correctness
RandomForest	0.133	5.1	2.1	1.9	20.9	86.67%
SVR	0.137	4.7	2.5	1.6	21.2	86.33%
KNN	0.163	4.1	3.1	1.8	21.0	83.67%
GaussianNB	0.163	6.0	1.2	3.7	19.1	83.67%
LogisticRegression	0.150	5.2	2.0	2.5	20.3	85.00%

The results indicate that the Random Forest model consistently achieves the lowest MSE and the highest level of accuracy. However, it's noteworthy that the accuracy of the Random Forest model shows a slight decline compared to its performance when trained with a more comprehensive dataset that includes both programming and theoretical courses. This observation raises an intriguing question: Does the inclusion of a broader selection of previous courses enhance the predictive accuracy of a model? Interestingly, this does not seem to be the case for other models like Logistic Regression or Gaussian Naive Bayes, suggesting that the relationship between the breadth of course selection and predictive accuracy is not straightforward and may vary across different ML models.

This further confirms the necessity of an automated process that involves implementing various ML algorithms to allow users to choose the best model after the evaluation step. Users can select different models/algorithms for different forecasting problems or even different models/algorithms for different subjects in a specific learning outcome forecasting problem.

V. Conclusion

Our study embarked on an journey to unravel the potential of integrating various machine learning models in an automation process to predict educational outcomes. The heart of our exploration was the rigorous experiment that tested models like Logistic Regression, Random Forest, KNN, and Gaussian Naive Bayes against the challenging task of forecasting course results.

The findings are illuminating. The Random Forest model, in particular, demonstrated exceptional proficiency, marked by the lowest MSE and highest correctness in predictions. This underscores its potential as a reliable tool in educational settings. Moreover, our analysis revealed an intriguing trend: the accuracy of predictions increases with the inclusion of more previous course grades. This insight is pivotal for educational institutions aiming to leverage data-driven approaches for student assessment and support.

Our study also emphasized the importance of a user-friendly interface in the Presentation stage, allowing educators and stakeholders to seamlessly interact with the predictive models. The practical application of our research, illustrated through a simple web interface, bridges the gap between complex algorithms and real-world usability.

In conclusion, this research marks a significant stride towards integrating machine learning in educational technology. It not only sheds light on the efficacy of various predictive models but also paves the way for future investigations. Areas ripe for exploration include enhancing model robustness and exploring their adaptability across diverse educational contexts. As we tread into this future, our endeavor remains rooted in the goal of harnessing technology to enrich learning experiences and outcomes.

Acknowledgment

We are grateful for the opportunity to conduct this research within the framework of the Project BIG - BI for Greenwich at FPT University (Greenwich Vietnam). Our thanks extend to the university for providing access to real anonymized data, which was crucial for this study.

***Abstract*—As the volume and complexity of data continue to grow exponentially, finding efficient and accurate clustering algorithms has become crucial for many applications. K-means clustering is a widely used unsupervised machine learning technique for data analysis and pattern recognition. Despite its popularity, k-means suffers from certain limitations, such as sensitivity to initial conditions, difficulty in determining the optimal number of clusters, and the potential for misclassification. This research paper proposes an enhanced approach for improving the accuracy and performance of the k-means clustering algorithm by incorporating post-processing techniques using a gradient boosting algorithm. The proposed method comprises training the gradient boosting model on the labeled training set, i.e., the samples with correct cluster assignments obtained from the k-means algorithm, to predict the correct cluster assignments for the misclassified samples in the testing set. This results in refined cluster assignments for the testing set. The k-means algorithm is only used initially to cluster the data and obtain initial cluster assignments. The effectiveness of the proposed approach is validated through experiments on several benchmark datasets, and the results show a significant improvement in clustering accuracy and robustness compared to the standard k-means algorithm. The proposed approach has the potential to enhance the performance of k-means in various real-world applications and domains.**

Keywords*—K-means; gradient boosting; post-processing; misclassification; machine learning

I. Introduction

Enhancing the performance of clustering algorithms has become essential for obtaining accurate and effective clustering in the era of contemporary data, with its growing amount and diversity. Clustering is a strategy that is used for analyzing data, collecting similar data points together, and recognizing patterns in data that would otherwise be invisible [1]. There are several types of clustering algorithms, such as hierarchical methods, density-based methods, grid-based methods, and partitioning-based methods, each of which differs in the way they measure the similarity or distance between entities [2].

The k-means algorithm is an unsupervised algorithm that was improved by MacQueen in 1967 [3]. The k-means algorithm is a type of partitioning-based method that is used to group similar data. Each group of data is called a cluster. In the first stage, the algorithm randomly assigns an initial set of points for k clusters based on the nearest center of the clusters. Then, it modifies the points until it reaches the nearest cluster center. The process is iterative and continues until the centroids no longer update, resulting in the final centroids representing the ultimate centers of k clusters. The function of updating and modifying centroids is performed by calculating the distance measure specified in the algorithm [4].

The k-means algorithm offers several advantages, including its speed, simplicity, and ease of implementation [5]. It is useful in different applications such as marketing, recommendation systems, smart city services, the analysis of business data, and the analysis of user behaviors [6]. However, even with the advantages of the k-means algorithm, it still faces some drawbacks, such as its problem with local optima and its sensitivity to initial centroids. The k-means algorithm is sensitive to the centroids and will give different results whenever the initial centroids change [5]. In this study, we build upon a previous research paper that explored techniques for enhancing the k-means algorithm [7]. While acknowledging the contributions of the original work, we present an extended methodology that incorporates optimization techniques to further improve the clustering outcomes. The aim of this study is to surpass the performance achieved in the earlier study.

Several previous studies have been conducted in the field of improving the k-means algorithm. In [7], the authors presented a novel concept of post-processing the clusters obtained by the classical k-means algorithm to improve the quality of the resulting clusters. The post-processing approach consists of four steps that combine the k-means algorithm with a supervised learning algorithm, resulting in hybrid k-means-supervised learning (KM-SML). The paper proposed an approach to extract the majority of misclassified records from the clustered dataset and post-process them using the supervised machine learning algorithm. The results obtained from applying the proposed approach demonstrated significant improvements compared to the classical k-means algorithm. Precision and recall, two evaluation metrics, were used to assess the enhancements brought by the KM-SML approach. In both cases, better results were achieved using the KM-SML approach compared to the classical k-means algorithm. In [8], the researchers suggest a method that combines an optimization algorithm, namely Particle Swarm Optimization (PSO), with a k-means clustering algorithm. According to the comparison analysis, using PSO to determine the initial centroids yields promising results. While other studies highlight the benefits of combining metaheuristic optimization algorithms and data mining techniques, opening avenues for further research in this field, in [9], the researchers propose the integration of nature-inspired optimization algorithms, such as ant, bat, cuckoo, firefly, and wolf search algorithms with k-means clustering to overcome the drawback of getting stuck at local optima determined by random initial centroids. By combining these algorithms with k-means, the researchers aim to achieve unprecedented performance enhancements in terms of clustering accuracy. The results of the evaluation experiments show significant improvements in performance, particularly for the C-Bat and C-Cuckoo hybrid algorithms.

It is evident from the literature that researchers integrate various techniques with the k-means algorithm to achieve better outcomes or performance; Likewise, based on the previous work [7], this paper presents an enhanced approach for increasing the accuracy of the k-means algorithm by utilizing post-processing techniques with the gradient boosting algorithm. The proposed approach is implemented using the Python programming language and the Scikit-learn library [10] and applied to three datasets, which are the Iris dataset, Forest, and Banknote datasets [11], [12], and [13] respectively. The proposed approach implements the Split Criterion (SC) [7] for detecting potentially misclassified points. Additionally, the paper utilizes an extra set of threshold values for the SC and compares the results to other approaches [7], [14].

The proposed approach calculates the Euclidean distance of data points and the centroids of k clusters and scales the data using MinMaxScaler. Based on the SC threshold, the k-means results from the datasets are separated into training and testing sets. If the value of SC exceeds a predetermined threshold, the data point is considered a misclassified point and transferred to the test set, while the correct labels are transferred to the train set. The labels generated are used to train the gradient boosting classifier. As a result, the approach reached up to 97% accuracy on the Iris dataset. The approach presented in this paper assists in improving the performance of k-means clustering by minimizing the number of misclassified points, which helps to increase the accuracy of the algorithm.

The rest of the paper is organized as follows: Section II presents the literature review. Section III describes the techniques used in this paper. Section IV presents the results and discussion. Section V covers the conclusions.

II. Literature Review

The k-means method is an unsupervised clustering algorithm. It is extensively used in data mining because it is easy to use and understand and due to its applicability to various application domains [15]. The k in k-means represents the number of resulting clusters. The k-means algorithm accepts unlabeled data and groups it into k non-overlapping groups called clusters based on how close each point in a cluster is to the mean, called the centroid center, of that cluster [16].

In numerous papers, the k-means algorithm is combined with another algorithm to enhance execution efficiency, improve results, or achieve both. In [17], k-means and long short-term memory (LSTM) neural networks are used to analyze the behavior of electricity consumption for generating targeted marketing and recommending usage strategies. The data is first clustered using the k-means algorithm. Then, it is labeled based on a previous dataset and fed into LSTM to produce the results. The results are more accurate and efficient than using the LSTM directly. Instead of using LSTM, [18] uses a hybrid method that employs k-means with the Gaussian mixture model (GMM) for detecting malignant and benign breast cancer tumors using mammographic images. This approach has higher accuracy, signal-to-noise ratio, and a lower error rate than non-hybrid existing techniques such as k-means, GMM, and thresholding.

While [18] uses a hybrid model of k-means and GMM, [19] employs a hybrid model based on two evolutionary algorithms. It uses the fireworks-based and cuckoo-search-based evolutionary algorithms to improve the quality of the resulting clusters. In addition to these two algorithms, the method in [19] selects representatives of data using instance reduction to solve the empty cluster issue. The empty clusters problem happens when the number of clusters increases [20]. Moreover, this method enhances the selection of the initial centroids by using heuristics alongside evolutionary-based algorithms.

Both [21] and [22] use the Support Vector Machine (SVM) method with the k-means algorithm. Both techniques use k-means to cluster the values before inputting them into the SVM algorithm. In [21], the approach is to monitor and predict student performance in higher education. The resulting clusters from the k-means algorithm are further analyzed using SVM to accurately classify students as high-performing or low-performing students, which produces more accurate results than using the SVM only, whereas [22] uses the k-means algorithm on unlabeled data to generate a subset of the significant features to be the training set for the SVM instead of the complete dataset. According to [22], this approach improves the classification accuracy and performance in some situations compared to other approaches such as C-SVC and S4VM.

Unlike [21] and [22], which use SVM after k-means, [7] utilizes a supervised learning technique, in particular, the random forest classifier [23] is employed to improve the results of k-means. In addition, [7] proposes a method to detect potentially misclassified points. After applying the k-means algorithm to the Iris dataset [11], the results are examined for any potentially misclassified points. The detection of the misclassified points is done as follows, for each of the chosen minimum distances, divide each by the minimum distance to each cluster. If the values cross a predetermined threshold, then there is a possibility of misclassification for this point. After determining the possible misclassified points, they are extracted from the dataset, and the supervised learning algorithm is trained with the correctly clustered data. Finally, the misclassified points are entered into the model for classification. This proposed approach produces more accurate results than using the k-means method exclusively.

The k-means algorithm is sensitive to the initial clustering centers since the initial selection of centroids can affect the number of iterations and execution time [16]. To reduce the number of iterations and the running time, [6] have proposed reducing the dimensions of the data using percentile techniques and the Principal Component Analysis (PCA). The centroids are selected from the resulting reduced data. This technique has better results than both random and k-means++ initializations.

Another issue related to the selection of the cluster centers is that the non-optimal choice of centers leads the algorithm to converge to local minima [16]. Therefore, it is imperative to select the optimal centroid location to avoid getting stuck in local minima. The author in [14] proposes a method to determine optimal centers. This method employs an ant colony algorithm and uses positive and negative pheromone feedback to optimize the initialization of centroids. An additional issue is the instability of the assignment of clusters [16]. To overcome instability, [24] combines density and multiple clustering. This solution improves the running time and stability of the clustering by choosing the centroids according to the furthest distance and the highest density principle. However, solutions that use just density have a high time complexity [24].

Determining a suitable number of clusters requires domain knowledge [25]. Unfortunately, domain knowledge is not always readily available. To mitigate this issue, [26] proposes a method that does not require the manual specification of the number of clusters. One notable benefit of employing this method is its ability to accelerate the execution process and improves accuracy. It outperforms k-means when the data has lower dimensionality. Another proposed approach that does not require the specification of the number of clusters is in [27]. In [27], the authors propose and test a fully unsupervised k-means algorithm that does not need initialization and parameter selection. It auto-determines the optimal number of clusters using the entropy concept. In addition, it has good results when compared with the existing methods.

Traditional k-means implantations use the Euclidean distance to find the distances between the points [28]. However, [29] opted to use the evidence distance, which can deal with uncertainty. Instead of using the Euclidean distance, the method utilizes the evidence distance, resulting in higher accuracy and a reduced number of iterations. In contrast, [30] have proposed a k-means algorithm, L2-weighted k-means, whose mean is computed using the weighted feature space transformation. The L2-weighted k-means algorithm described in [30] was used to help in drilling for groundwater. Specifically, it was used to find the capacity of the average digging per day and to optimize profitability and productivity.

The authors of [31] state that the Lloyd algorithm for k-means does not perform well in dealing with large data. Therefore, [31] presents a k-means algorithm that uses neighbor information for assigning and updating the points. This algorithm reduces the distance calculations and increases the accuracy of the produced neighbors.

MapReduce, a programming model for parallel and distributed clusters, and Hadoop, a framework for distributed processing and storage of big data [32], have been used to enhance the scalability and parallelize the execution of k-means methods, as demonstrated in several studies [5], [19], [33]. The author in [5] describes a technique for news classification that uses MapReduce and Hadoop for parallelization. It also improves the selection of the initial centroids by leveraging the organizational structure of the data. The results show a 30% decrease in execution time over the method that does not employ parallelism.

Despite these efforts to enhance the performance of the k-means algorithm, gaps persist in the existing literature, including the reliance on domain knowledge for parameter selection or initialization, which limits applicability across diverse domains. Additionally, few methods provide a unified solution to address multiple shortcomings of k-means, such as sensitivity to initial conditions and misclassification issues. The proposed approach aims to bridge these gaps by introducing a post-processing technique using gradient boosting to refine cluster assignments obtained from k-means. Unlike prior methods that focus on specific enhancements or manual parameter tuning, the approach offers a comprehensive solution to improve clustering accuracy and robustness across various datasets and application domains.

III. Methodology

By adopting the data analysis techniques and the clustering approach, this research paper proposes an improvement to the performance of the k-means clustering algorithm by using gradient boosting in post-processing. The proposed approach intends to improve the quality of the k-means by post-processing the resulting clusters, which will contribute to delivering new insights in the context of clustering problems. This section describes the overall methodological approach of the present research paper by covering six fundamental elements. Section III-A describes the utilized datasets. The k-means clustering algorithm is then described in Section III-B. Section III-C provides an in-depth explanation of the split criterion technique. As well, Section III-D illustrates the post-processing methodology. Section III-E presents the evaluation matrices used to assess the proposed model. Eventually, the experimental setup is presented in Section III-F.

A. Datasets

The proposed approach is examined by using three benchmark datasets from the UCI Machine Learning Repository, which are popular datasets in the machine learning community. Namely, the Iris, Forest, and Banknote datasets [11], [12], and [13]. Table I describes the characteristics of each dataset, including the number of instances, the number of attributes, and the number of clusters for k-means. Additionally, a normalization technique is applied to the datasets in order to facilitate and improve the classification. The normalization is accomplished by using MinMaxScaler from the Scikit-learn toolkit [10] to scale each feature between 0 and 1. Consequently, the k-means outcomes utilizing the datasets are classified into training and testing sets based on SC results and the selected SC threshold. If the SC result of any point is higher than the predetermined SC threshold, the point will be added to the misclassified points, which are defined as the test sets to be used in the process of testing in the post-processing phase, while the correct labels are defined as the training set in the training process in the post-processing.

TABLE I. Datasets Description

Dataset	Instances	Attributes	Initial k
Iris [11]	150	4	k = 3
Forest [12]	523	27	k = 4
Banknote [13]	1372	5	k = 2

B. K-means Clustering Algorithm

The k-means algorithm is perhaps the most widely utilized clustering method. It has been explored for several decades. Therefore, it serves as the basis for several advanced clustering techniques [34]. The k-means algorithm is widely used because it uses straightforward, non-statistical principles, is extremely adaptable and flexible, and performs well. Furthermore, [34] mentions that the k-means algorithm is essentially composed of two phases. First, it assigns points to an initial set of k clusters. Second, it modifies and updates the assignment points. The process of assigning points is based on the nearest cluster center according to the distance function. Traditionally, k-means clustering uses Euclidean distance to compute the distance between points and the cluster centers [34]. Eq. (1) shows the distance metric formula used in this paper.

$$dist(x_i, y_c) = \sqrt{\sum_{j=1}^{a}(x_{ij} - y_{cj})^2}$$
$$i = 1, ..., n; \; c = 1, ..., k \tag{1}$$

where:

x is the data point

y is the centroid

n is the number of points

k is the number of clusters

a is the number of attributes

Consequently, updating and assigning points take place repeatedly until the cluster fitness is no longer improved by changes. The procedure ends at this stage, and the clusters are complete. Listing 1 shows the optimal values for the k-means parameters that produced the best outcomes.

Listing 1: k-means Parameters

```
KMeans(n_clusters=n, init='k-means++', n_init=10, max_iter
     =300, tol=0.0001,verbose=0, random_state=0, copy_x=True
     , algorithm='lloyd')
```

C. Split Criterion

In the proposed method, the SC [7] phase in the post-processing step plays a crucial role in determining potentially misclassified points by the k-means algorithm. This phase is significant for cluster analysis as it contributes to determining the accuracy of the clustering algorithm. It does this by finding and separating the likely misclassified points so they can be used as input for the final phase in post-processing.

Upon the completion of the k-means algorithm, k groups are generated, each of which comprises a center and a set of data points. In order to enhance the accuracy of clustering, misclassified data points must be identified and corrected. Here is where the SC method is applied.

The SC method begins by calculating the Euclidean distance between each data point and the centers of all clusters. For each point x, the minimum distance from it to each center is determined and referred to as min_{xc}. Then, min_{xc} is divided by the distance of each centroid to the point. This yields values between 0 and 1, representing the ratio of the minimum distance from point x to cluster c to each cluster center.

A threshold value between 0 and 1 is chosen to identify the misclassified data points. If any of the values calculated for data point x exceeds the chosen threshold, then x is considered misclassified. However, the point with the minimum distance to a cluster to which the point belongs is excluded from the comparison with the threshold since it will also result in 1.

For instance, if a point x_1 and three centers c_1, c_2, and c_3 are given, the distance between this point and the three cluster centers is calculated, resulting in three distances: $dist(x_1, c_1)$, $dist(x_1, c_2)$, and $dist(x_1, c_3)$. Then, the minimum distance, say $dist(x_1, c_2)$, is determined, and the SC result R of each distance can be calculated as follows:

$$SC(x_1, c_1) = \frac{dist(x_1, c_2)}{dist(x_1, c_1)} = R \quad 0 \leq R \leq 1 \tag{2}$$

$$SC(x_1, c_2) = \frac{dist(x_1, c_2)}{dist(x_1, c_2)} = R \qquad R = 1 \tag{3}$$

$$SC(x_1, c_3) = \frac{dist(x_1, c_2)}{dist(x_1, c_3)} = R \quad 0 \leq R \leq 1 \tag{4}$$

If the value obtained from Eq. (2) or (4) exceeds the specified threshold, the data point x_1 is considered misclassified. The minimum distance to the cluster, represented as $dist(x_1, c_2)$, is excluded from the comparison according to Eq. (3), resulting in a value of 1.

The SC method is a (moderate) technique for identifying misclassified data points in k-means clustering. By utilizing the threshold value, the SC technique can identify misclassified points so they can be minimized, thereby improving the accuracy of the clustering algorithm.

D. Post-processing Approach

Post-processing is a technique used with clustered data of k-means to improve the accuracy and quality of the resulting clusters [7]. In this phase, possibly misclassified labels are detected, and a corrective process is applied to obtain more accurate results. This study incorporates gradient boosting as a post-processing technique after applying the SC method. Gradient boosting is a popular machine learning method utilized for regression and classification tasks. It involves combining multiple weak models, usually decision trees, to form a powerful model that can make precise predictions. Gradient boosting is effective in handling imbalanced datasets, noisy data, and high-dimensional data [35].

To determine the optimal number of estimators for gradient boosting, a method is employed where the data is divided into training and testing sets, and multiple iterations of training and testing are conducted. Various ranges of estimators are tested, and the results are compared to identify the ideal number. The experiments indicate that the best outcomes were obtained with 100-200 estimators.

Gradient boosting also requires additional parameters such as learning rate, maximum depth, and random state. The best values for these parameters are found using a grid search technique, which entails trying a range of values for each parameter and choosing the combination that results in the highest performance [36]. However, in this study, the default values provided by the library were used for these parameters, as they are generally well-suited for a wide range of scenarios and models, as shown in Listing 2.

Listing 2: Gradient Boosting Parameters

```
ensemble.GradientBoostingClassifier(loss='log_loss',
     learning_rate=0.1, n_estimators=100, subsample=1.0,
     criterion='friedman_mse', min_samples_split=2,
     min_samples_leaf=1, min_weight_fraction_leaf=0.0,
     max_depth=3, min_impurity_decrease=0.0, init=None,
     random_state=None, max_features=None, verbose=0,
     max_leaf_nodes=None, warm_start=False,
     validation_fraction=0.1, n_iter_no_change=None, tol
     =0.0001, ccp_alpha=0.0)
```

The k-means clustering algorithm's performance was successfully enhanced by employing gradient boosting during the phase of post-processing. The proposed approach substantially increased algorithm accuracy through the detection of potentially misclassified labels and the attempts to correct them. Algorithm 1 demonstrates the process of training, testing, and evaluating the performance of the gradient boosting algorithm in the post-processing phase.

Algorithm 1 Gradient Boosting in the Post-processing Phase

```
Input: Correctly labeled set $X_{train}, y_{train}$ and the misclassified set $X_{test}$
Output: Predicted labels $y_{pred}$ for all dataset
Set the parameters for the gradient boosting algorithm
Train the gradient boosting classifier on $X_{train}$ and $y_{train}$
$y_{test} \leftarrow$ Apply the trained gradient boosting classifier on $X_{test}$
$y_{pred} \leftarrow \textsc{Append}(y_{train}, y_{test})$
Evaluate classifier performance using evaluation metrics (accuracy, precision, recall, F1-score) on the corrected labels.
return $y_{pred}$
```

E. Evaluation Metrics

The performance of the proposed approach is evaluated in terms of classification accuracy, precision, recall, and F1 scores to the formerly indicated datasets. The evaluation metrics are calculated using the following equations, which are measured by utilizing the true positive (TP), true negative (TN), false positive (FP), and false negative (FN). Accuracy represents the number of correctly classified data instances over the total number of data instances. Eq. (5) shows the accuracy formula:

$$Accuracy = \frac{TN + TP}{TN + FP + TP + FN} \tag{5}$$

The precision result represents the positive predictive value in the classified data instances. Eq. (6) shows the precision formula:

$$Precision = \frac{TP}{TP + FP} \tag{6}$$

The recall value represents the true positive rate of data instances. Eq. (7) shows the recall formula:

$$Recall = \frac{TP}{TP + FN} \tag{7}$$

The F1 score represents the harmonic mean of both precision and recall. Eq. (8) shows the F1 score formula:

$$F1\ Score = 2 \times \frac{Precision \times Recall}{Precision + Recall} \tag{8}$$

The results of all the evaluation metrics used to measure the performance of the proposed approach on the previously described datasets are discussed in the Results and Discussion section.

F. Experimental Setup

For the experimental setup, the proposed method is implemented using the Python programming language. The libraries NumPy, Pandas, and Scikit-learn are chosen for their ease of use and their popularity in the machine learning community. The experiments are conducted on a computer with an Intel Core i7 processor and 16GB of RAM.

As mentioned previously, Iris, Forest, and Banknote are the three UCI datasets that were employed in the experiment. After obtaining clustered data with k-means, each data is split using SC into correctly classified points, a training set, and possibly misclassified points, a testing set. Then, the training set employed to train the model using the training set processed by the k-means algorithm. These labeled data are stable and will not be modified after the post-processing phase is performed. Furthermore, the testing set containing all misclassified labels is fed forward to the trained model, which modifies the labels to obtain correct and enhanced results.

The proposed approach is conducted using the following steps:

Step 1. Normalize the dataset using the MinMaxScaler.

Step 2. Process the normalized data by the k-means algorithm to produce a k number of clusters.

Step 3. Split the clustered data using the SC method. The correct labels are used as the training set for the gradient boosting algorithm, while the misclassified labels are stored for later use.

Step 4. Predict the labels for the misclassified data. The final result is obtained by combining the correct and predicted labels.

The entire process of the proposed method is shown in Fig. 1.

Eventually, the results of the experiments have demonstrated that the post-processing accompanied by SC and gradient boosting approaches is a powerful tool for enhancing the results of the k-means clustering algorithm. The approach offers a flexible and effective method to refine the results of the k-means algorithm, making it a valuable tool for various applications and datasets. A comprehensive and detailed presentation of the results is provided in the Results and Discussion section of the research.

IV. Results and Discussion

The outcomes of the experiment that has been successfully and effectively conducted, based on the mentioned steps earlier, will be detailed and compared to other approaches from [7], [14] in this section. The section is divided into three subsections. The first subsection is to show the SC results and understand the effect of various threshold values. In the second subsection, the enhanced accuracy of the supervised model employing the gradient boosting algorithm is presented

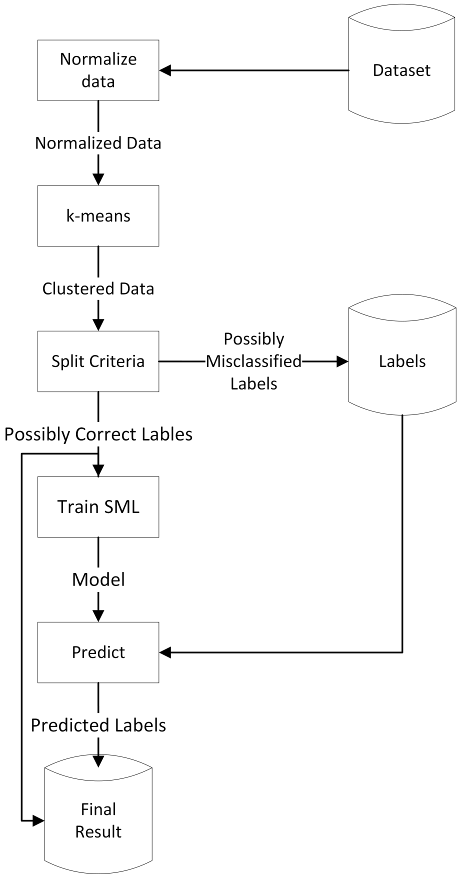

Fig. 1. A flowchart of the proposed approach.

and compared against random forest for the Iris dataset. For the last subsection, the enhanced model is compared with other improved k-means algorithms, and the model outperforms all of them in two datasets. Before showing the post-process results, the accuracy of k-means for the three datasets needs to be shown. It is as follows:

- 89% for the Iris dataset (133 out of 150 correctly clustered).
- 55% for the Banknote dataset (790 out of 1372 correctly clustered).
- 77% for the Forest dataset (405 out of 532 correctly clustered).

A. Split Criteria

The split criteria are used to detect misclassified points, but its modest and adequate mechanism could also identify correctly classified points as misclassified. Choosing a specific threshold for split criteria is not straightforward. Therefore, a range of values for the threshold is sufficient to work on all datasets. The study of split criteria has been accomplished previously for the Iris dataset using three variables: total points, correctly classified points, and misclassified points [7]. In this study, a new variable called "remaining misclassified points" is introduced, which represents the points that should have been detected as misclassified by the split criteria. Additionally, the exploration of various threshold values for the split criteria is conducted. Furthermore, the study is extended with two additional datasets, the Banknote and Forest datasets.

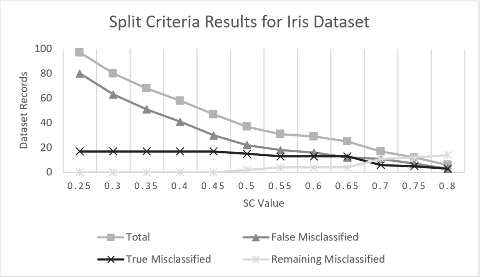

Fig. 2. Split criteria results for iris dataset.

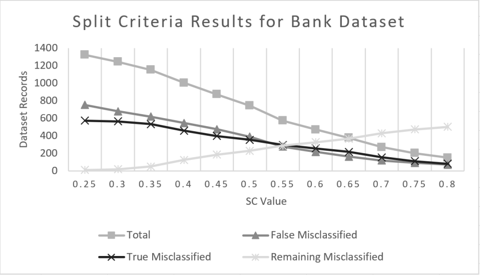

Fig. 3. Split criteria results for banknote dataset.

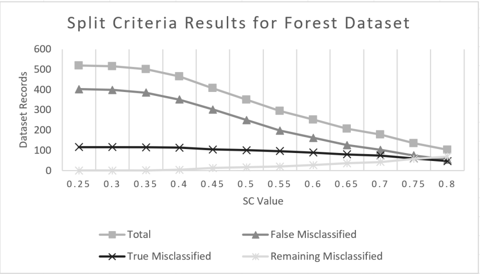

Fig. 4. Split criteria results for forest dataset.

Based on a previous study of the SC results for the Iris dataset, the appropriate threshold values for balanced results are between 0.4 and 0.6 [7]. With the previous conclusion as a guide, this study confirms that threshold values between 0.4 to 0.6 are also sufficient for all three datasets. When the threshold value is small, all misclassified points are almost detected right, true misclassified, as shown in Fig. 2, 3, and 4 precisely at 0.25 SC value. At the same time, the points that are correctly clustered by k-means are also considered as possibly misclassified points, false misclassified. Accordingly, gradually increasing the threshold value decreases both true and false misclassified while increasing the remaining misclassified points that should be detected as misclassified. Unfortunately, a compromise should be made by choosing balanced results for the threshold value with the main focus on decreasing the remaining misclassified points as much as possible, as follows: 0.45-0.65 for the Iris dataset as shown in Fig. 2, 0.35-0.50 for the Banknote dataset as shown in Fig. 3, 0.4-0.6 for Forest dataset as shown in Fig. 4. Therefore, continuing to use the same range for the threshold between 0.40 and 0.60 seems reasonable while also considering comparing results and being consistent with previous findings. In addition, the SC threshold value is incremented by 0.5. Therefore, the set of points within the two endpoints [0.40,0.60] are 0.40, 0.45, 0.50, 0.55, and 0.60.

B. Gradient Boosting Post-process for the Iris Dataset

The Iris dataset has 150 data points and three classes, each with 50 data points [11]. This section focuses on presenting the results obtained from processing the Iris dataset exclusively. The results of post-process precision and recall for each class of the Iris dataset with a set of threshold points between two endpoints [0.25, 0.75] are shown in Fig. 5 and 6. The two figures represent the three classes as Class 0, Class 1, and Class 2. In addition, each figure is associated with a data table containing the precise percentage value. The data table is essential in this context as the Iris dataset has been used extensively in testing algorithms, and even a slight variation in the percentage is considered a significant accomplishment. A comparison of precision and recall results with random forest results is shown in Table II. This paper uses k-means with gradient boosting, abbreviated as K+GB, while the previous work has used k-means with random forest, abbreviated as K+RF. Besides precision and recall, the accuracy of both models is set out in Table III. Both Tables II and III illustrate the results of a set of threshold values between 0.40 and 0.60. It is apparent from both tables that a few cell values are empty. All these missing values are related to random forest results since the previous experiment did not provide the results of either 0.45 or 0.55 threshold values.

	0.25	0.3	0.35	0.4	0.45	0.5	0.55	0.6	0.65	0.7	0.75
Class 0	0.81	1	1	1	1	1	1	1	1	1	1
Class 1	0.62	0.67	0.77	0.86	0.92	0.78	0.92	0.92	0.92	0.74	0.77
Class 2	0.82	0.96	0.97	0.98	0.96	1	0.96	0.98	0.98	0.87	0.97

Fig. 5. Iris dataset precision for each class vs. SC Value.

	0.25	0.3	0.35	0.4	0.45	0.5	0.55	0.6	0.65	0.7	0.75
Class 0	1	1	1	1	1	1	1	1	1	1	1
Class 1	0.68	0.98	0.98	0.98	0.96	1	0.96	0.98	0.98	0.9	0.98
Class 2	0.54	0.52	0.7	0.84	0.92	0.72	0.92	0.92	0.92	0.68	0.7

Fig. 6. Iris dataset recall for each class vs. SC Value.

Class 1 and 2 misclassified points are misallocated between Class 1 and 2, while all Class 0 points hold steady along all threshold values except at 0.25, as seen in Fig. 5 and 6. What stands out in both figures is the 100% precision and recall for Class 0, except at 0.25, which has 81% precision but still has 100% recall. Obviously, misclassified points are only within Class 1 and Class 2. Class 2 has higher precision than Class 1, while Class 1 has higher recall than Class 2. Further statistics by calculating the average reveals that the model precision percentage is less than 90% at three threshold values: 0.25, 0.30, and 0.70 with 75%, 88%, and 87% precision, respectively. In contrast, the recall percentage is less than 90% at five different threshold values: 0.25, 0.30, 0.35, 0.70, and 0.75 with 74%, 83%, 89%, 86%, and 89% recall, respectively. Overall, excellent results are easily observed at four different threshold values.

Without including rows with missing values, the proposed model outperforms random forest by two out of three threshold values in Class 1 and Class 2 in Table II and accuracy in Table III. In Table II, for Class 1, the model's precision is better at 0.40 and 0.60, and its recall is better at 0.40 and 0.50. Accordingly, for Class 2, the model's precision is better at 0.40 and 0.50, and its recall is better at 0.40 and 0.60. Moreover, in Table III, its accuracy is higher for both 0.40 and 0.60. The most interesting point of these results is that the random forest's best result is at a 0.60 threshold value with 94% accuracy. In contrast, the best accuracy for the proposed model is at the same threshold value with 97% accuracy.

C. Gradient Boosting Post-process vs. Other Improved K-Means

The proposed model has been tested with two additional datasets besides the Iris dataset, and the findings are presented with the results of other approaches as benchmarks. The model's accuracy and average accuracy using a set of threshold values are reported in Table V. The average accuracy is calculated for two reasons. First, the approach implemented can not be validated by one threshold value to be viable for comparison with other approaches. Second, the other approaches used as benchmarks have presented their accuracy values by taking the average values after running the algorithms several times. Therefore, Table IV compares the obtained average accuracy from the proposed model with four other algorithms: k-means, FCM, three-way k-means, and improved three-way k-means [14]. The accuracy is the only finding reported in this section.

The proposed method using gradient boosting outperforms other algorithms with two out of three datasets for one algorithm and three out of three for the rest of the algorithms as reported in Table IV. After obtaining the accuracy for the set of points between 0.40 and 0.60 threshold values as shown in Table V, the average accuracy is calculated as 94.67% for the Iris, 63.24% for the Banknote, and 78.61% for the Forest datasets. The proposed approach outperforms all algorithms for the Iris and Banknote datasets, achieving an approximate increase in accuracy of 4% and 2%, respectively. Only for the Forest dataset, the model slightly exceeds all algorithms except for the improved three-way k-means.

V. Conclusion

Clustering algorithms are frequently used to identify dispersed patterns and group them into clusters. In order to improve the quality of the k-means clustering algorithm, this research paper has been introduced. The proposed research paper enhances the performance of the k-means clustering

algorithm by employing gradient boosting as a post-processing phase. Consequently, the proposed model optimizes misclassified candidate clusters from the k-means algorithm by post-processing them using the gradient boosting algorithm. Across three well-known benchmark datasets, the proposed approach performance is assessed in terms of accuracy, precision, recall, and F1 score. According to the experimental outcomes, the proposed model achieved an average accuracy of 94.67% for the Iris dataset, 63.24% for the Banknote dataset, and 78.61% for the Forest dataset. The outcomes of the proposed model confirm its effectiveness and demonstrate its applicability to a wide variety of clustering problems. Thus, several real-life domains can take advantage of the proposed model in order to enhance the data analysis process. The proposed approach has been explored on a limited number of benchmark datasets that do not encompass real-world data. For this reason, the model's capacity for generalization is likely to be optimized in future research. Eventually, based on these principles, future research will concentrate on enhancing the accuracy of the proposed model by utilizing a real-world dataset, assimilating it with other learning approaches, and offering a sophisticated split criteria technique to achieve more promising outcomes.

ACKNOWLEDGMENT

Researchers would like to thank the Deanship of Scientific Research, Qassim University, for funding the publication of this project.

Optimizing Grape Leaf Disease Identification Through Transfer Learning and Hyperparameter Tuning

Hoang-Tu Vo, Kheo Chau Mui, Nhon Nguyen Thien, Phuc Pham Tien, Huan Lam Le
Information Technology Department
FPT University, Cantho city, Vietnam

***Abstract*—Grapes are a globally cultivated fruit with significant economic and nutritional value, but they are susceptible to diseases that can harm crop quality and yield. Identifying grape leaf diseases accurately and promptly is vital for effective disease management and sustainable viticulture. To address this challenge, we employ a transfer learning approach, utilizing well-established pre-trained models such as ResNet50V2, ResNet152V2, MobileNetV2, Xception, and InceptionV3, renowned for their exceptional performance across various tasks. Our primary objective is to identify the most suitable network architecture for the classification of grape leaf diseases. This is achieved through a rigorous evaluation process that considers key metrics such as accuracy, F1 score, precision, recall, and loss. By systematically assessing these models, we aim to select the one that demonstrates the best performance on our dataset. Following model selection, we proceed to the crucial phase of fine-tuning the model's hyperparameters. This fine-tuning process is essential to enhance the model's predictive capabilities and overall effectiveness in disease identification. To accomplish this, we conduct an extensive hyperparameter search using the Hyperband strategy. Hyperparameters play a pivotal role in shaping the behavior and performance of deep learning models, and by systematically exploring a wide range of hyperparameter combinations, our goal is to identify the most optimal configuration that maximizes the model's performance on the given dataset. Additionally, the study's results were compared with those of numerous relevant studies.**

Keywords*—*Grape disease recognition; disease identification; transfer learning; hyperparameter optimization; hyperband strategy; fine-tuning; deep learning

I. Introduction

The presence of plant diseases can result in a notable reduction in agricultural yields, causing decreased crop productivity and financial setbacks for farmers [1], [2], [3], [4], [5], [6]. Prompt identification and timely management of these diseases are essential to minimize their adverse consequences and optimize crop yields. Swift detection and intervention strategies are key to preventing disease outbreaks and fostering sustainable crop production. Through swift detection and proactive measures against plant diseases, farmers can employ suitable control methods like precise fungicide applications or crop rotations to reduce yield losses and protect their harvests [7], [8]. Furthermore, timely disease detection can also assist in preventing the spread of diseases to nearby plants, preserving the overall well-being of agricultural ecosystems. Traditional approaches for diagnosing plant diseases have been acknowledged as problematic and ineffective in numerous agricultural contexts. These methods often depend on visual symptoms and physical inspections, posing challenges in accurately identifying diseases, particularly during their initial development stages. Relying solely on visual symptoms can be deceptive, as various diseases may manifest similar signs, resulting in misdiagnoses and improper treatments. Additionally, these traditional methods may not effectively detect pathogens that lack visible indications on plant surfaces, adding complexity to the diagnostic procedure. Acknowledging these constraints, there has been an increasing focus on embracing contemporary technology-driven solutions, including advanced image-based recognition systems and artificial intelligence-based methods, to enhance the precision and efficiency of plant disease diagnosis and management. Deep Learning (DL) and Machine Learning (ML) techniques have gained extensive utilization in image recognition applications across diverse fields. Including medicine [9], [10], [11], [12]. In self-driving cars [13], [14], [15], [16], [17], [18]. In agriculture [19], [20], [21], [22], [23]. Especially when it comes to automating the identification of plant diseases [24], [25], [26], [27], [28], [29], [30], etc.

This article makes a significant contribution to the agricultural and viticulture sectors by addressing the substantial challenges associated with grape disease management and precise identification. The study's primary contribution lies in the adoption of advanced technological solutions, including transfer learning and pre-trained models renowned for their exceptional performance such as ResNet50V2, ResNet152V2, MobileNetV2, Xception, and InceptionV3. By employing these cutting-edge techniques, the research aims to provide more accurate and efficient grape leaf disease classification, thereby bolstering disease management strategies. Additionally, the study highlights the critical role of fine-tuning model hyperparameters through extensive hyperparameter searches, which is pivotal in enhancing the predictive capabilities and overall effectiveness of the selected model. This comprehensive approach serves to optimize grape disease management and advance sustainable viticulture practices, making a valuable contribution to the field of agricultural research and disease management.

The structure of the paper is as follows: A comprehensive review of the literature is provided in Section II. The Grape Disease Recognition Methodology, comprising the Data Set, Data Preparation, and Model Evaluation Metrics, is described in Section III. Section IV describes the experimental system and final results. Section V provides a summary of the study's results, concluding notes, and a comparison of current approaches to our suggested model for a similar problem. Lastly, Section VI outlines potential avenues for future study.

II. Related Works

Recent advancements in deep learning methodologies, in particular, convolutional neural networks (CNNs) and models of transfer learning (TL), have demonstrated significant progress in automating agricultural disease identification techniques. Multiple studies have explored the utilization of deep learning techniques to identify leaf diseases in general, including grape leaves in particular. Researchers are actively exploring innovative approaches to enhance the accuracy of disease identification.

Ullah, Zahid, et al. in [31] introduces a hybrid deep learning (DL)-based approach, combining EfficientNetB3 and MobileNet into the EffiMob-Net model, to accurately detect tomato plant diseases from leaf images. The study addresses overfitting by employing techniques like regularization, dropout, and batch normalization. The proposed EffiMob-Net model achieved a 99.92% success rate in accurately identifying tomato leaf diseases when evaluated on a dataset of diseased and healthy tomato leaf images, highlighting its excellent feature extraction capabilities.

In [32], Jing, Jiaping, et al. visually differentiates between nine different infectious diseases in tomato leaves and healthy leaves. The study applied EfficientNetB5 to a dataset of tomato leaf diseases (TLD) without segmentation, achieving an impressive average test accuracy of 99.07%. To enhance model interpretability, the paper introduces the use of gradient-weighted class activation mapping (GradCAM) and local interpretable model-agnostic explanations. This interpretability is vital for improving predictive performance, fostering trust, and enabling the integration of the model into agricultural practices.

In [33], the authors have developed a lightweight model for identifying tomato leaf diseases, which they named LightMixer. This model combines a depth convolution with a Phish module and a light residual module. Experimental findings reveal that the LightMixer model achieved an impressive 99.3% accuracy when tested on public datasets, all while maintaining a minimal parameter count of 1.5 million.

In [34], the authors introduce a pipeline for automated tomato leaf disease identification, incorporating three compact convolutional neural networks (CNNs). They leverage transfer learning to extract deep features from The final fully connected layer within the Convolutional Neural Networks (CNNs), resulting in a more concise and high-level representation. These features are then combined from all three CNNs to harness the strengths of each structure, followed by the application of a hybrid feature selection method to generate a comprehensive feature set with reduced dimensions. Notably, the results demonstrate that the K-nearest neighbor and support vector machine classifiers achieved remarkable accuracy, reaching 99.92% and 99.90%, respectively, using a minimal feature set of 22 and 24 features.

The authors in [35] introduces a convolutional neural network-based model for the identification and classification of tomato leaf diseases. The model is trained using a publicly available dataset and supplemented with field photographs. To prevent overfitting, generative adversarial networks are employed to generate data with similar characteristics to the training set. The results demonstrate the model's exceptional performance, with an accuracy exceeding 99% on both the training and test datasets in the detection and classification of tomato leaf diseases.

In [36], an integrated deep learning solution is introduced for the detection and classification of banana diseases. The approach involves the examination of various parts of the banana plant, not just the leaves, utilizing convolutional neural networks (CNN) and a combined binary and multiclass Support Vector Machine (FSVM). This method yields outstanding results, with an impressive overall accuracy of 99%, alongside excellent precision-recall and F1-score performance metrics.

The research in [37], an efficient method for detecting rice plant diseases is developed, leveraging convolutional neural networks. The study concentrates discusses three major rice illnesses: leaf smut, brown spot (caused by fungus), and bacterial leaf blight (caused by bacteria). The proposed approach focuses on recognizing and identifying these diseases based on the size, shape, and color of lesions in rice leaf images. By employing Otsu's global thresholding method for binarizing images, background noise is effectively removed. The fully connected CNN model, trained with 4000 samples of each diseased and healthy rice leaf, demonstrates impressive performance, reaching 99.7% accuracy on the dataset.

The research in [38] introduces a CNN model for the classification of rice and potato plant leaf diseases. The study employs a dataset of 5932 rice leaf images and 1500 potato leaf images. The proposed CNN model effectively captures hidden patterns in raw images, achieving an impressive accuracy of 99.58% for rice leaf classification and 97.66% for potato leaves. The results reveal that the CNN model outperforms other machine learning image classifiers, including Support Vector Machine (SVM), K-Nearest Neighbors (KNN), Decision Tree, and Random Forest.

The authors in [39] presents a novel approach for precise detection and classification of rice leaf diseases, utilizing a Deep Convolutional Neural Network (DCNN) with transfer learning. The method includes a modification of the VGG19-based transfer learning technique and successfully detects and diagnoses six distinct classes of rice leaf diseases. The maximum average accuracy achieved is 96.08% when using a non-normalized augmented dataset, with corresponding values of 0.9620 for precision, 0.9617 for recall, 0.9921 for specificity, and 0.9616 for the F1-score.

In [40], the authors employ convolutional neural network (CNN) methods to address the classification of five distinct potato disease classes, including Healthy, Black Scurf, Common Scab, Black Leg, and Pink Rot. Their study utilizes a dataset of 5000 potato pictures and compares their classification results with various alternative techniques, including Transfer Learning, R-CNN, VGG, Alexnet, and Googlenet. Notably, the deep learning method proposed in the paper outperforms existing approaches, achieving accuracy rates of 100% and 99% in some of the individual disease classes.

In [41], the impact of hyperparameters and training approaches on model performance is examined. The study evaluates the performance of four deep learning models, with three trained from scratch and one using a pre-trained ResNet50 model, in the context of detecting potato plant diseases, specifically early blight and late blight, using the plant village dataset. The experimental results demonstrate that models trained from scratch outperform the pre-trained ResNet50 model, achieving accuracies of 96.75% and 94.43% compared to 93.5%. This suggests that pre-trained models may not always be the best choice for all datasets.

The study in [42] introduces an efficient deep learning-based solution to detect crop diseases, effectively preventing disease spread and ensuring healthy plant growth. In the experiment, the model achieved an impressive overall accuracy of 99.55% in identifying three diseases in corn, potato, and tomato. Furthermore, individual testing of these plants revealed classification accuracies of 98.44% for corn, 99.43% for potato, and 95.20% for tomato, showcasing the effectiveness of the proposed model.

The author in [43] conducts a comprehensive exploration of deep transfer learning and deep convolutional neural networks (CNNs). The primary focus of the research is to put carried out a model that has been pre-trained, specifically ResNet50 for plant disease detection and classification, utilizing the ImageNet dataset. Corn (maize) and Potato images from the plant village dataset are used to assess the model's performance. The model processes input images of Corn (maize) or Potato leaves through preprocessing techniques like data augmentation and segmentation before using the Resnet50 model. The evaluation of the Resnet50 model yielded the following results: 98.0% accuracy, 77.0% precision, 99.0% recall, and 86.0% F1-score.

The study in [44] explores the use of well-known Convolutional Neural Network (CNN) models—EfficientNetB5, MobileNet, ResNet50, InceptionV3, and VGG16—for classifying plant diseases. Notably, EfficientNetB5 exhibited superior performance, achieving a remarkable 99.2% classification accuracy.

Numerous studies have been carried out concerning the application of deep learning for disease identification in grape leaves.

The study [45] introduces an approach for grape leaf disease detection by utilizing convolutional capsule networks, which represent a promising neural network paradigm in deep learning. These networks use capsules, groups of neurons, to effectively capture spatial feature information. The novelty of this work lies in the inclusion of convolutional layers before the primary caps layer, reducing the number of capsules and expediting the dynamic routing process. The suggested approach, tested on both augmented and non-augmented datasets, successfully identifies grape leaf diseases with an impressive accuracy of 99.12%.

In this research [46], authors introduces the EfficientNet B0 deep learning model for the classification of grapevine leaves. The proposed deep learning architecture is compared with established counterparts, and the grapevine leaf dataset serves as the training data with 3000 images. The EfficientNet B0 model is trained through transfer learning and fine-tuning approaches, ultimately achieving the highest accuracy of 99.67%. This outperforms classical CNN and state-of-the-art models like VGG19, MobileNet V2, Inception V3, and ResNet152.

The study [47] delves into the classification of grapevine leaves using deep learning techniques. Initially, 500 pictures of vine leaves from 5 different species were captured using a specialized self-illuminating system, and this dataset was subsequently expanded to 2500 images through data augmentation. The classification process involved three methods: fine-tuning a state-of-the-art CNN model, MobileNetv2; obtaining features from the pre-trained Logits layer of MobileNetv2 and employing several SVM kernels; and selecting and reducing 1000 features from MobileNetv2's Logits layer to 250 using the Chi-Squares method, followed by classification with different SVM kernels. The most successful method involved feature extraction and reduction, with the Cubic SVM kernel achieving an impressive classification accuracy of 97.60%.

In [48], the study centers on the early identification and classification of grape diseases, introducing a novel framework that combines deep learning with conventional architecture for superior performance. The process involves three key steps: (a) feature extraction using transfer learning with pre-trained deep models like AlexNet and ResNet101, (b) feature selection employing the novel Yager Entropy and Kurtosis (YEaK) technique to identify the best features, and (c) merging these strong features using a parallel approach, followed by classification through least squared support vector machine (LS-SVM). The approach is validated through simulations on infected grape leaves from the plant village dataset, achieving an impressive accuracy of 99%. The results indicate the exceptional performance of the proposed approach in comparison to various existing methods.

In [49], the authors aimed to enhance grape leaf disease identification accuracy within constraints of limited computing resources and a small training dataset, utilizing deep transfer learning and an improved MobileNetV3 model named GLD-DTL. By retraining the modified networks using a grape leaf diseases dataset with six diseases constructed with data augmentation and image annotation techniques, the authors achieved exceptional results, with an identification accuracy of 99.84% and a compact model size of just 30 MB.

Highlighting the significance of proactive disease control, agricultural specialists and researchers persistently strive to innovate advanced technologies and techniques aimed at early disease detection, thereby enhancing the resilience and productivity of crop production systems worldwide. Therefore, the purpose of this study is to focus on the adoption of advanced technological solutions, including powerful pre-trained models like ResNet50V2, ResNet152V2, MobileNetV2, Xception, and InceptionV3. The study leverages these state-of-the-art techniques to achieve more precise and efficient classification of grape leaf diseases, ultimately strengthening disease management strategies. Furthermore, the research underscores the critical importance of fine-tuning model hyperparameters through extensive hyperparameter searches, using a hyperparameter optimization algorithm called Hyperband, a pivotal step in enhancing the predictive capabilities and overall effectiveness of the chosen model.

III. Methodology

A. *Data Collection and Preparation*

In this study, we worked with a dataset comprising 9,027 images, sourced from Kaggle [50], known as the Grape Disease dataset. This dataset is divided into four classes: Grape-Esca-(Black-Measles) (Class 1), Grape-Black-rot (Class 2), Grape-Leaf-blight-(Isariopsis-Leaf-Spot) (Class 3), and Grape-healthy (Class 4). Sample images of grape diseases from this dataset are shown in Fig. 1, and the dataset distribution is visually represented in Fig. 2. Before proceeding with model training and evaluation, a preprocessing step is conducted on the images, which involves using an image preprocessing technique and sizing them to 224 x 224. The dataset is then divided into subsets, with 5,416 images allocated for the training set, 1,806 images for the validation set, and 1,805 images for the test set.

B. *Overall Methodology*

The research process can be divided into two primary phases.

1) Phase 1: Model selection and evaluation: The initial phase focuses on selecting the most suitable network architecture for classifying grape leaf diseases. This involves employing a transfer learning approach with established pre-trained models renowned for their performance. Rigorous evaluation criteria, including accuracy, F1 score, precision, recall, and loss, are used to assess these models. The objective here is to scientifically identify the model that performs best with the dataset (Fig. 3). Models used in this phase include: ResNet50V2 [51], ResNet152V2 [52], MobileNetV2 [53], Xception [54], and InceptionV3 [55].

2) Phase 2: Fine-tuning and hyper-parameter optimization: Following model selection, the next phase involves fine-tuning the chosen model's hyperparameters. This crucial step aims to improve the model's predictive abilities and overall effectiveness in identifying diseases. Extensive hyperparameter search utilizing the hyperband [56] strategy is conducted to refine and optimize the model's performance (Fig. 4).

The primary objective of hyperparameter optimization is to increase the efficiency and automate the hyperparameter tuning process. Unlike the model parameters (weights and

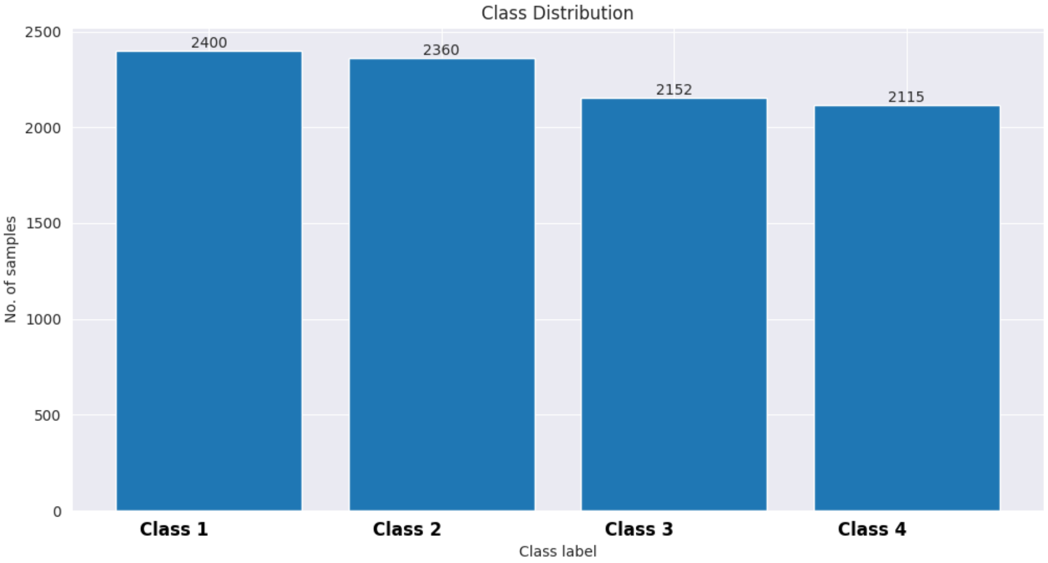

Fig. 2. A distribution of datasets.

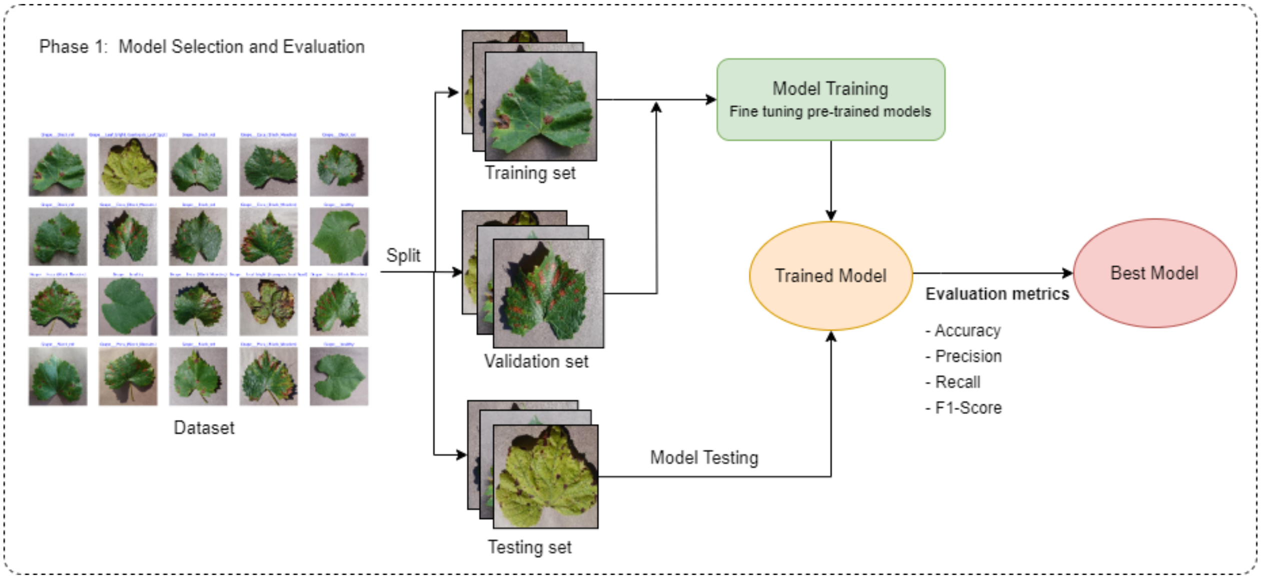

Fig. 3. The Process of model selection and evaluation.

biases), hyperparameters are set before the training begins and significantly influence the model's performance. The main goal is to find the most optimal set of hyperparameters that maximize the model's performance metrics. The ultimate goal of a hyperparameter optimization issues is to achieve Eq. (1).

$$x^* = \arg \underset{x\in X}{min} f(x) \tag{1}$$

Where $f(x)$ is the objective function; x^* represents the set of hyperparameter configurations that produce the best possible value for $f(x)$; The hyperparameter x can take on any value within the search space X.

C. Fine Tuning Pre-trained Models

In this research, the research team aim to employ a transfer learning methodology due to the scarcity of images depicting diseases on grape leaves. This approach offers substantial advantages in identifying crucial characteristics associated with grape leaf diseases. By utilizing trained models such as ResNet50V2, ResNet152V2, MobileNetV2, Xception, and InceptionV3, known for their high performance across diverse tasks, our goal is to determine the most suitable network architecture for our specific classification needs. These models will be adjusted before the training phase, keeping all of the original layer structure while adjusting the output using Batch Normalization layer. Additionally, they include a Global Aver-

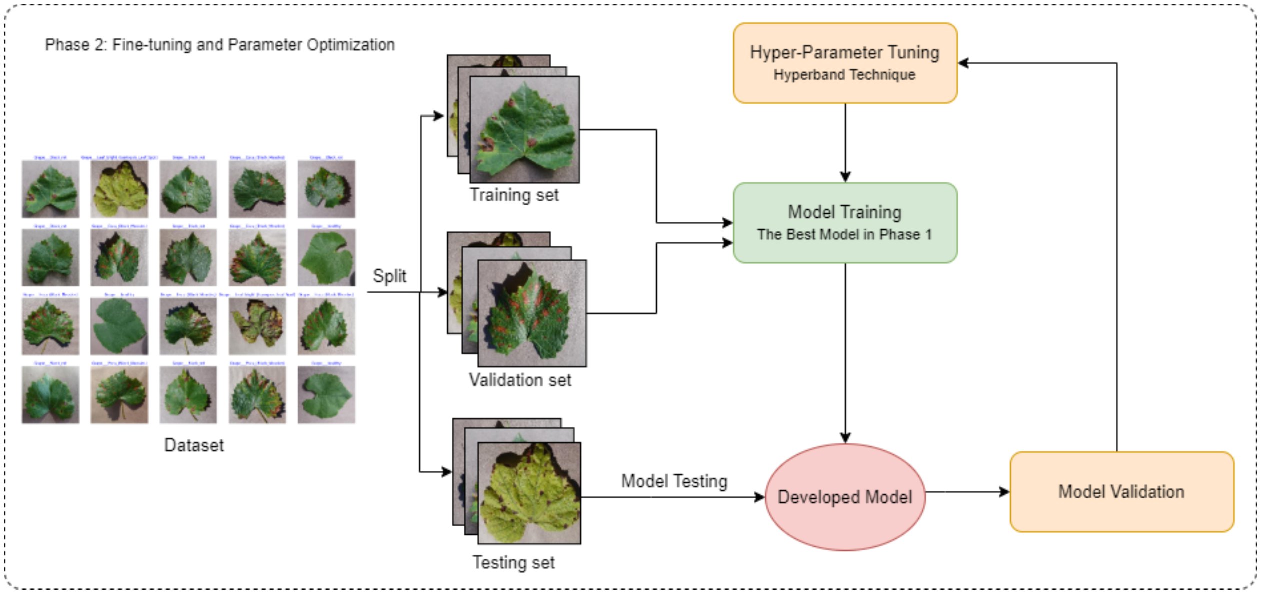

Fig. 4. The Process of fine-tuning and parameter optimization.

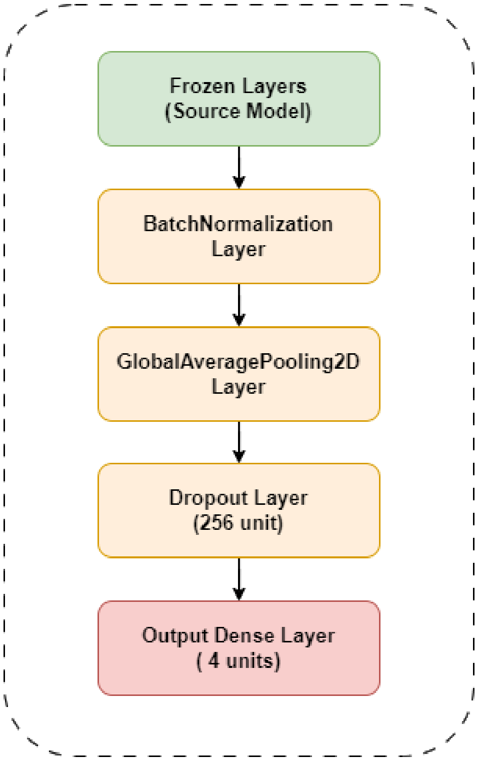

Fig. 5. Fine tuning pre-trained model.

age Pooling layer for spatial dimension reduction, a Dropout layer, a Dense layer featuring 256 units activated by ReLU, and finally, an output Dense layer with ’class count’ units employing softmax activation for classification purposes. Fig. 5 shows an overview of the fundamental structure of fine tuning pre-trained model.

D. Performance Evaluation Measures

The evaluation of the proposed model involved a comprehensive analysis using various key metrics. Precision, which measures the accuracy of positive predictions among all predicted positives, showcased the model’s capability to minimize misclassification of non-diseased instances in grape leaf disease classification. Recall, indicating the proportion of accurately predicted positives among all actual positives, highlighted the model’s effectiveness in identifying all relevant disease instances. The F1-score, derived from the harmonic mean of precision and recall, offered a balanced evaluation of how well the model balances precision and recall. Accuracy, a crucial metric in classification tasks, assessed the model’s ability to correctly predict instances overall within the dataset. Specifically in grape leaf disease recognition, accuracy indicated the model’s general correctness in identifying and categorizing various disease types from input grape images.

$$Accuracy = \frac{TP + TN}{TP + TN + FP + FN} \tag{2}$$

$$Precision = \frac{TP}{TP + FP} \tag{3}$$

$$Recall = \frac{TP}{TP + FN} \tag{4}$$

$$F_1 - Score = \frac{Precision * Recall}{Precision + Recall} \tag{5}$$

In which, FP stands for False Positive, TN for True Negative, TP for True Positive, and FN for False Negative.

IV. Results

A. Environmental Settings

The experiments were carried out using the Kaggle platform in order to obtain the experimental results. The Tesla P100-PCIE GPU, which was employed in the research, had 16GB of memory, and the system had 13GB of RAM. The model was trained using a batch size of 32 over a duration of 30 epochs.

B. Experiment

1) Experiment 1: Model selection and evaluation: Table I displays performance metrics for various models. Among them, MobileNetV2 stands out with the highest accuracy of 97.00%, coupled with strong precision, recall, and an F1 score, all at 97.00%. Additionally, MobileNetV2 boasts the lowest loss value of 0.175 among the listed models.

This demonstrates that MobileNetV2 not only achieves the highest accuracy but also maintains the lowest loss, signifying robust overall performance and superior generalization compared to other models in this context. Therefore, MobileNetV2 remains in use for phase 2 to fine-tune hyperparameters and strengthen the model's robustness. Details on the Training/Validation Loss and Accuracy of the models in this study during training are presented in Fig. 6, Fig. 7, Fig. 8, Fig. 9, and Fig. 10.

TABLE I. The Fine-tuning Model's Testing Set Result

Models	Accuracy	Precision	Recall	F1 score	Loss
ResNet50V2	95.45%	96.00%	95.75%	95.75%	0.227
ResNet152V2	93.29%	93.50%	93.75%	93.50%	0.290
MobileNetV2	**97.00%**	**97.00%**	**97.00%**	**97.00%**	**0.175**
Xception	91.30%	91.75%	91.75%	91.50%	0.389
InceptionV3	89.19%	89.75%	89.75%	89.50%	0.415

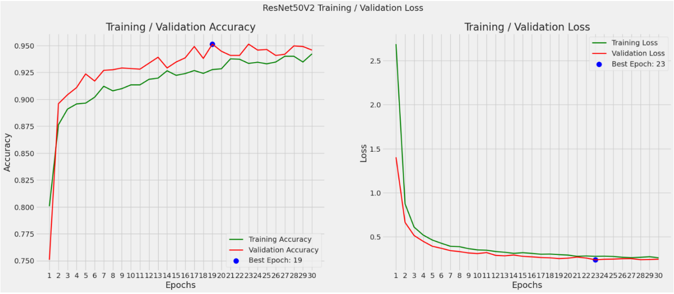

Fig. 6. ResNet50V2 training / validation accuracy and loss.

2) Experiment 2: Fine-tuning and hyper-parameter optimization: The search space for hyperparameters such as: Dropout rate, The number of units, Optimizer and Learning rate is given in Table II.

TABLE II. The Hyperparameter Search Space

The hyperparameters	Space for research
Dropout rate	Search space=[0.2, 0.3, 0.4, 0.5]
The number of units	Search space =[128, 256, 512, 1024]
Optimizer	Search space=['Adam', 'RMSprop', 'SGD', 'Adamax']
Learning rate	Search space=[1e-1, 1e-2, 1e-4, 1e-6]

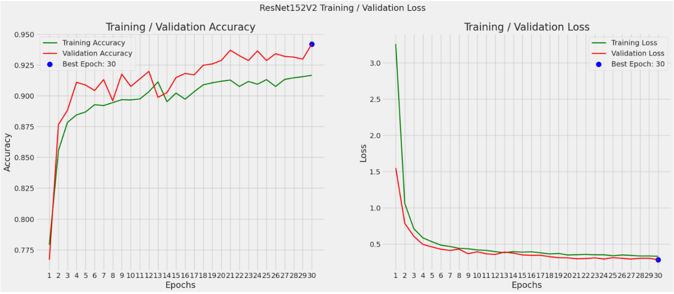

Fig. 7. ResNet152V2 training / validation accuracy and loss.

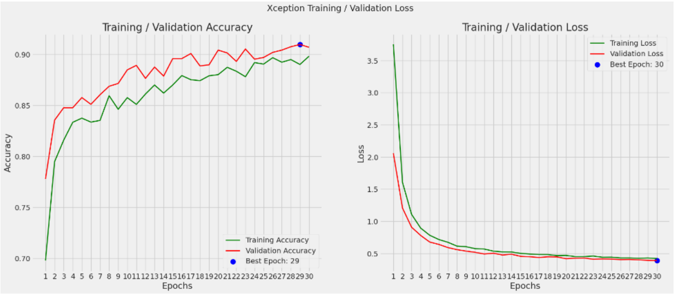

Fig. 8. Xception training / validation accuracy and loss.

After a thorough investigation of hyperparameters using Hyperband approaches and 45 trials, we achieved an outstanding 99.94% validation accuracy on the test set. The Test Loss that has been recorded is 0.144. Through careful tuning, the model was greatly improved, indicating an important improvement of 2.94%. The optimized hyperparameters, determined using Hyperband Optimization for fine-tuning the pre-trained MobileNetV2-based model, are presented in Table III.

TABLE III. Hyperparameter Values Found using Hyperband Optimization

Hyper parameter	Value
Dropout rate	0.4
Number of units	512
Optimizer	Adamax
Learning rate	0.0001

The best architectural model, obtained after determining the hyperparameter values, is shown in Fig. 11.

The presentation of Fig. 12 showcases a detailed comparison chart illustrating the performances of the best models concerning accuracy and loss scores.

And the confusion matrix of the best architectural model is shown in Fig. 13.

Table IV presents a comparative examination of the proposed model (the fine-tuned MobileNetV2-based model) with the state-of-the-art approaches on related issues. The table includes The plant's name, the number of disease labels, the number of pictures in the dataset, the detection method, and the accuracy rate.

According to research results, model proposed achieved a

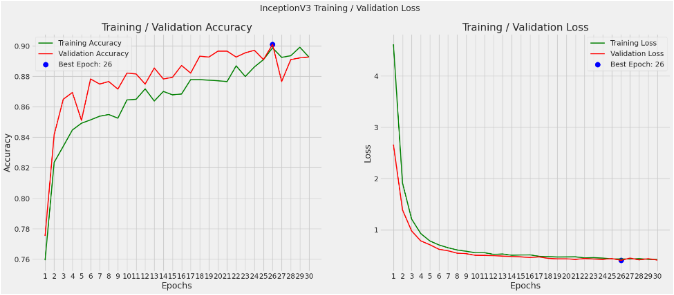

Fig. 9. InceptionV3 training / validation accuracy and loss.

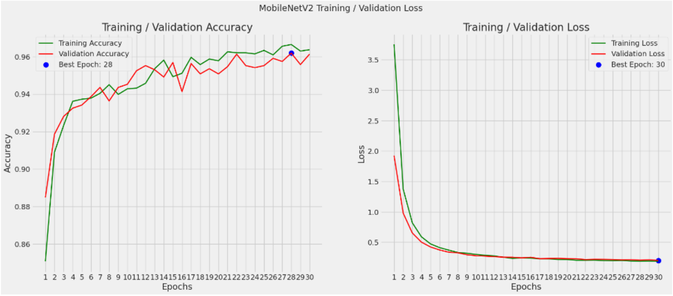

Fig. 10. MobileNetV2 training / validation accuracy and loss.

99.94% accuracy rate, outperforming all other techniques listed in the table for similar problems.

V. Conclusion

Growing grapes is an important worldwide enterprise that is essential for both nutritional value and economic survival. However, the quantity and quality of the crop are seriously threatened to a number of diseases. It is critical to identify these illnesses as soon as possible in order to maintain grape health and guarantee maximum yields.

To address this critical problem, we utilized a transfer learning approach that made use of a collection of reliable pre-trained models, including ResNet50V2, ResNet152V2, MobileNetV2, Xception, and InceptionV3. These deep learning models are known for their outstanding performance on a variety of tasks.

We carried an in-depth evaluation of these models, taking into consider a range of important metrics including as accuracy, F1 score, precision, recall, and loss. This comprehensive evaluation aims to determine which model performed the best given our particular dataset.

TABLE IV. Compare Current Approaches to our Suggested Model for a Similar Problem

Study	Dataset	No. Classes	No. Images	Method of Use	Accuracy
[57]	Soybean Diseases	4	12,673	CNN model	99.32%
[58]	PlantVillage's Apple Crop	4	2,086	VGG16	90.40%
[59]	Apple Leaf Disease	6	2,462	DenseNet-121	93.71%

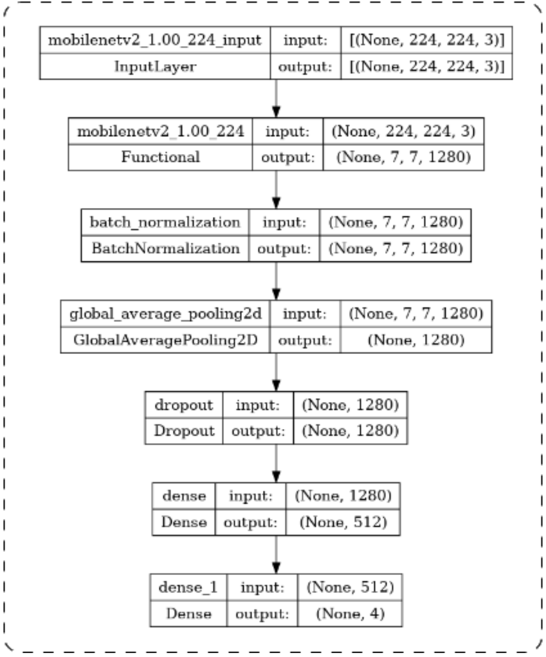

Fig. 11. The best architectural model, obtained after determining the hyperparameter values.

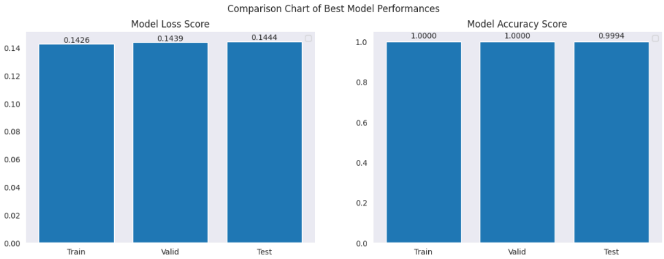

Fig. 12. Comparison chart of best model performances.

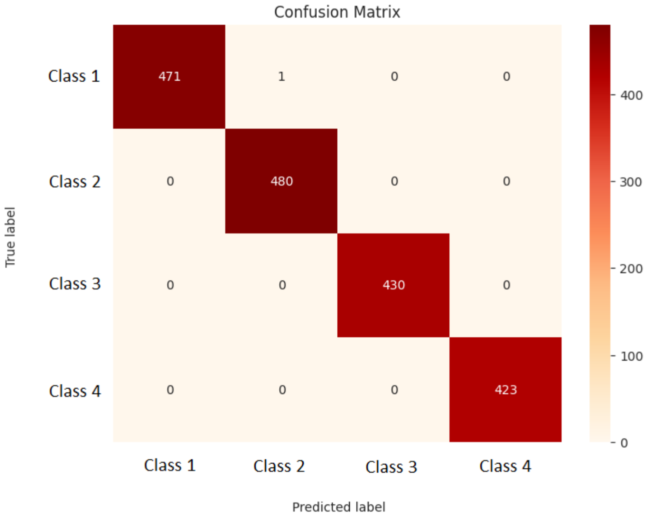

Fig. 13. The confusion matrix of the best architectural model.

We then moved on to the crucial step of fine-tuning the hyperparameters of the model that was performing at its best. This fundamental improvement process increases the model's overall efficacy in accurately recognizing grape leaf illnesses.

Our approach to fine-tuning involved an extensive exploration of hyperparameters using the hyperband strategy. This configuration was aimed at maximizing the model's performance specifically within the context of our dataset.

By using these careful procedures—model evaluation, selection, and refinement combined with carefully hyperparameter optimization, the model's accuracy on the test set was 99.94% and its loss was 0.1444.

VI. Future Works

Further investigations could explore into examining the influence of alternate hyperparameters based on optimization techniques—like weight decay, activation functions and batch sizes—aimed at enhancing the efficacy of transfer learning models in detecting grape leaf diseases.

***Abstract*—Intensive care units commonly utilize mechanical ventilators to treat patients with different medical conditions, which are crucial for patient care and survival. ICU ventilators have evolved through four distinct generations, each displaying unique features. Despite progress made since the 1940s, contemporary designs are insufficient to meet the increasing needs of patients and hospitals. Malfunctions in mechanical ventilators pose significant dangers to patients, highlighting the importance of focusing on their safety, security, precision, and dependability. Our study aims to address the significant issue at hand. Furthermore, the IoT industry has garnered significant attention because of rapid progress in smart devices, sensors, and actuators. The healthcare industry has seen a notable increase in health data as a result of the growing utilization of IoT and cloud computing technologies. To enhance growth, new models and distributed data analytics strategies must be developed to fully utilize the value of the vast datasets generated, including the incorporation of embedded machine learning. The study focuses on conducting Pareto and Failure Modes and Effects Analysis (FMECA) on ventilators in a specific hospital's ICU, specifically those manufactured by the same company and unit. The analysis aims to identify the most critical and failure-prone component. Subsequently, we propose an IoT-focused framework for a predictive maintenance system implemented at the component level. The architecture comprises a monitoring framework and a data analytics module to predict potential system failures in advance, enhancing overall reliability.**

Keywords*—Internet of things; predictive maintenance; embedded Machine learning; data analytics; failure modes; mechanical ventilator

I. Introduction

Nowadays, an average to large-sized hospital houses around 10,000 different types of medical devices, and one of the most pressing challenges for healthcare institutions throughout the world is to guarantee the safety of these devices and manage the risks connected with their use. Medical devices are tools or machinery used to detect, monitor, treat, or prevent illness or other disorders [1]. Providing health services through the use of diagnostic and therapeutic technologies is an essential component of health care, particularly in hospitals. In addition to being necessary for safe and effective patient care, medical equipment has a substantial impact on the income and consequently the viability of healthcare institutions [2]. Their rapid advancement has considerably benefited the health of individuals and society. This technological advancement has increased patients' survival in the face of sickness or injury, as well as considerably improved their life quality via improved diagnostic and therapy outcomes [3]. However, without effective maintenance management, the delivery of healthcare services to communities suffers dramatically. Medical equipment maintenance management is critical to ensuring that a machine performs by manufacturer specifications and ensures the safety of patients and users [4]. Inadequate maintenance of medical equipment causes downtime, reduces device performance, and wastes costs and resources. As a result, medical equipment requires both scheduled and unscheduled maintenance throughout its useful life and close monitoring by healthcare administrators [5]. Hospitals should ensure that medical equipment is kept in working order, is safe, accurate, and reliable, and functions at the appropriate level of performance successfully. Therefore, the ultimate goal of maintenance is reliability and safety. It should always be safe for both patients and users [6]. To that aim, the World Health Organization (WHO) specifies a standard regulation for periodic maintenance of medical devices that includes the rate of failure of specific types of replaceable components (e.g. batteries, valves, pumps, and seals) to assure device dependability and safety [7].

Thanks to digitalization in the healthcare domain, the generated health-related data have grown exponentially in the past decades with the increasing use of the Internet of Things (IoT) and cloud computing technologies in this field. As a result of this digitalization, a large volume of data is generated from these various IoT sources and information services. This motivates the health business to create new models and distributed data analytics approaches to maximize the value of the generated data [8]. In addition to this, advancements in information and communications technology, big data technologies, and analytics tools were the key elements in realizing the transition from traditional maintenance approaches to predictive maintenance (PdM) [9]. The IoT sector has attracted substantial interest due to the rapid pace of technical breakthroughs in smart device, sensor, and actuator technologies. A multitude of these IoT devices can potentially generate significant amounts of big-data streams which are not only too voluminous but also too fast and complex to be processed and stored using traditional data analytics approaches. Therefore, predictive maintenance systems should be highly scalable, resilient, and fault-tolerant to process and store big data in an effective manner [10]. Through the use of information and communication technologies, specifically intelligent devices (such as IoT sensors, edge devices, and computing), data collection has increased as a result of the incorporation of autonomous and smart systems where data and advanced data analytics (i.e., big data, artificial intelligence (AI) / Machine Learning (ML)) can be used [11]. With this development, PdM solutions, such as those for estimating remaining usable life, detecting anomalies, and monitoring machine health (condition), also increased. PdM entails making optimum decisions to sustain a system's capacity and functioning by monitoring its performance in real-time using huge data streams provided by the system. The use of predictive maintenance approaches enables us to reduce operational maintenance costs for medical devices, enhance operational activity without breakdowns, and thereby improve healthcare quality.

In other words, PdM is described as a set of procedures used to assess the state of equipment and predict future failures. These estimations are then utilized to schedule maintenance activities through smart scheduling of maintenance procedures, which aids in preventing or at least minimizing the impacts of unanticipated breakdowns. PdM requires employing analytical tools to analyze machine-generated data to get valuable insights. Further, create a machine learning (ML) model using this data to forecast upcoming failures. Sensors with limited data processing capabilities are used for data collecting. Due to this, edge devices were developed and are now capable of processing data, cleansing data, and many other functions in addition to acting as sensors [12]. PdM techniques are very similar to medical diagnostic techniques. A symptom appears whenever a human body is experiencing a problem. The information is provided by the nervous system; this is the detection stage. Pathological tests are also performed if necessary, to diagnose the problem. On this basis, appropriate treatment is suggested. Similarly, defects in a machine always produce a symptom in the form of vibration or some other parameter. However, on machinery systems with human perceptions, this may or may not be easily detected.

The rest of the paper is organized as follows; in Section II, the maintenance strategies are described and the related works are reviewed. Section III describes the functioning of the mechanical ventilator. Section IV addresses the study case and discusses the proposed architecture for predictive maintenance in the big-data era. The opportunities and challenges of the proposed architecture are discussed in Section V. We conclude paper and give directions for future research in Section VI.

II. Background and Related Works

A. Background

In light of the technological advances in the medical field, medical equipment has become widely used in all aspects of health care, including prevention, screening, diagnosis, monitoring, and therapeutics, as well as rehabilitation. It is now nearly impossible to provide health care without them. Medical equipment, unlike other types of healthcare technologies (such as drugs, implants, and disposable products), requires maintenance (both scheduled and unscheduled) throughout its useful life. Inadequate and improper maintenance and safety procedures have always been the leading cause of major incidents frequently involving patients that result in serious injuries or deaths.

Maintenance can be defined as the function of keeping a machine, or system (whether simple or complex) in working order by using it properly, repairing broken parts or components, or replacing some of the broken parts so that it is available and fit for the intended purpose whenever the need arises. A maintenance strategy is a methodical approach to device upkeep that includes actions like ”identification, investigations, and execution of many repairs, replace, and inspect decisions”. According to [13] a maintenance strategy includes a set of policies and actions that are used to “retain” or “restore” equipment as well as the decision support system in which maintenance activities are planned. As the sophistication and cost of medical equipment have increased, so has the complexity and cost of its maintenance over the last few decades.

Maintenance philosophy has always evolved in pari-passu with the ever-changing technological innovations in designing simple machines and equipment that have now metamorphosed into complex, sophisticated, and indispensable systems. Maintenance strategies have evolved gradually, and the process is still ongoing. Over the last two decades, maintenance strategies and reliability engineering techniques have been significantly improved, and they have been successfully applied in many industries to improve the performance of equipment maintenance and management. Maintenance strategies can be categorized as first, second, third, and recent generations, as depicted in Fig. 1.

Corrective maintenance (CM) [14] is a reactive maintenance policy that is applied following a machine malfunction. The following sentence serves as the foundation for the concept of corrective maintenance: Fix it when it breaks. CM is classified as first generation as it was the standard practice until the 1960s when preventive maintenance (PM) concepts emerged and gained public recognition.

PM [15] categorized as second generation, entails inspecting and maintaining equipment while it is in operation to reduce the likelihood of a breakdown. Preventive maintenance can be scheduled in advance (time-based schedule) or as needed (usage-based schedule). While this strategy reduces failures thus improving equipment efficiency, reducing downtime, and extending the life of your equipment by ensuring it is always in good working order. The issue with the PM strategy is that it can be excessively proactive. Because you are following a standard timetable, you can schedule a part replacement well in advance of when it is required. This will increase the cost of maintenance.

Condition-based maintenance (CBM) [16] classified as third generation, emerged in the second half of the 1980s as a result of sensor and condition monitoring technology development. To reduce unnecessary scheduled tasks, this strategy limits the number of times maintenance activities are initiated to when there is clear evidence of deterioration. Monitoring the condition of the equipment and performing necessary maintenance are all part of CBM. When compared to preventive maintenance, there is no need to be concerned about performing condition-based maintenance too soon. When something goes wrong but before it stops working, sensors notify you that maintenance is required at the optimal time. Condition-based maintenance is also known as condition-based monitoring because it requires regular monitoring of your equipment. The major drawback is that you can't plan for maintenance because you won't realize you need it until the changes happen.

The concept of prognostics, which deals with fault prediction before it occurs, was recently introduced to the proactive maintenance community in recent years. In this context, PdM [17] is a CBM policy that incorporates prognostics into its decision-making process. As a result, PdM contains more information about asset degradation, such as the remaining useful life (RUL). PdM represents the recent generation of maintenance philosophies.

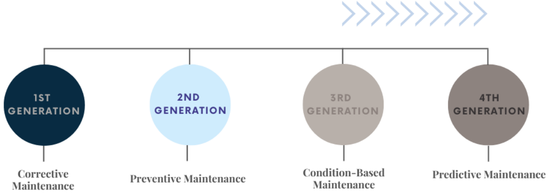

Fig. 1. Evolution through time of maintenance strategies.

B. Related Works

Several articles in the literature propose a system architecture for predictive maintenance in the healthcare domain. Two different architectures for PdM systems were proposed in 2013. D. Andriţoi, C. Luca, C. Corciovă, and R. Ciorap, have developed a novel application with a robust evaluative facility. Using the medical equipment maintenance records stored in this application's database, a mathematical model for predictive maintenance can be developed [18]. A second method was proposed by M. Ullrich, K. Ten Hagen, and J. Lässig, who described a new approach for categorizing maintenance visits according to PdM [19]. To enhance medical device decision-making, the following study [20] details a comprehensive PdM management system that makes use of Information and Communication Technologies (ICT) and predictive analysis tools. This paper [21] proposes the following guidelines for a PdM model: It is important to 1) conduct daily QA treatment; 2) transfer and automatically interrogate the resulting log files; 3) analyze daily operating and performance values using statistical process control (SPC) once baselines are established; 4) determine if any alarms have been triggered; and 5) notify facility and system service engineers. A significant part of this research involved the development of software modules to automate the interrogation of trajectory log files, perform the SPC evaluation, and display the results in a graphical dashboard interface.

In 2018, [22] and [8] outline a PdM architecture for medical devices that makes use of modern big data, cloud, and IoT technologies. The following work [23] also delves into the challenge of healthcare organizations' maintenance by examining an autonomous integrity monitoring approach for devices that transmit massive amounts of real-time data via the Internet of Things. By combining an integrity monitoring framework with a data analytics module, the proposed architecture provides full visibility into medical devices and permits the anticipation of future problems.

In [24] a theoretical design employing Internet of Things technology is proposed. Furthermore, infrared cameras, such as those used for infrared thermal imaging, which have the incredible capacity to observe things that conventional diagnostic instruments cannot, are proposed as an effective tool for PdM strategy in the following paper [25]. Finally, [26] proposes a methodology that takes into account data sets, features, evaluation strategies, prediction strategies, ML algorithms, and performance evaluation.

III. Mechanical Ventilator

A. Evolution of Mechanical Ventilator

A mechanical ventilator is a device that facilitates or replaces spontaneous breathing, it aids in respiration or takes breaths for the patient. Mechanical ventilation is lifesaving when natural breathing is ineffective or has ceased. The patient's ventilation is increased by the ventilator, which fills their lungs with oxygen or air and oxygen. Mechanical ventilators have made significant advancements since their introduction, in addition to their use in the intensive care unit (ICU), Mechanical ventilators have many applications inside and outside of hospitals. Ventilators are crucial in the management of patients undergoing general anesthesia inside the operating room, in patients' homes for extended treatment, and the transporting vehicles. This was accomplished by combining advances in our understanding of respiratory physiology, pathophysiology, and clinical patient management with technological advancements in mechanical, electronic, and biomedical engineering. New devices and an increasing number of ventilation modes and strategies are introduced to improve outcomes, patient–ventilator interactions, and patient care in the present day. The primary indication for mechanical ventilation is difficulty in the patient's ventilation and/or oxygenation due to any respiratory or other condition. The objectives of mechanical ventilation are to provide adequate oxygen to patients with a limited vital capacity, to treat ventilatory failure, to reduce dyspnea, and to allow breathing muscles to relax. There are two types of ventilation: Positive pressure ventilation (PPV) involves forcing air into the lungs through the airways, while negative pressure ventilation (NPV) involves drawing air into the lungs.

The use of assisted ventilation dates back to biblical times. In the early 1800s, however, mechanical ventilators in the form of NPV first appeared. The negative-pressure ventilator was the standard method of providing respiratory support throughout the latter half of the 19th century and the first half of the 20th. These devices were capable of applying alternating subatmospheric pressure around the body and were used to restore ventilation in patients by expanding the chest wall. The initial description of a negative pressure ventilator involved a full-body ventilator. In 1838, the "tank ventilator" was described for the first time by the Scottish physician John Dalziel. It consisted of an airtight box in which the patient was held in a seated position. By manually pumping air into and out of the container, negative pressure was created.

Sauerbrach even created a negative-pressure operating chamber in 1904. Except for the head, the patient's body was maintained within the chamber. Numerous other types of negative-pressure chambers, such as the "raincoat" and the "chest cuirass," were developed and used with varying degrees of success over time.

In the 1960s, however, there was a shift away from negative-pressure ventilation due to several factors. For example, access to the patient was limited, and "tank shock" was a recurring problem with full-body ventilators. However, mechanical ventilation became widespread only after the introduction of positive-pressure ventilation during the resurgence of poliomyelitis in the 1950s. This global pandemic has limited the availability of cabinet ventilators. To overcome this challenge, Bjorn Ibsen, a Danish anesthesiologist, utilized a modified anesthetic circuit with a squeezed bag to provide intermittent positive pressure ventilation (IPPV).This demonstrated a dramatic reduction in mortality in patients manually ventilated via tracheostomy led to the development of the intensive care unit.

In 1940, the first positive-pressure mechanical ventilators became commercially available. Even though they possessed a high level of sophistication, they could only deliver a predetermined tidal volume at a given respiratory rate (volume-control ventilation mode) and had no or very limited monitoring capabilities for ventilation variables.

The field of respiratory physiology had already established its foundations and was expanding rapidly at the time. In 1903, Dixon and Brodie introduced the application of mathematical modeling to describe the relationships between flow and pressure, which marked the beginning of the mechanics of breathing. They modeled the lung as resistance and compliance. In 1946, Rahn et al. presented pressure–volume diagrams of the lung and thorax as well as the concept of relaxation curves, laying the groundwork for the development of respiratory energetics. These and other studies provided the physiological foundation that led to the clinical application of positive-pressure ventilation.

Beginning in the early 1970s, ventilators began incorporating more advanced monitoring of flow and pressure variables due to advances in electronics. Improvements in monitoring also permitted the use of real-time variables to control the action of the machine, with the intermittent mandatory ventilation mode paving the way for the development of assisted mechanical ventilation as a means to wean patients from volume-controlled ventilation.

Beginning in the early 1980s, the introduction of microprocessors in mechanical ventilators led to the introduction of improved technologies for monitoring ventilation and lung conditions, as well as the introduction of new, advanced ventilation modes.

From the original ventilators of the 1940s to the present day, there have been four generations of ICU ventilators, each with features distinct from the previous generation.

B. Operation Principle of Mechanical Ventilator

Mechanical ventilation (MV) functions by applying a positive pressure breath and is dependent on the airway system's compliance and resistance. During spontaneous inspiration, the lung expands as transpulmonary pressure (P) is primarily generated by the inspiratory muscles' negative pleural pressure. During controlled mechanical ventilation, on the other hand, a positive airway pressure forces gas into the lungs, resulting in a positive P. The tidal volume (VT) is the volume of air that enters or leaves the lungs during each respiratory cycle. Physiologically, VT is dependent on a person's height and gender and ranges from 8 to 10 mL/kg of ideal body weight. Multiple modes of MV delivery exist, including mandatory mode and assisted mode. In the assisted mode, the patient's inspiratory effort activates the MV to deliver the breath, while P is the product of negative pleural pressure and positive alveolar pressure. The most prevalent modes of MV include: Volume-limited assist control ventilation (VAC), Pressure-limited assist control ventilation (PAC), and Synchronized intermittent mandatory ventilation with pressure support ventilation (SIMV-PSV).

Once a ventilation strategy has been determined, it should be administered to the patient in the most precise manner possible. To accomplish this, the machine must accurately detect all variables that define the breathing pattern and adapt its action in real-time. Modern ventilators accomplish this by combining sophisticated data processing algorithms with cutting-edge actuators, sensors, and digital electronics.

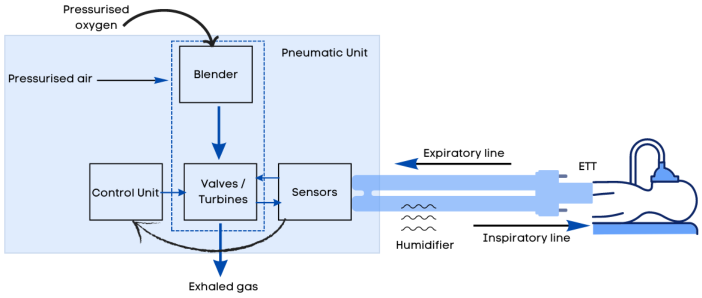

Fig. 2. Representative illustration of the mechanical ventilator functioning.

Fig. 2 depicts a representative illustration of the mechanical ventilator functioning, with the operation principle including:

1) Pneumatic unit: The pressure source provides the energy necessary to overcome the elastic and resistive load imposed by the patient's respiratory system and is used to reduce the patient's work of breathing. The pressurized air is mixed with the appropriate amount of oxygen by the blender and delivered to the patient through fast valves that modulate the amount of gas flowing into and out of the patient. In some modern ventilators, instead of using valves, a fast-response, brushless-driven turbine functions as a variable pressurized air source, making the device independent of centralized medical compressed air distribution while still delivering excellent performance.

2) Sensors: In contemporary mechanical ventilators, all relevant ventilation parameters like pressure, flow, and F_iO_2(The fraction of oxygen in the inspired air or gas that is being provided from a ventilator) are measured by sensors that provide information to the control unit so that the valves/turbines can be adjusted in real time to deliver the desired ventilation mode.

IV. Study Case : CARESCAPE R860

A. Objective

The ICU ventilator is characterized by its long-term use. Indeed, it must be able to act continuously on the same patient for multiple days. Any ICU ventilator malfunction has the potential to be catastrophic and fatal for patients. Despite the presence of alarm systems, continuous monitoring is required to minimize machine-related errors. Therefore, this study aims to propose an IoT-based architecture for predictive maintenance of the CARESCAPE R860 ICU ventilators.

The primary objective of our architecture surpasses the limitations of a single healthcare facility. The objective of this study is to establish the potential for widespread implementation of the suggested approach on CARESCAPE R860 ICU ventilators within a wide range of healthcare institutions. To establish a comprehensive and adaptable predictive maintenance (PdM) system, our objective is to develop a flexible framework that can effectively accommodate diverse hospital structures. This endeavor is driven by the goal of establishing a centralized approach that effectively harmonizes with a multitude of healthcare settings.

This study was conducted on a collection of CARESCAPE R860 ICU ventilators located in various medical centers.

B. General Description of the CARESCAPE R860

The CARESCAPE R860 is a sophisticated ICU ventilator that integrates modern technology with a user-friendly interface, as shown in Fig. 3. The icons in the interface reflect customizable depictions of historical patterns, patient status, and clinical decision assistance for future patient needs. The ventilator includes a display, ventilator unit, trolley with optional AC plug, optional EVair compressor, and module bay with optional gas module.

Users have complete control over the system setting due to the wide range of performance options provided. This comprehensive ventilator system includes breathing, monitoring, and the ability to connect with central monitoring systems. The user-friendly touch screen allows quick and easy access to information and operations, catering to adult, pediatric, and neonatal patients.

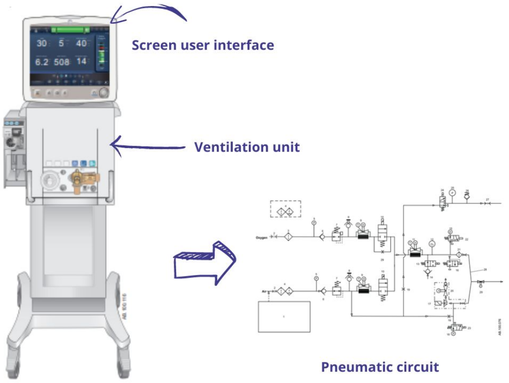

Fig. 3. Overview of the ICU ventilator.

1) Screen user interface: The interactive panel screen displays the patient's and ventilator's current status. Even during normal ventilation, all modes, controller, alarm, and monitoring windows are accessible directly from the main screen. The menu, the menu for the current patient, alarm management, and the user's favorite procedures are grouped at the top of the screen in the user interface. The status of the patient (the airway pressure bar) and the workspace/monitoring area are located in the center of the display. At the bottom of the screen are the navigation bar, message areas, battery status, standby button, and shortcut keys.

2) Ventilation unit: The ventilation unit is located on the front of the ICU ventilator, below the screen user interface, and is equipped with all the necessary ports for connecting the various breathing circuit accessories.

3) Pneumatic circuit: The pneumatic circuit of the ventilator provides patient gases from compressed air and oxygen sources. Two distinct inspiratory channels (air and O_2) are incorporated into the system to provide dynamic O2 percentage mixing control.

4) Electronic circuit: The electronic unit contains the various electronic circuits used to control and adjust the pneumatic system, the monitoring represented by the ventilator's alarm set, and the machine user interface.

C. Pareto Analysis for the CARESCAPE R860

The ABC method or Pareto analysis permits the analysis of the most significant malfunctions. It enables us to assert that 20% of the causes are accountable for 80% of the problems encountered and, as a result, to analyze all of the problems in order to formulate an appropriate response.

In our case, we have performed a Pareto analysis on different CARESCAPE R860 ventilators from the same unit. This method will allow us to identify the CARESCAPE R860 component that is most failing.

The Pareto analysis is accomplished by following the steps outlined below:

- Step 1: Sort the failures according to the number of failures in descending order
- Step 2: Determine the percentage
- Step 3: Determine the cumulative percentage
- Step 4: Draw the curve and identify the three zones: A, B, C

Fig. 4 depicts the outcomes of the Pareto analysis of a CARESCAPE R860. The curve illustrates a convexity with the selection of three zones; each zone contains a certain number of components in proportion to the significance of their total number of breakdowns; the following are the three zones that I discovered:

1) Zone A: Highest risk area. 80% of the risks originate from the five following components and processes:

⇒ Changing the air block

⇒ Changing the backup batteries

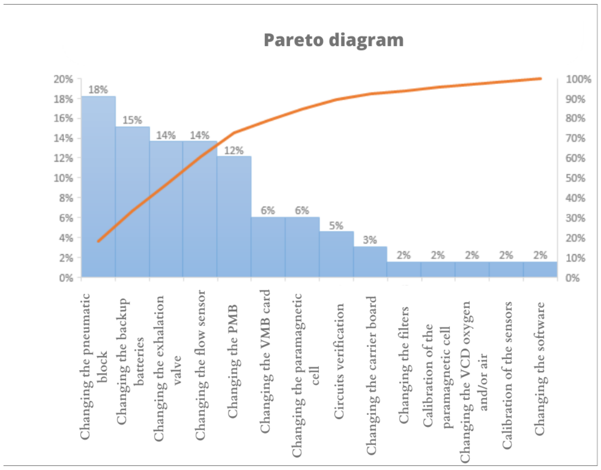

Fig. 4. Pareto analysis of a CARESCAPE R860.

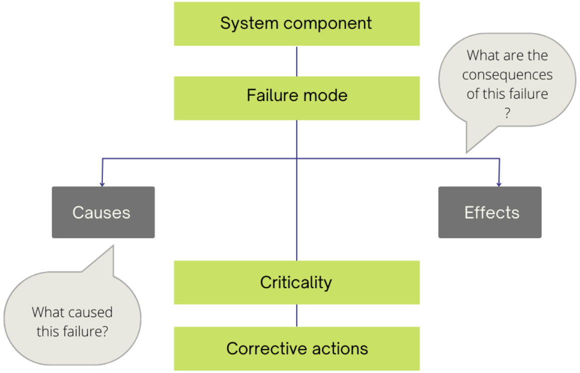

Fig. 5. FMECA analysis of the system.

⇒ Changing the exhalation valve

⇒ Changing the flow sensor

This means that we will be concentrating our solution-finding efforts on these parts, as their failure would have the most severe consequences.

2) Zone B: Medium risk area. 15% of the risks are caused by the following five parts or procedures:

⇒ Changing the PMB

⇒ Changing the VMB card

⇒ Changing the paramagnetic cell

⇒ Circuits verification

⇒ Changing the carrier board

3) Zone C: Low risk area. 5% of the risks are caused by the following parts or procedures:

⇒ Changing the filters

⇒ Calibration of the paramagnetic cell

⇒ Changing the VCD oxygen and/or air

⇒ Calibration of the sensors

⇒ Changing the software

After conducting this analysis on the different CARESCAPE R860, it has revealed that all ICU ventilators have the same pneumatic block issue.

D. Develop a Failure Mode and Effects Analysis for the CARESCAPE R860

To conduct this investigation, we also performed a Failure Mode and Effects Analysis (FMEA), also known as a Failure Mode, Effects, and Criticality Analysis (FMECA), on the selected equipment. The FMECA is a technique for predictive analysis that estimates the risks of failure and their effects on the equipment's proper operation and then implements the necessary corrective actions. Its primary objective is to maximize availability. This analysis will allow us to determine which component of the machine is the most critical and malfunctioning in our scenario.

The FMEA method is based on a multi-step process as shown in Fig. 5. The different steps are described as follows:

1) Identify possible failures and their effects: This step involves identifying all potential failure modes, determining the effects of each, and searching for their most probable causes.

2) Determine Gravity (G): The gravity G represents the severity of the effects of a failure. G is rated on a scale from 0 to 4, with 0 being the least severe and 4 being the most severe.

3) Determine the occurrence frequency (F): The frequency of occurrence F represents the failure occurrence frequency. This frequency represents the probability of the failure mode occurring in conjunction with the failure cause. F is rated on a scale from 0 to 4, where 0 represents the probability that a failure is practically impossible to occur and 4 represents the certainty of a failure occurring.

4) Failure detection (D): Detection mode D refers to the likelihood that a user will detect the occurrence of a failure. Detectability is a crucial component. Failure to predict a failure will increase the likelihood that the system will shut down. D is rated on a scale from 0 to 4, where 0 indicates the presence of sensors capable of detecting the onset of a failure and 4 indicates that the malfunction is undetectable or that its location requires extensive knowledge.

5) The criticality evaluation (C): Criticality is a quantitative evaluation of risk based on the combination of the three previously mentioned factors:

⇒ The frequency with which the mode-cause pair occurs.

⇒ The severity of the effect.

⇒ The possibility of employing detection methods.

Calculated using the formula $C = G \times F \times D$, it is intended to assess the risk associated with equipment functionality.

We have divided criticality into four categories:

→ Level A: Negligible criticality

→ Level B: Medium criticality

→ Level C: High criticality

→ Level D: Very high criticality

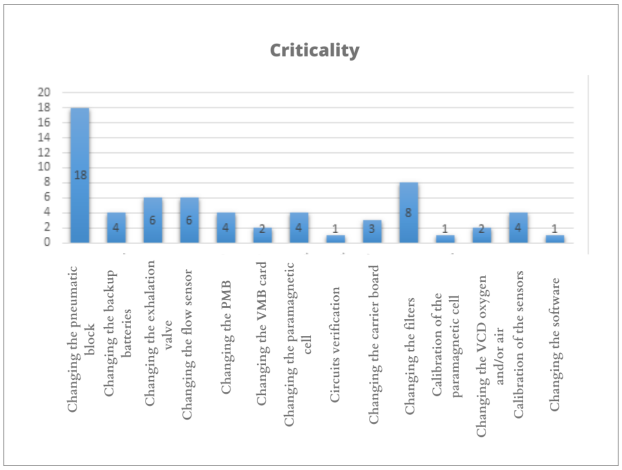

Fig. 6. Criticality Rate Diagram based on the number of failures.

After identifying the various potential failures that the ICU ventilators may encounter during their operation, we analyzed and investigated the effects of these failures on the CARESCAPE R860's proper operation, the user, the patient, and the environment. We then determined for each failure the three previously mentioned parameters, namely severity, occurrence frequency, and mode of detection, in order to calculate the criticality of each failure. Fig. 6 illustrates the results of the FMECA analysis.

With a criticality of C=18, we can conclude that the pneumatic block is the ICU ventilator's most critical component. If the pneumatic block fails, this can directly result in an outage of our ventilators, which can alter the patient's course of treatment or be fatal.

E. Proposed Architecture

Following our primary objective of achieving centralization, the architectural framework we have developed is intricately connected with the knowledge acquired through our extensive research. The present investigation was carried out with a specific emphasis on intensive care unit (ICU) ventilators, with particular attention given to the CARESCAPE R860 model. The study was conducted within a single hospital unit, aiming to achieve a comprehensive comprehension of the challenges associated with this particular model. The present study employed the Pareto and Failure Modes and Effects Analysis (FMECA) methodologies to conduct an analysis, thereby facilitating the identification of the critical parameters and components that exhibit a higher susceptibility to failure.

Patients are put in an intolerable position of risk when their mechanical ventilators malfunction, so ensuring the safety of these devices is crucial [27]. It is more cost-effective to perform preventative maintenance on the mechanical ventilators rather than repair work on them. An organization or a person with expertise in technical installations is required to perform continuous monitoring and maintenance on the air unit that serves as the source of air for both the ICU service and the neonatology service. The performance of the installation is something that must be guaranteed, which is why maintenance is performed. The following are the components of maintenance:

→ Ensure that optimal filtration is maintained at all times by performing follow-up and monitoring of filtration. Regularly dispose of and replace filters.

→ Perform routine maintenance on the motor-fan assembly in order to ensure consistent flow rates.

→ Ensure that power plants are kept clean in order to preserve the quality of the air.

→ Ensure that all of the electrical, regulatory, and safety equipment is in proper working order (antifreeze thermostat, smoke detection, etc.)

It is necessary to ensure that the maintenance actions implemented have been properly carried out. As a result, the system ought to be monitored in a manner that is both sustainable and capable of ensuring that the ventilators continue to function normally without exhibiting any signs of performance degradation. As a result, we propose incorporating a humidity monitoring system at the chain level of the medical air filtration process. Consequently, we propose an IoT-based architecture for predictive maintenance that collects and processes a massive data stream from several CARESCAPE R860 in real-time.

Our proposed structure comprises four layers (Fig. 7):

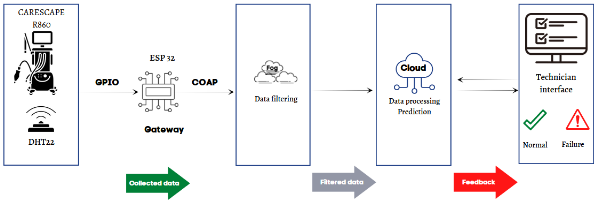

Fig. 7. Proposed architecture for the CARESCAPE R860.

1) The first layer: The first layer is the input layer. It is composed of a humidity and temperature sensor known as DHT22 which is an inexpensive digital temperature and humidity sensor. Using a capacitive humidity sensor and a thermistor, it monitors airflow and outputs a digital signal on the data pin. It sends information every two seconds. The DTH22 will be installed in the air filtration chain of the machine in order to monitor the performance of the pneumatic block. The data, which consists of the measured humidity levels at a variety of time intervals, will be transmitted to the fog through the Constrained Application Protocol (CoAP) by utilizing the ESP32 microcontroller as a gateway.

2) The second layer: The second layer within our Predictive Maintenance (PdM) framework is an essential element referred to as the fog computing layer. The present layer is strategically situated in the intermediary position between the peripheral devices, specifically the ventilators equipped with DHT22 sensors that are deployed across various hospital services, and the centralized cloud server. The principal aim of integrating the fog computing layer is to augment the efficacy, responsiveness, and scalability of our predictive maintenance system.

a) Centralized data processing and filtering: In the context of fog computing, the data coming from the distributed ventilators is gathered, subjected to real-time processing, and subsequently filtered. The adoption of a decentralized approach in information processing has been shown to have significant benefits in terms of reducing latency and facilitating prompt analysis of critical information within local networks. This approach effectively minimizes the dependence on distant cloud servers for immediate decision-making purposes.

b) Local anomaly detection and classification: The utilization of fog computing technology facilitates the implementation of localized anomaly detection and classification algorithms, thereby facilitating the rapid identification of potential issues that are unique to each ventilator system. The presence of localized intelligence plays a crucial role in effectively addressing immediate concerns and mitigating the negative impacts of faults on patient care. The fog layer functions as a discerning filter, selectively transmitting solely pertinent and practicable data to the central cloud server.

c) Bandwidth optimization: In light of the limitations imposed by bandwidth constraints and the unpredictable nature of network conditions, the fog layer exhibits intelligent behavior in order to optimize the transmission of data. The proposed system effectively employs a filtering mechanism to eliminate redundant or non-critical information, thereby significantly reducing the overall volume of data that necessitates transmission to the cloud. The optimization of system efficiency is not only observed but also found to be positively correlated with cost savings in the context of data transfer and storage.

d) Edge machine learning for quick decision-making: The utilization of machine learning models implemented at the fog layer significantly contributes to the facilitating of localized decision-making processes. These models are trained on historical data and regularly updated to promptly detect patterns and trends related to potential malfunctions in ventilators. The significance of localized intelligence becomes especially apparent in situations necessitating prompt intervention to prevent detrimental impacts on patient well-being.

e) Scalability and interoperability: The integration of ventilators from various hospital services is facilitated by the fog computing layer, ensuring a seamless and efficient process. The proposed solution offers a scalable and interoperable framework, thereby enabling the predictive maintenance system to effectively adapt to diverse ventilator models and configurations. The establishment of interoperability within the healthcare sector is of the highest priority to facilitate extensive acceptance and utilization across diverse healthcare facilities.

f) Centralization objective: The primary objective of incorporating fog computing within our predictive maintenance architecture is to establish a centralized framework for managing predictive maintenance operations associated with a diverse range of ventilators sourced from multiple services and hospitals. The process of centralization facilitates the efficient management of operations, and maintenance of algorithms, and offers a comprehensive assessment of ventilator performance within the hospital network.

In this study, we propose a novel approach to enhance the utilization of computing resources and facilitate effective coordination of predictive maintenance operations by implementing a centralized management system through the fog. The fog computing paradigm is leveraged to achieve these objectives. By adopting this approach, we aim to optimize the allocation and utilization of computing resources, thereby improving the overall efficiency of predictive maintenance operations. This approach additionally facilitates the comprehensive observation of failure patterns, rates of maintenance, and operational efficacy, thereby presenting a comprehensive methodology for the management of crucial equipment.

3) The third layer: The cloud computing layer plays a crucial role in our Internet of Things (IoT) predictive maintenance architecture by serving as the fundamental infrastructure for centralized data storage, processing, and analytics. Per our objective of attaining thorough centralization, this particular layer assumes a crucial function in the consolidation and administration of the extensive volume of data produced by the predictive maintenance system for CARESCAPE R860 ICU ventilators.

The cloud infrastructure is designed to efficiently handle real-time data streams originating from a multitude of ventilators distributed across diverse healthcare institutions. The primary objective of this infrastructure is to ensure a seamless and uninterrupted flow of data, encompassing reception, storage, and processing operations. By capitalizing on the built-in scalability and flexibility offered by cloud computing, our proposed architecture guarantees the adaptability of the system to accommodate diverse data volumes and computational demands. The necessity of scalability in healthcare environments is of utmost importance, as it addresses the inherent dynamism of such settings by effectively accommodating variations in patient load and ventilator usage.

The cloud-based analytics module within our architectural framework incorporates cutting-edge algorithms and machine learning models to conduct a comprehensive analysis of the gathered data. It aims to investigate the identification of patterns, anomalies, and potential failure indicators within the specific setting at hand.

Furthermore, the presence of the cloud layer enables the convenient and efficient retrieval of essential maintenance insights from remote locations. In this study, we investigate the ability of authorized personnel, regardless of their geographical location, to securely access real-time analytics, performance trends, and predictive alerts.

In the context of security, our cloud-based architecture implements an extensive range of measures that strengthen the safety of patient data and guarantee adherence to healthcare regulations. The implementation of encryption protocols, access controls, and secure communication channels is crucial in safeguarding sensitive information that is transmitted and stored within cloud environments. These measures are designed to mitigate potential risks and threats to the confidentiality, integrity, and availability of data. By employing robust encryption protocols, data is transformed into an unreadable format, thereby preventing unauthorized access and ensuring that only authorized individuals can decipher the information.

The present study aims to investigate the utilization of cloud computing capabilities in the architecture for predictive maintenance of CARESCAPE R860 ICU ventilators. By leveraging these capabilities, the proposed architecture not only facilitates the centralization of data processing and analysis but also establishes a platform that is scalable, secure, and accessible.

4) The fourth layer: The fourth layer is the output or interface for technicians. The system indicates when humidity levels approach a dangerous threshold and alerts the technician to perform preventative maintenance before machine failure. Initially, we will implement supervised machine learning; the technician will report malfunctions to better train the algorithm through reactive decision-making. Then, proceed to semi-supervised machine learning, followed by unsupervised machine learning. The effectiveness of these methods for fault classification, anomaly detection, and real-time prediction will then be evaluated.

a) The getaway: By utilizing the ESP32 microcontroller as the gateway, we can effectively bridge the CoAP communication between the DHT22 sensor and the cloud server for predictive maintenance of the CARESCAPE R860 ventilator. Its built-in Wi-Fi, processing power, MicroPython support, community backing, and cost-effectiveness make it an excellent choice for this IoT application. The ESP32 ensures smooth data transmission, preprocessing, and security features, providing a reliable and efficient gateway solution for your predictive maintenance architecture.

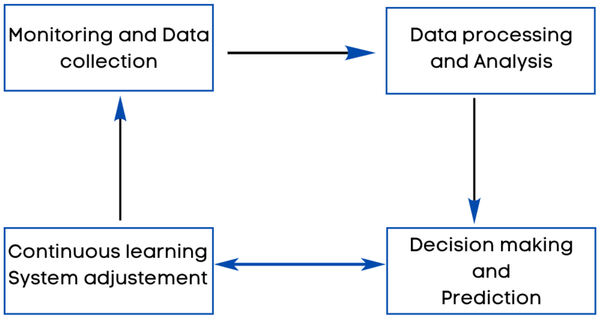
b) Communication: CoAP's lightweight design and RESTful architecture make it an optimal choice for resource-constrained IoT environments, such as healthcare. By seamlessly enabling communication between the DHT22 sensor and the cloud server, CoAP efficiently transmits crucial environmental data, including temperature and humidity, in real time. This real-time data monitoring empowers prompt detection of anomalies and proactive measures for predictive maintenance. The simplicity and elegance of CoAP facilitate straightforward implementation, while its broad community support offers a rich array of libraries, tutorials, and resources, easing development efforts. CoAP is an indispensable tool in this context, showcasing its efficacy in bridging the gap between resource-constrained sensors and cloud-based infrastructure, elevating predictive maintenance capabilities, and enhancing patient safety in healthcare settings. To facilitate accurate and reliable data acquisition from the DHT22 sensor, we meticulously implemented a data retrieval method utilizing the MicroPython environment on the ESP32 microcontroller. A critical step in this process involved the installation of the ”Adafruit DHT” library, a reputable external library developed by Adafruit Industries. Leveraging the advanced features and robust error-handling mechanisms inherent to the ”Adafruit DHT” library, we ensured a seamless data acquisition process from the DHT22 sensor. Installing the ”Adafruit DHT” library involved utilizing the ”ampy” tool, a commonly used utility in the MicroPython ecosystem. This tool enabled us to efficiently copy the ”Adafruit_dht” library to the ESP32 board, allowing it to interact with the DHT22 sensor effectively.

The library installation process was methodically executed by adhering to proper software engineering practices and following established protocols. Subsequently, we crafted a specialized data retrieval function within our MicroPython script. This function, designed to interact with the DHT22 sensor, effectively accurately retrieved temperature and humidity data. Utilizing the GPIO pins and communication interfaces of the ESP32, the data retrieval function measured environmental parameters from the DHT22 sensor. The successful execution of the data retrieval method on the ESP32 microcontroller facilitated the collection of vital environmental data from the DHT22 sensor. The retrieved temperature and humidity data were foundational inputs for our predictive maintenance model, enhancing the CARESCAPE R860 ventilator's operational efficiency and patient safety. The data transfer process from the microcontroller to the cloud through CoAP in our IoT-based predictive maintenance architecture involves a systematic and efficient approach. Following the successful retrieval of environmental data from the DHT22 sensor, the ESP32 microcontroller, armed with the ”Adafruit DHT” library, acts as the intermediary gateway to facilitate seamless communication between the sensor and the cloud infrastructure. Upon data retrieval, the ESP32 microcontroller employs the CoAP protocol to package the acquired temperature and humidity data into CoAP messages, adhering to the lightweight and RESTful principles of CoAP. With the help of the built-in Wi-Fi capabilities, the ESP32 initiates a secure communication link to the cloud server, where the CoAP messages are transmitted. The CoAP server on the cloud, configured to host specific resources corresponding to the sensor data types, promptly receives the incoming CoAP messages. Using CoAP's resource observation feature, the cloud server continuously monitors the environmental data in real-time, facilitating immediate responsiveness to fluctuations in temperature and humidity levels. CoAP's Datagram Transport Layer Security (DTLS) extension is employed to ensure data integrity and privacy during transmission, safeguarding sensitive operational data from potential threats. The implementation of CoAP over DTLS provides robust security critical to the protection of patient information and the preservation of data integrity. Once the CoAP messages reach the cloud server, the data is processed, analyzed, and stored for further predictive maintenance operations. Cloud-based algorithms and analytics are employed to detect anomalies, predict potential equipment issues, and facilitate proactive maintenance actions, thus enhancing the CARESCAPE R860 ventilator's operational efficiency and reducing the risk of unplanned breakdowns. The system will continuously adjust a threshold based on the detected humidity levels that led to the failure of the ICU ventilators (Fig. 7).

The Predictive Maintenance Process for the CARESCAPE R860 involves a dynamic system that modifies a threshold based on observed humidity levels, as shown in Fig. 8. This adaptive technique is based on observations where high humidity levels were a key factor in the malfunction of ICU ventilators. The predictive maintenance technology enhances the reliability and performance of the CARESCAPE R860 ventilators by continuously monitoring and adjusting settings to proactively address possible faults.

F. Practical Deployment: Node-RED within the Proposed Architecture Framework

In this simulation (Fig. 9), we simulate the transmission of environmental data from a simulated DHT22 sensor to the cloud for processing and visualization via a secure communication method. It is important to highlight that this simulation is intended to act as a conceptual visualization to aid in understanding the proposed architecture. There is currently no active data flow; instead, it represents the projected data travel.



Monitoring and Data collection
Data processing and Analysis
Decision making and Prediction
Continuous learning System adjustement

Fig. 8. Predictive maintenance process for the CARESCAPE R860.

A simulated DHT22 sensor injects data, a security function applies protection measures, CoAP communication from the ESP32 microcontroller, and fog processing layer operations are all part of the sequence. Following that, the encrypted data is processed in the cloud, where it is subjected to further processing before being stored. A Debug node is strategically situated to monitor in real-time, whereas a Dashboard node is the endpoint for seeing processed data.

It is critical to note that, while this simulation assists in the conceptualization of the architecture, the real data flow implementation is part of our planned future projects.

V. Discussion

When developing our predictive maintenance architecture, we chose this specific framework based on important factors. The focus was on centralization, aiming to create a cohesive system to effectively handle predictive maintenance operations for various ventilators, with a specific emphasis on the CARESCAPE R860 model. Thorough research was conducted on the details of this particular model in a hospital unit, with a focus on key parameters that are prone to failure. This thorough approach guided the architectural design to create a customized solution for the issues related to ICU ventilators. To overcome current constraints, our design incorporates a humidity monitoring system into the chain level of the medical air filtration process. This new feature improves the capability to identify and address potential problems associated with humidity, a crucial factor highlighted in past cases of ICU ventilator malfunctions. Utilizing IoT-based predictive maintenance allows us to gather real-time data from various CARESCAPE R860 ventilators, providing a comprehensive and flexible method for monitoring equipment.

The suggested design for predictive maintenance of CARESCAPE R860 ICU ventilators is notable in the field of related studies for its thorough and inventive approach that combines IoT, fog computing, and cloud computing technologies. Standing out in the realm of predictive maintenance in healthcare, this architecture boasts a well-defined four-layer structure that covers centralized management, humidity monitoring, and real-time analytics. It is worth mentioning that the integration of adaptive threshold techniques for proactive maintenance, focus on local processing via the fog computing layer, and the use of machine learning models all play a role in its distinctiveness. This study presents a more comprehensive and innovative approach to enhancing the safety, reliability, and performance of critical medical equipment in healthcare settings, building upon previous research.

VI. Advantages and Challenges

The proposed IoT architecture represents a significant advancement in healthcare, employing predictive analytics to improve the management of mechanical ventilators. Utilizing extensive data analysis, the proposed framework holds the potential to enhance the quality and effectiveness of healthcare services by addressing the challenges posed by equipment malfunctions. This is vital for ensuring the well-being of patients and optimizing organizational expenses.

This architecture uses a centralized data approach to consolidate information from multiple CARESCAPE R860 ventilators, allowing for unified analysis and proactive maintenance strategies. The incorporation of IoT technology guarantees the ability to monitor in real time, facilitates effective communication, and enhances the dependability of the system. Intuitive interfaces and comprehensive training enable healthcare professionals to effectively analyze machine learning insights, enhancing the efficiency of the predictive maintenance model.

The architecture offers a versatile solution that can be applied to various hospital settings, showcasing its strengths in scalability and adaptability. This novel approach effectively streamlines predictive maintenance, optimizes workflows, and enhances patient safety, thereby contributing to the advancement of healthcare services.

However, due to their complex infrastructures and programming models, emerging data technologies necessitate a high level of data science and IT domain expertise in order to be utilized and installed. This is the main challenge of the proposed framework. This may impede the adoption of big data technologies in the healthcare industry.

The successful deployment of a system of this nature necessitates addressing not only the technical challenges but also the ethical implications that arise. The issues regarding the preservation of patient confidentiality, acquisition of informed consent, and the conscientious utilization of health-related information. The delicate balance between maximizing the advantages of predictive analytics and safeguarding the confidentiality of sensitive patient data necessitates diligent contemplation and adherence to ethical principles.

The issue of security presents itself as a significant challenge within the context of implementing the suggested architectural framework. The system deals with the management of sensitive health data, emphasizing the necessity of implementing robust security measures to effectively protect against unauthorized access, data breaches, and potential misuse. The preservation of patient data integrity and confidentiality is of utmost importance to achieve optimal performance and widespread adoption of the predictive maintenance system [9].

The utilization of embedded systems presents a set of obstacles, particularly within the realm of healthcare envi-

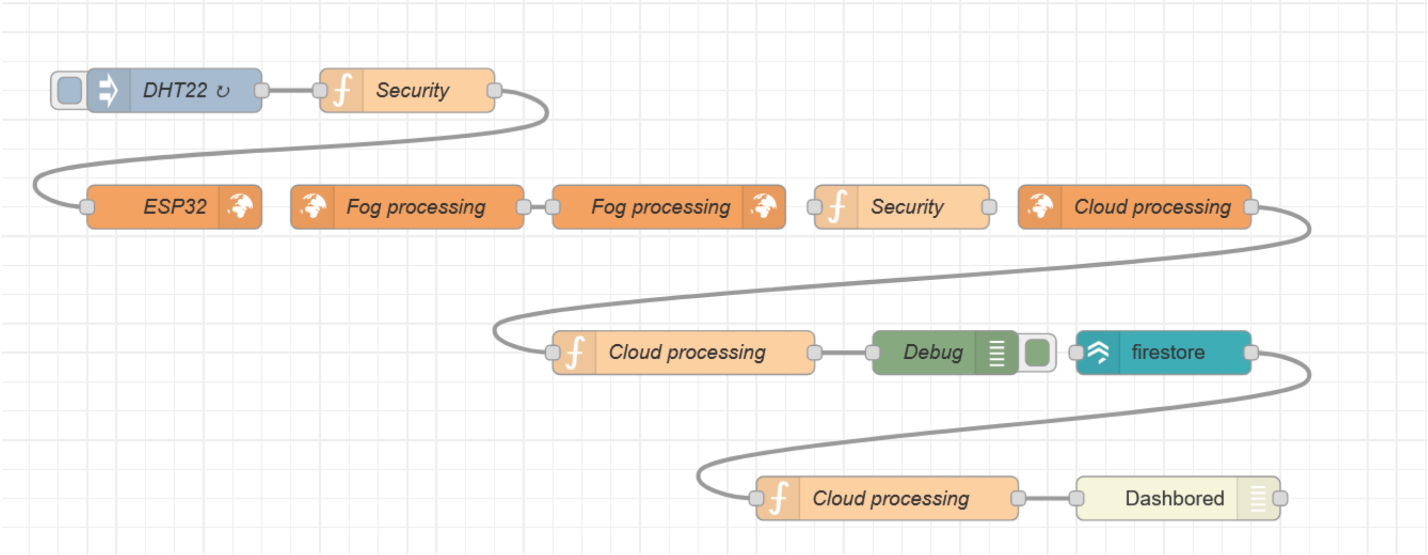


Fig. 9. Visual diagram of Node-RED implementation.

ronments, wherein the crucial role of reliability and real-time responsiveness is evident. The successful integration and ongoing maintenance of embedded systems in the context of ventilators necessitates a meticulous and methodical approach to guarantee seamless functionality and reduce any potential disruptions to healthcare services.

The human factor is a challenging aspect that requires careful analysis and attention when implementing predictive maintenance systems. In healthcare, healthcare professionals and staff must acquire the necessary knowledge and skills to effectively use and understand the data generated by the predictive maintenance system. This is essential for ensuring high-stakes patient care.

One notable facet of this challenge is the necessity for healthcare personnel to have knowledge and skills in machine learning for this to succeed [8]. Healthcare professionals need to have a thorough understanding of the machine learning algorithms used in the predictive maintenance system to accurately interpret the predictions and recommendations provided by the model. This knowledge enables them to differentiate between typical system functioning and possible irregularities, facilitating prompt and well-informed decision-making.

Moreover, Healthcare personnel need a thorough understanding of how the predictive maintenance system works. Understanding a system requires knowledge of both its technical components and its operational intricacies. Training programs should provide healthcare professionals with a comprehensive understanding of the functioning of the system, including its data inputs and the underlying logic used for making predictions.

In addition to their expertise in machine learning, healthcare personnel need to have a comprehensive understanding of the healthcare system and how it integrates with existing hospital workflows. This comprehension guarantees a seamless cooperation between predictive maintenance technology and the everyday functions of healthcare environments. It facilitates the integration of system insights into healthcare professionals' decision-making.

It is important to consider the concerns and preferences of healthcare workers. Effective communication, thorough training, and continuous support are crucial for establishing confidence and trust in predictive maintenance technology. Healthcare professionals should be knowledgeable and confident in using technology to improve patient care and make maintenance processes more efficient.

The complex nature of introducing AI and IoT technologies in healthcare is underscored by a range of challenges, including technical complexity, ethical considerations, security, embedded systems integration, and the human factor. The successful resolution of these obstacles is of utmost importance to fully unlock the capabilities of predictive maintenance systems and guarantee their beneficial effects on patient care and operational efficacy.

VII. Conclusion

This article presented a real-time monitoring architecture for inspecting and maintaining ICU ventilators in several healthcare organizations. Since the quality and quantities of medical devices in hospitals have increased, traditional maintenance techniques could have been more efficient and practical. The proposed architecture enables biomedical engineers or technicians to monitor the outcomes of data analysis, the predicted health status of ICU ventilators, and maintenance schedules in real time through device notifications and live charts. Consequently, the occurrence of a significant event on the selected devices can be detected and communicated to interested parties in real time. This architecture uses big data and IoT technologies to identify any component wear or breakage and monitor the status of these ventilators. It is founded on the monitoring and surveillance of the pneumatic block. Implementing an intelligent humidity detection system is optimal, as humidity monitoring significantly contributes to product quality. Sufficiently dry and only compressed air can reduce the risk of corrosion and condensation, equipment failures, and poor product quality.

As for our future projects, we aim to achieve a system-wide predictive maintenance system by implementing an integrity monitoring framework.

Predicting Aircraft Engine Failures using Artificial Intelligence

Asmae BENTALEB, Kaoutar TOUMLAL, Jaafar ABOUCHABAKA
Laboratory of Research in Informatics, Faculty of Science,
Ibn Tofail University, Kenitra, Morocco

***Abstract*—Nowadays, the aviation sector continues to develop especially with the emergence of new technologies, and solutions. Hence, there is an increasing demand for enhanced safety and operational efficiency in the aviation industry. As to guarantee this safety, the aircraft's engines must be monitored, controlled and maintained, however in an efficient way. Thus, the research community is working continuously in order to provide solutions that are efficient and cost effective. Artificial intelligence and more specifically machine learning models have been employed in this sense. Here comes the proposition of this article. It presents solutions implementing predictive maintenance using machine learning models. They help in predicting aircraft's failures. This is in order to avoid operations of unscheduled maintenance and disruptions of services.**

Keywords*—*Aircraft engine failures; machine learning; predictive maintenance; C-MAPSS; aviation safety

I. Introduction

The aviation industry has entered a new phase of aircraft maintenance and reliability through the integration of cutting-edge technology and advanced data analysis. In aviation, the availability and well functioning of aircraft components have always been crucial. Aircraft systems and component availability is increased by making accurate failure predictions. The timing of maintenance operations is a crucial factor in determining the total cost of maintenance and overhaul for aircraft components, which account for a substantial amount of all operating expenses for aviation systems. In the aviation industry, there are three primary forms of equipment maintenance. Corrective maintenance deals with maintenance procedures and unplanned issues, such as machine and equipment breakdowns, that arise when using aircraft equipment. Preventive maintenance aims to reduce unplanned repairs through periodic maintenance, preventing equipment failures or machinery breakdowns. Tasks are planned to avoid unexpected downtime and breakdown events, minimizing the need for repair operations. Predictive maintenance, as its name implies, utilizes parameters measured during equipment operation to anticipate potential failures. Its goal is to intervene before faults occur, reducing unexpected failures by providing people working in maintenance, with more reliable scheduling options for preventive maintenance. Evaluating system reliability is crucial in selecting the appropriate maintenance strategy. With the emergence of artificial intelligence technologies, preventive maintenance has know interesting progress. Thanks to AI approaches, and its ability to analyse large historical data including aircraft components, engine performance, sensor readings, and maintenance records, preventive analytics can be implemented in order to predict issues before they happen. This reduces the risk of unplanned downtime and allow timely intervention. AI also helps in the efficient prioritisation of tasks based on their criticality, and optimises the resources allocation accordingly. Finally, AI technologies allow the monitoring of aircrafts in real time thanks to deploying sensor and other IoT devices on the aircrafts components in order to monitor their health and performance. In this article, one of the aspects of AI will be used to implement the predictive maintenance, which is the machine learning one. The choice of these models is based on their performance in the literature. They will be explored in analysing and exploring the extensive Commercial Modular Aero-Propulsion System Simulation (CMAPSS) dataset. The article suggests an approach that starts with an in depth exploration and preparation of the data which is the core module of machine learning and the decision making system. This includes using histograms to understand the distribution of relevant variables. This step offers insights into the statistical characteristics of the data and aids in identifying potential patterns and anomalies. This process involves selecting and engineering relevant attributes that provide a comprehensive view of engine health and potential failure scenarios. These meticulous steps serve as the foundation for constructing robust predictive models with the potential to redefine aviation maintenance practices, which is the next step of building machine learning models. This article elucidates the significance of these advancements, the methodologies deployed, the resulting insights, and their far-reaching implications for the aerospace industry in order to enhance the safety and efficiency of aircraft engines.

A. Problem Statement

Predictive maintenance in aviation is a key factor in ensuring flight safety and performance. Using advanced technologies such as analysis of sensor data, artificial intelligence, airlines can anticipate potential failures and take corrective action before problems become critical. This proactive approach helps minimize flight interruptions, reduce maintenance costs and optimize resources use. It is within this framework that this project is located.
Hence, here the main issue is how to allow the prediction of these engines' failures?

II. Related Works

Prognostics and health management are critical in today's industrial big data era because they improve the accuracy of failure predictions in the future, which reduces expenses associated with inventory, maintenance, and labor. The NASA Commercial Modular Aero-Propulsion System Simulation dataset, an open-source benchmark with simulated turbofan engine units subjected to realistic flight circumstances, was used for the 2021 PHM Data Challenge. The goal of earlier deep learning applications in this field was to forecast how long engine units would stay useful. Nevertheless, the lack of identification of failure mode information in these methods, has limited their Interpretability and practical usefulness.

To overcome these constraints, a novel prognostics approach has been introduced, incorporating a tailored loss function. This approach aims to concurrently assess the remaining usable life, identify the probable failing component or components, and anticipate the current state of health. The suggested approach combines principal component analysis to orthogonalize statistical time-domain characteristics, which are then fed into supervised regressors like XGBoost, artificial neural networks, random forests and extreme random forests. Almong these approaches, ANN-Flux was considered to be the most effective, with AUROC and AUPR values higher than 0.95 for every classification assignment.

Furthermore, ANN-Flux demonstrates a remarkable 38% reduction in the root mean square error (RMSE) for remaining useful life compared to previous methodologies, utilizing the same test split of the dataset. Importantly, this improvement is achieved with significantly less computational cost, showcasing the potential of the proposed approach in advancing the field of prognostics and health management in industrial contexts [1].

This study describes the aviation industry, and how it involves a vast amount of information and maintenance data holding the potential to yield meaningful insights into forecasting future actions. This study seeks to introduce machine learning models that include feature selection and data elimination techniques for predicting aircraft systems failures. Over a two-year period, maintenance and failure data for aircraft equipments were systematically collected, identifying nine input variables and one output variable. A hybrid data preparation model is proposed to enhance the accuracy of failure count predictions in a two-stage process.

The first step uses ReliefF, a feature selection technique, to determine which factors have the greatest and least impact. To remove inconsistent or noisy data, a modified version of the K-means method is applied in the next step. Using Multilayer Perceptron (MLP) as an Artificial Neural Network (ANN), Support Vector Regression (SVR), and Linear Regression (LR) as machine learning techniques, the hybrid data preparation model's performance is evaluated on the maintenance dataset. The models' efficacy is measured using evaluation measures such as the Root Mean Square Error (RMSE), Mean Absolute Error (MAE), and Correlation Coefficient (CC).

The findings indicate that the hybrid data preparation model successfully predicts the failure count of the equipment, showcasing its efficiency in enhancing the accuracy of forecasting in the aviation industry [2].

An essential facilitator of intelligent maintenance systems is the capability to foresee the remaining useful lifetime (RUL) of their components, known as prognostics. Constructing data-driven prognostics models necessitates datasets that encompass run-to-failure trajectories. Nevertheless, in many real-world applications, obtaining large, representative run-to-failure datasets proves challenging as failures are infrequent in numerous safety-critical systems. In order to stimulate the advancement of prognostics methodologies, authors in [3] have formulated a new authentic dataset comprising run-to-failure trajectories for a fleet of aircraft engines operating under genuine flight conditions. This dataset was generated utilizing the Commercial Modular AeroPropulsion System Simulation (CMAPSS) model developed by NASA.

This dataset incorporates damage propagation modeling that adds two more levels of accuracy to the methodology developed in previous research. First of all, it takes into consideration actual flying circumstances as reported by a commercial aircraft. By connecting the degradation process to its operational history, it also improves the degradation modeling. This dataset is useful not just for predictive issues but also for providing health and fault class information. Because of this, it has two uses: it can be used for fault diagnostics as well as prognostics.

It is necessary to have datasets with run-to-failure trajectories available in order to generate data-driven prognostic models. The dataset offers a new realistic dataset of run-to-failure trajectories for a small fleet of aircraft engines under realistic flight conditions in order to aid in the development of these approaches. This synthetic dataset was created using damage propagation modeling, which adds two new levels of authenticity to the modeling approach utilized in earlier research. It starts by taking into account actual flight circumstances as reported by a commercial aircraft. By connecting the degradation process to the operating history, it further expands the degradation modeling. The dataset was created using the dynamic model of the Commercial Modular AeroPropulsion System Simulation (C-MAPSS) [4].

This study [5] outlines the methodology for modeling damage propagation within the components of aircraft gas turbine engines. The proposed approach involves generating response surfaces for all sensors through a thermo-dynamical simulation model that considers variations in flow and efficiency across the modules of interest. Specifically, an exponential rate of change for both flow and efficiency loss is applied to each dataset, starting from a randomly selected initial deterioration set point. The rate of change signifies an unspecified fault with a progressively deteriorating impact, with constraints on the upper threshold but otherwise random selection for fault rates.

Damage can continue to spread until a certain failure criterion is satisfied. At each instant in time, a health index is defined as the minimum of several overlaying operating margins; when the health index approaches zero, the failure criterion is met. The time series (cycles) of sensed measurements, usually from aircraft gas turbine engines, make up the model's output. The produced data are used by Prognostics and Health Management (PHM) as challenge data [6].

III. The Proposed Approach

The main objective of this work is to set up a system capable of predicting potential failures in the turbofan engine of aircraft. To do this, an accurate and reliable artificial intelligence model was created, using data analysis and predictive techniques to anticipate failures.

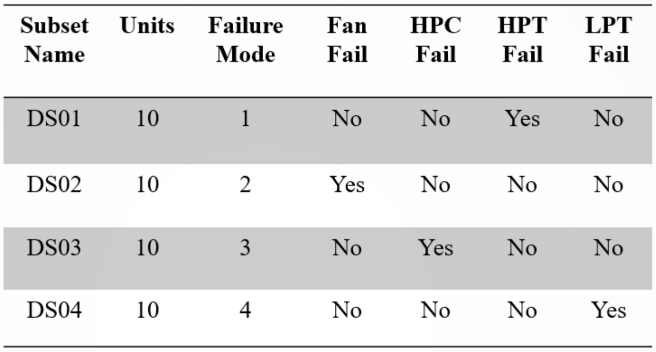
- Early detection of anomalies: The main objective is to use models and advanced AI technologies to detect early signs of anomalies or failures in the engine before they become critical.

- Increasing aircraft reliability: By identifying potential failures in advance, this work aims to improving the flight reliability and safety.

Initially, a detailed description of the C-MAPSS dataset is provided, including an introduction to the input variables and dataset composition. The suggested approach uses the categorization method in order to predict the eventual failure components. Three steps sum up the proposed methodology: First, histograms 2) Equilibrium data 3) smoothing of data 4) extraction of features; 5) obtaining the final predictions by developing a supervised machine learning model.

A. Dataset Description

The N-CMAPSS dataset has 40 engine units altogether and is divided into four supplied subsets. An overview of the failure mechanisms found in each subset is given in Fig. 1. The dataset's overall goal is to predict the RUL till catastrophic failure. Engine units are normally rated between 60 and 100 cycles. The duration of each flight cycle varies, and it is distinguished by 18 time series signals: Four descriptors of the flight data that summarize the dynamic operating conditions and fourteen real-time sensor measurements. Each cycle comprises the following additional variables in addition to the time series signals that are helpful in understanding the context of a flight cycle: the unit number, cycle number, a binary health state variable hs (set to 0 for unhealthy status and 1 for healthy status), and a categorical flight class variable Fc that represents the flight' length that is (set to 1 for short flights, 2 for medium flights, and 3 for long flights). Here, the simulated engines are operated past their optimal state until they eventually shut down [7].



Subset Name	Units	Failure Mode	Fan Fail	HPC Fail	HPT Fail	LPT Fail
DS01	10	1	No	No	Yes	No
DS02	10	2	Yes	No	No	No
DS03	10	3	No	Yes	No	No
DS04	10	4	No	No	No	Yes

Fig. 1. The N-CMAPSS dataset failure mode description.

B. Data Preparation

1) *Histograms:* To analyze the distribution of values in the dataset, a histogram was created, as shown in the Fig. 2 below. This histogram provides a clear graphical representation of the frequencies of the different values of the variable to be studied. On the horizontal axis, the different ranges of values were placed, and on the vertical axis, the frequency or density of occurrences in each bin, was represented. The shape of the histogram gives us immediate insight into the central tendency, the overall shape of the data distribution. This visualization allows us to identify patterns, thus providing important information for understanding the nature of this dataset.

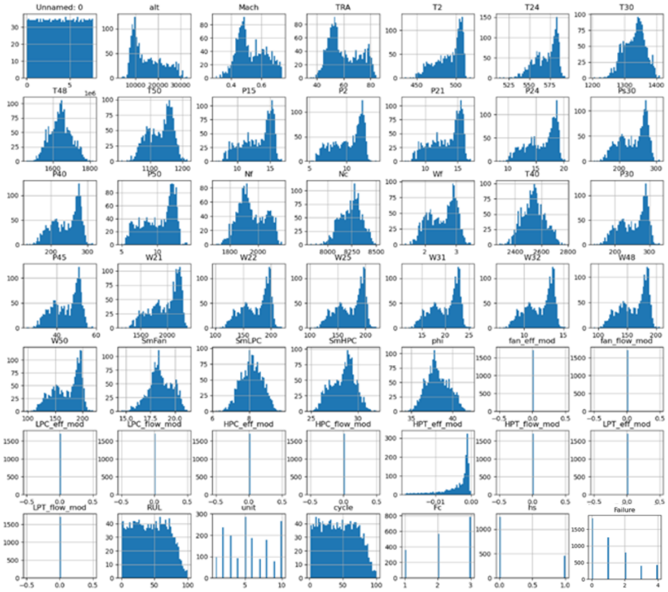


Fig. 2. The distribution of the N-CMAPSS dataset.

2) *Data balancing:* To address the issue of unbalanced data which is a challenging issue in machine learning, the Synthetic Minority Over-sampling Technique (SMOTE) has been opted in that sense. When one class significantly outnumbers the other, it can lead to biased model performance. SMOTE offers a solution by creating synthetic instances of the minority class. By interpolating between existing data points, SMOTE effectively increases the number of minority class samples, rebalancing the dataset. This approach not only mitigates the bias but also enables machine learning models to better recognize and generalize from the minority class. When coupled with other techniques or algorithms, SMOTE contributes to improved classification accuracy and, in turn, more robust and equitable model predictions [8] (Fig. 3 and 4).

3) *Data smoothing:* Using the Simple Moving Average (SMA), which is a straightforward yet effective technique widely employed in data analysis and time series forecasting. as shown in Fig. 5, SMA involves calculating the average of a fixed number of data points within a specified window or interval. This rolling average smooths out short-term fluctuations and emphasizes the overall trend in the data. SMA is particularly useful in identifying trends, cycles, and underlying patterns in time series data. Its simplicity and ease of implementation make it a popular choice for quick, preliminary analyses and trend detection. By reducing noise and highlighting long-term changes, SMA offers valuable insights for decision-making across various domains [9] (Fig. 5).

4) *Data normalization:* The Min-Max Scaler was used which is a widely used technique in data preprocessing, particularly in machine learning and statistics. This method

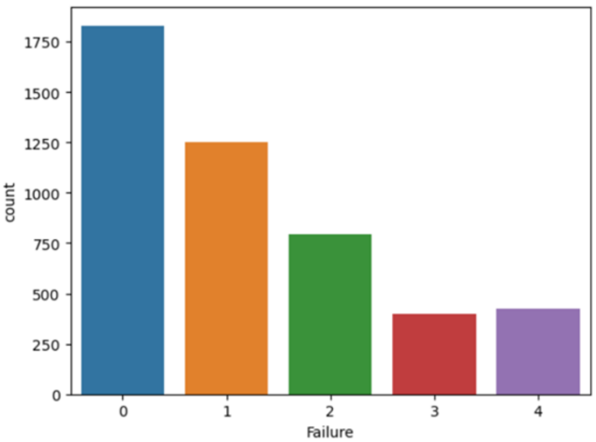

Fig. 3. The imbalanced dataset classes.

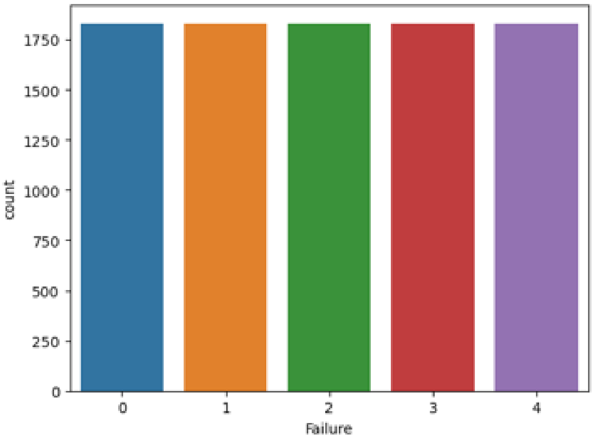

Fig. 4. The balanced dataset classes after using smote method.

scales and transforms data to fit within a specified range, typically between 0 and 1, by subtracting the minimum value and dividing by the range of values within a feature. The Min-Max Scaler ensures that all features share a common scale, eliminating discrepancies in magnitudes and helping machine learning models perform optimally. This approach is valuable in scenarios where maintaining the original data distribution is not critical, and consistent feature scaling is more crucial [10].

C. Feature Extraction

Feature extraction is a fundamental process in data analysis and machine learning that involves transforming raw data into a more concise and informative representation. The objective is to retain essential information while reducing dimensionality and computational complexity. In essence, feature extraction selects the most relevant attributes or characteristics from the original dataset, thereby enhancing the efficiency and effectiveness of subsequent analysis or modeling [11].

Selection and extraction of features are required in order to lower the dataset's input dimensionality. Fig. 1 of the C-MAPSS dataset shows that there are only 40 turbofan engine units; however, the dataset has over 63 million timestamps and needs to be reduced for further data processing. Predictions were provided on a per-cycle basis, as in earlier studies.

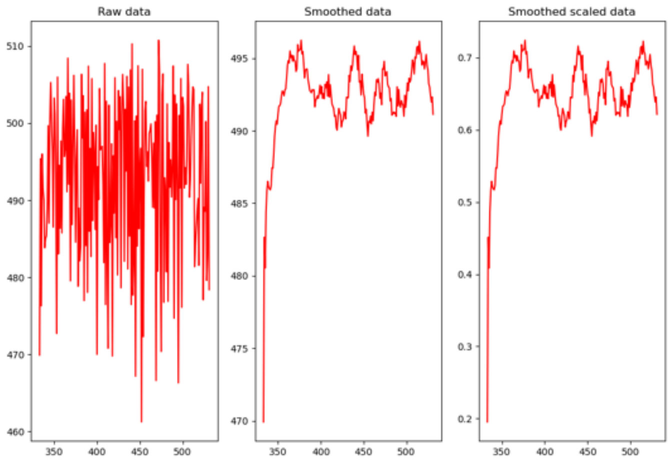

Fig. 5. The dataset before and after data smoothing.

$$\text{Scaled Value } (x') = \frac{x - \text{min}}{\text{max} - \text{min}}$$

In this article, the main focus is on the extraction of the cycle-wide statistical time domain feature to summarize the distribution for each time series using the mean.

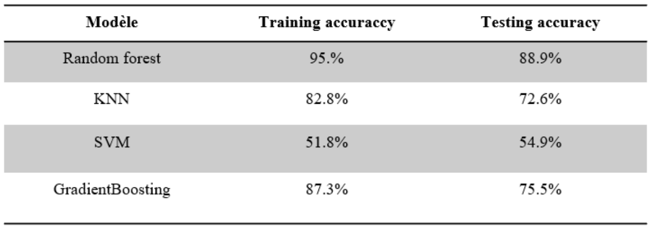
D. Training the Models

In this article, four diverse machine learning models have been trained and developped including: Random forest [12], Support Vector Machines (SVM) [13], K-Nearest Neighbors (KNN) [14], and Gradient Boosting [15]. Each of these models represents a unique approach to solving predictive tasks, showcasing the versatility of machine learning techniques.

Here are the reasons why these models have been chosen. Decision Trees are known for their simplicity and interpretability. They are like a flowchart, making decisions by splitting data based on features. SVM, on the other hand, excels at finding optimal decision boundaries, making it valuable in tasks like classification and regression. K-Nearest Neighbors relies on the wisdom of the crowd, assigning data points to the most common class among their neighbors, while Gradient Boosting combines the wisdom of many weak learners to create a robust, ensemble model (Fig. 6).

E. Hyperparameters Finetuning

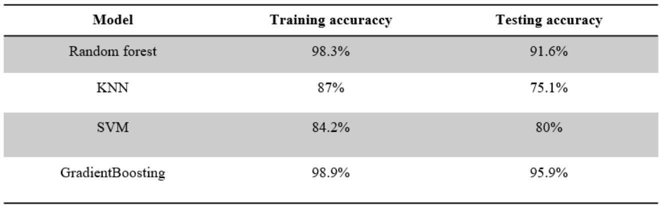
Hyperparameter adjustment is a pivotal phase in fine-tuning machine learning models, where the optimal set of hyperparameters is sought to achieve peak model performance. These hyperparameters, like learning rates, regularization terms, or tree depths, shape a model's behavior and its ability to generalize to new data. Two prominent methods for hyperparameter optimization are Grid Search and Random Search [16]



Modèle	Training accuraccy	Testing accuracy
Random forest	95.%	88.9%
KNN	82.8%	72.6%
SVM	51.8%	54.9%
GradientBoosting	87.3%	75.5%

Fig. 6. Models accuracy with the defaults parameters.

Grid Search systematically explores a predefined hyperparameters space by evaluating models at various combinations of hyperparameters' values. It involves a structured and exhaustive search, where every possible combination is assessed. While Grid Search ensures thorough coverage of the hyperparameters space, it can be computationally expensive and impractical for large search spaces [17] (Fig. 7).

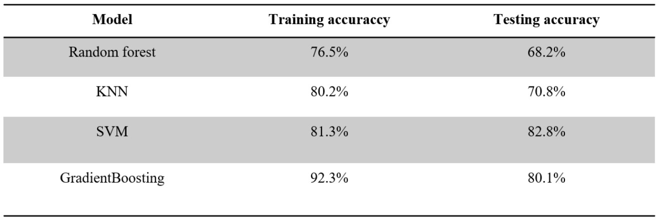


Model	Training accuraccy	Testing accuracy
Random forest	98.3%	91.6%
KNN	87%	75.1%
SVM	84.2%	80%
GradientBoosting	98.9%	95.9%

Fig. 7. Models accuracy with the Grid Search parameters.

In contrast, Random Search takes a more stochastic approach. It randomly samples hyperparameters values from specified distributions, which allows for a more efficient exploration of the hyperparameters space. Random Search can often yield excellent results with fewer iterations, making it a valuable alternative, particularly in scenarios where computational resources are limited [18].

Both methods serve as powerful tools for finding the optimal hyperparameters. The choice between Grid Search and Random Search depends on the nature of the problem, available resources, and the desired balance between thoroughness and efficiency in the hyperparameter optimization process (Fig. 8).



Model	Training accuraccy	Testing accuracy
Random forest	76.5%	68.2%
KNN	80.2%	70.8%
SVM	81.3%	82.8%
GradientBoosting	92.3%	80.1%

Fig. 8. Models accuracy with the Random Search parameters.

IV. Results

The comparative analysis of machine learning models' performances on the engines' related data within was conducted with particular rigor to select the model best suited to the studied problem. The four examined models, namely Random Forest, kNN, SVM, and Gradient Boosting, underwent thorough evaluation, with meticulous optimization of their hyperparameters to maximize their performance.

The results of this evaluation revealed interesting achievements. As shown in the figure, the Gradient Boosting model emerged as the leader, displaying a remarkable accuracy of 90.9%. This outstanding result underscores the model's ability to effectively capture complex and non-linear relationships present in the dataset. The superior performance of Gradient Boosting compared to other models indicates its relevance and predictive power for the specific application.

The decision to select the Gradient Boosting model as the final model is supported by this superior performance. However, it is crucial to consider other aspects, such as the model's complexity and the resources required for its deployment. While Gradient Boosting is powerful, it may be more demanding in terms of training time and computational resources (Fig. 9).

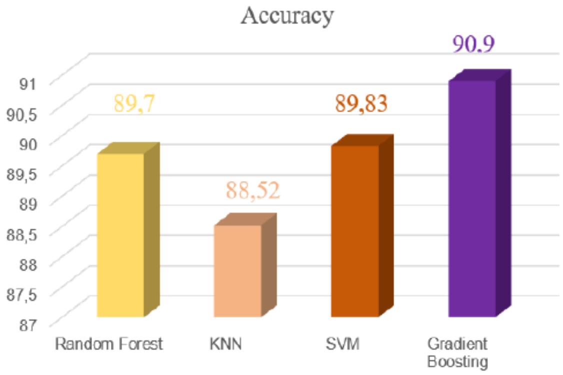


Fig. 9. The performance of the models.

As to position our results, gradient boosting algorithm in this article has given better accuracy value thanks to the used finetuning methods. If compared with the literature results [19], it gave better results. For example, in this article, gradient boosting has given less interesting results when applied to aircraft' dataset.

V. Conclusion

In conclusion, this article has performed a fascinating exploration of the world of machine learning in the context of predicting aircraft engine failures. A deep dive has been taken into the intricacies of four key machine learning models: Gradient Boosting, Decision Trees, Support Vector Machines (SVM) and K-Nearest Neighbors (KNN). These models serve as powerful tools in addressing the critical challenge of aviation engine reliability.

Throughout this journey, the inner workings of these models has been identified and their implication in the real-world applications in enhancing aircraft maintenance practices, has been witnessed. The significance of predictive maintenance in aviation safety and efficiency cannot be overstated, and machine learning provides a pathway to achieving this pivotal goal. Furthermore, the article has shed light on the importance of hyperparameters' adjustment, as well as two powerful techniques, Grid Search and Random Search, that empower data scientists to fine-tune these models. This hyperparameters' optimization process represents a crucial step in ensuring the effectiveness of AI-driven predictive maintenance. In the realm of aviation, where safety is paramount, the fusion of data and artificial intelligence is transforming the landscape of engine failure prediction. The diversity of machine learning models, coupled with meticulous hyperparameters' tuning, have allowed the proactive detection and handling of potential engine issues, thus enhancing both the safety and efficiency of aircraft operations. Thus, the domain of Artificial intelligence is going to play a pivotal role in redefining the standards of excellence in aircraft engine maintenance.

VI. Data Availability

Concerning the availability of the C-MAPSS dataset, it can be downloaded from the Center of Excellence Data Repository of NASA; through the following link: https://www.nasa.gov/content/prognostics-center-of-excellence-data-set-repository.

***Abstract*—Ischemic stroke is the most prevalent type of stroke and a leading cause of mortality and long-term impairment globally. Timely identification, precise localization, and early detection of ischemic stroke lesions brain are critical in healthcare. Various modalities are employed for detection, and magnetic resonance imaging stands out as the most effective. Different magnetic resonance imaging techniques have been proposed for the detection of ischemic stroke lesion tumors, allowing for image uploading and visualization. Automated segmentation of ischemic stroke lesions from magnetic resonance imaging images has an important role in the analysis, prognostic, diagnosis, and clinical treatment planning of some neurological diseases. Recently, computer-aided diagnosis systems based on deep learning techniques have demonstrated significant promise in medical image analysis, particularly in multi-modality medical image segmentation. Automated segmentation is a difficult task due to the enormous quantity of data provided by magnetic resonance imaging and the variation in the location and size of the lesion. In this study, we develop an automated computer-aided diagnosis system for the automatic segmentation of ischemic stroke lesions from magnetic resonance imaging images using a Convolution Block Attention Module (CBAM) and hybrid UNet-ResNet50 model. The UNet model is integrated into the architecture, and the ResNet50 backbone is pre-trained to enhance feature extraction. CBAM block is a model applied in this approach to extract the most effective feature maps. The proposed approach is evaluated on the public Ischemic Stroke Lesion Segmentation Challenge 2015 dataset, arranged into weighted-T1(T1), weighted-T2(T2), FLAIR, and DWI sequences. Experimental results demonstrate the efficacy of our approach, achieving an impressive accuracy value of 99.56%, a precision value of 97.12%, and a DC of 79.6%. Notably, our approach outperforms other state-of-the-art methods, particularly in terms of accuracy values, highlighting its potential as a robust tool for automated ischemic stroke lesion segmentation in magnetic resonance imaging.**

I. Introduction

Stroke, characterized by the sudden onset of cerebral dysfunction, is a global health concern with significant mortality rates and long-term disability [1]. Recognized as a pandemic by the World Health Organization (WHO), the projected increase in stroke cases underscores its growing impact, with estimates reaching 23 million by 2030 [2], [3], [4]. This surge in incidence, now at 12 million cases annually, demands heightened attention from the medical community [5].

In the United States, approximately 800,000 people suffer from strokes each year, a number expected to significantly increase in the future due to the aging population [6]. In Tunisia, stroke stands as the leading cause of physical disability in adults and the third cause of death, with an annual incidence of around 10,000 new cases [7]. The aftermath of stroke, affecting around 70% of survivors, are often left with severe cognitive problems, requiring intensive and specialized care over a long period to facilitate recovery [3].

Stroke is categorized into two primary types: ischemic and hemorrhagic. In this study, we focuses on Ischemic Stroke Lesions (ISL) due to their widespread prevalence and the imperative for early intervention, including thrombolysis or thrombectomy. The automatic segmentation of ischemic stroke lesions from Magnetic Resonance Imaging (MRI) images plays a pivotal role in improving diagnosis, prediction, and treatment planning. Advanced neuroimaging modalities, particularly MRI, have proven indispensable in enhancing the efficiency and accuracy of stroke interventions.

In our research, we focused on Ischemic Stroke Lesions (ISL) because they affect a lot of people and require early intervention and treatment which will be acts of thrombolysis or thrombectomy. Additionally, the assessment of ischemic stroke lesions is a critical endpoint in clinical trials. It can help to improve how we diagnose, predict, find, and treat this condition. The evaluation of ischemic stroke lesions is a pivotal endpoint in clinical trials, offering insights that can enhance diagnosis, prediction, localization, and treatment. The advancements in medical imaging technology have significantly improved the intervention and clinical treatment of strokes, making them more efficient and accurate. Advanced neuroimaging modalities including Magnetic Resonance Imaging (MRI), Computed Tomography(CT scan), and Magnetic Resonance Angiography (MRA), etc, are used for ISL diagnosis. CT imaging can diagnose stroke patients who have tumors well, but it is not good at showing other parts of the brain or early signs of damage. Angiography means putting an injection of a contrast agent into the patient, which can affect their health and cause implications for the patient's body [8]. MRI emerges as the most effective tool for assessing patients with ischemic stroke. It is a non-invasive tool, more sensitive and it can accurately analyze the diseases. It can help to track the disease and predict the outcome. Furthermore, her sequence acquisitions (Diffusion-Weighted-Images (DWI), T1, T2, and Fluid-Attenuated-Inversion-Recovery (FLAIR)), can provide specific information about the extent of the lesion and her localization which represents the main clinical detail in detection processing. Its multi-parametric nature, encompassing various contrasts and sequences, positions MRI as an indispensable and highly effective method for the comprehensive assessment of ischemic stroke patients, thereby influencing critical aspects of their care and recovery. The ability to automatically detect infarct lesions proves invaluable for medical diagnosis, facilitating timely intervention and treatment planning. MRI stands as a cornerstone in post-stroke issue resolution, offering unparalleled advantages such as detailed disease monitoring, early lesion visualization, tissue characterization, and outcome prediction.

Ischemic strokes have a complex structure that makes their segmentation in MRI images difficult. Therefore, automatic stroke segmentation has been achieved by using Artificial Intelligence (AI) algorithms, which are very important for the medical research field. AI techniques, such as deep learning and machine learning, are very popular in the medical field. They can handle multidimensional medical data as well as a trained expert. Moreover, it is widely used and adopted in the process of medical imaging processing, especially in segmentation, classification, diagnosis, detection, and prognosis of stroke ischemia. It offers reliable, accurate, and consistent outcomes. This would reduce the testing time and enable the neuroradiologists to examine and interpret more data for their patients, which would be more cost-efficient.

Currently, various Computer-Aided Diagnosis (CAD) systems based on deep learning models are commonly developed and applied in ISL segmentation. Specifically, Convolutional neural networks (CNNs) are the most employed models for image classification and segmentation tasks in neurodegenerative diseases. CNN has demonstrated enormous potential in analyzing and characterizing medical images, including ischemic brain stroke segmentation. Furthermore, these models have leveraged the power of CNNs for image analysis and the advantages of statistical methods for data processing. This makes many patterns have been developed by researchers around the world.

However, CNNs often suffer from limitations when segmenting medical images, due to their limited spatial awareness and difficulty in processing diverse anatomical structures. To overcome these difficulties, the adoption of the Convolutional Block Attention Module (CBAM) is proving advantageous. CBAM remedies the rigidity of CNN by incorporating attention mechanisms that enhance spatial awareness, enabling the model to capture long-range dependencies in medical images. In addition, the dynamic importance of CBAM features facilitates adaptation to complex structures, enabling the network to focus on relevant regions and improve segmentation accuracy. This transition to CBAM represents a promising advance in medical image analysis, offering a more robust and flexible approach to image segmentation tasks.

In this paper, we propose a CAD system for ischemic stroke brain segmentation based on CBAM and a hybrid ResNet50-Unet model from MRI sequences to overcome these issues. We enhance the ResNet50-UNet architecture performance by integrating the CBAM block. The ResNet50-UNet framework combines the deep feature extraction capabilities of ResNet50 with the precise segmentation abilities of the UNet architecture. To introduce attention mechanisms and enrich feature representations, we meticulously inserted CBAM block after each convolutional block within the network. At each convolution step, the CBAM module dynamically computes channel-wise and spatial-wise attention, allowing the model to focus on relevant features and significant regions in the medical images. This customized integration gives our model greater spatial awareness and adaptability to complex anatomical structures, increasing segmentation accuracy compared to the conventional ResNet50-UNet architecture. The CBAM-enhanced ResNet50-UNet not only leverages the strength of both architectures but also capitalizes on the attention mechanisms to achieve more refined, context-sensitive segmentation of medical images.

In this study, we propose a systematic approach for the segmentation of ischemic stroke brain lesions using a Computer-Aided Diagnosis (CAD) system. Our method employs a hybrid ResNet50-Unet model, and we enhance its capabilities by integrating the Convolutional Block Attention Module (CBAM) into the processing of MRI sequences. The methodology unfolds through several key steps. We begin by integrating a CBAM block into the ResNet50-UNet architecture, a step designed to significantly improve the model's performance. This integration capitalizes on the deep feature extraction prowess of ResNet50 while harnessing the precise segmentation abilities inherent in the UNet architecture. Subsequently, attention mechanisms are introduced by strategically placing a CBAM block after each convolutional block within the network. This meticulous insertion allows for the dynamic computation of channel-wise and spatial-wise attention at every convolutional step. As a result, the model becomes adept at focusing on relevant features and significant regions in the medical images. To further refine the approach, we customize the integration, providing our model with heightened spatial awareness and adaptability to complex anatomical structures. This customization proves instrumental in increasing segmentation accuracy compared to the conventional ResNet50-UNet architecture. The culmination of these efforts results in a CBAM-enhanced ResNet50-UNet model that not only leverages the strengths of both architectures but also effectively utilizes attention mechanisms to achieve a more refined and context-sensitive segmentation of medical images. This approach holds promise for advancing the field of ischemic stroke diagnosis and treatment planning.

The remaining parts of this research paper are organized as follows: In section two, we review the current reviews state of the art techniques segmentation for ISL. In Section Three, we present the dataset description and preprocessing and, eventually, discuss the proposed method based on mechanism attention and ResNet50-UNet (CBAM ResnNet50-UNet). Section four reports the experimental results and compares our method with the results of the state-of-the-art multimodal MRI dataset Ischemic Stroke Lesion Segmentation Challenge (ISLES) 2015. We also address some important challenges and drawbacks of the methods we propose in the same section. Finally, the paper is concluded in Section Five.

II. Related Work

Machine learning (ML) and deep learning (DL) have transformed the landscape of medical imaging significantly, providing unparalleled capabilities in analyzing intricate datasets. Classical machine learning methods heavily depended on features manually designed for the analysis of brain images. Identifying abnormalities, particularly in cases such as brain ischemia, presented challenges owing to irregular shapes and ambiguous boundaries. Deep learning models, specifically CNNs, autonomously acquire both local and global features, proving crucial for early diagnosis. In the context of brain ischemia, various methods leveraging CNNs have been developed for automatic early detection and segmentation. This section provides an in-depth overview of leading methods for brain ischemia segmentation from multimodal MRI sequences. Utilizing the ISLES 2015 dataset, which aligns with my proposed approach, our analysis aims to capture insights accumulated between 2017 and May 2023.

Kamnitsas et al. [9] proposed an architecture with a dual pathway for a brain tumor and ischemic stroke segmentation, which processes a 3D Fully connected Conditional Random Field (CRF) to remove false positives. To overcome the computational load of processing 3D medical scans, they created a dense training scheme that is effective and efficient for processing 3D medical scans. They merge the processing of nearby image patches into one network pass and automatically adapt to the natural class imbalance in the data. They obtain an average dice coefficient equal to 69%.

Additionally, Liang et al. [10] introduced a framework to segment stroke lesions with DWI sequences that are based on two CNNs. One is a combination of two DeconvNets, which is the EDD Net; the other CNN is the multi-scale convolutional label evaluation net (MUSCLE Net), which aims to assess the lesions detected by the EDD Net and eliminate possible false positives. They tested their method on a large dataset including 741 subjects from DWI. The mean accuracy achieved is 67% in total. The mean Dice scores for subjects with only small and large lesions are 61% and 83%, respectively.

Zhiyang et al. [11] suggested a residual structured fully convolutional network (Res-FCN) based on 2D slices from DWI, ADC, and T2 WI. The suggested Res-FCN is trained and tested on ISLES 2015-SISS with 212 clinically acquired MRIs, which achieves a mean dice coefficient of 64.5% with a mean number of false negative lesions of 1.515 per subject.

Furthermore, Rongzhao et al. [12] used 3D contextual information and automatically learned features to propose an end-to-end model. To alleviate the hardness of training deep 3D CNN, they equipped the network with dense connectivity to allow the unimpeded propagation of information and gradients throughout the network. The Dice objective function was used to train the model to deal with the severe class imbalance problem in data. The model was built up with a DWI dataset with 242 subjects regrouped as 90 for training, 62 for validation, and 90 for testing. It achieved a Dice similarity coefficient, lesion-wise precision, and lesion-wise F1 score equal to 79.13%, 92.67%, and 89.25% respectively.

In 2019, Liangliang et al. [13] proposed a multi-kernel DCNN (MK_DCNN) composed of two symmetrical deep sub-networks, in which dense block are used to reduce the overfitting problem of deep networks such as the extraction of effective features from sparse pixels. A multi-kernel and the dropout regularization method were used to split the network into two sub-networks for getting more sensory fields, and the dropout regularization method to achieve an effective feature mapping respectively. Then, they applied median filtering to reduce noise and preserve image edge detail. The developed architecture provided a dice coefficient of 57%, a symmetric surface distance value average equal to 2.01mm, and a Hausdroff distance equal to 2.38 mm with the SISS challenge dataset. With the same challenge, Amish et al. [14] created a modified U-Net model and a multi-path network. The model obtained an average dice coefficient of 70.07%, a sensitivity value of 49.28%, a specificity equal to 99.78%, and a precision of 98.72%.

In the same year, to perform segmentation, a model for the spatial arrangement of pixels preserved by learning the local characteristics of an image was proposed by Karthik et al. [15]. This research work presented a supervised fully convolutional network (FCN). The remarkable point of this research is the application of Leaky Rectified Linear Unit activation in the last two layers of the network for precise reconstruction of the ischemic lesion. This allows the network to learn from additional features that are not considered in the existing U-Net architecture. An average segmentation dice coefficient of 70% was obtained with ADAM optimizer based on experiments carried out on the ISLES 2015 dataset only on axial plane slices [15].

In 2020, Liangliang et al. [16] presented a Res-CNN based on a U-shaped structure and integrated the residential unit dual in the network to alleviate the degradation problem. Fusion methods and data augmentation were used before training the model to expand their dataset. The presented model obtained an average dice coefficient equal to 74.20% and a Hausdroff distance equal to 2.33mm. It's the same for Amish et al. [17] have also continued research on this topic. They proposed a new architecture based on the Classifier-Segmenter (CS-Net), which involves a hybrid learning strategy with a self-similar U-Net model, explicitly designed to perform the segmentation task. The advantage is to develop a cascade architecture, which improves the precision while removing redundant parts of the Segmenter's input. With the ISLES SISS-2015 dataset, they achieved a dice coefficient, a precision, and a recall of 63%, 74%, and 62% respectively. With ISLES 2017, they obtained a dice coefficient, a precision value, and a recall of 28%, 37%, and 45%, respectively.

Zhang et al. [18] presented a framework to quickly and automatically segment stroke lesions on DWI. First, they designed a detection and segmentation (DSN) to address data imbalance. Second, they proposed a triple-branch DSN architecture, which was used to extract the different features. Third, they developed a multi-plane fusion network (MPFN), which aimed to make the final prediction more accurate. The authors tested their methods on the ISLES 2015 SSIS DWI sequence dataset. Experimentally, they obtained dice coefficient and sensitivity values of 62.2% and 71.7%, respectively.

Liangliang et al. [19] have continued research on this contribution, now with a third approach after the two mentioned previously. In this point, a new network neural convolutional deep residual attention (DRANet) was proposed to accurately

TABLE I. Summary of Existing Methods for MRI Images Segmentation

Authors	**Methods**	**Dice Coefficient(%)**	**Accurracy(%)**	**Precision (%)**

and simultaneously segment and quantify lesions of stroke and white matter hyperintensity (WMH) in MRI images. Their solution's key architectural features are the use of the residual block and the Dice loss function to make the network training effective, as well as the use of the attention modules to produce a high-quality representation of the input images inside the network. Their proposed DRANET model obtains high-quality features from the input images. DRANet was trained and evaluated on 742 2D MRI images which are generated from (SISS) challenge and their approach achieves a dice coefficient of 76%.

Recently, Aboudi et al. [20], [21] developed two contributions to this idea. The first consists of developing a deep convolutional neural network (CNN) method inspired by the U-Net architecture. They applied a finetuning technique to adapt the U-Net architecture to our objectives. They evaluated her method on the public dataset ISLES 2015. Their model achieved a Dice Coefficient (DC) and accuracy equal to 55.77%, and 99.96% respectively. The second research consists of combining the UNet model with a pre-trained ResNet50 architecture to form a hybrid framework. They apply data augmentation techniques to improve the model's accuracy. They trained and tested their method on the ISLES 2015 dataset. The experimental results show the effectiveness of our method, which achieves a 99.43% average accuracy, and a 64.14% Dice Coefficient(DC).

The assessment of existing surveys underscores the rapid evolution of approaches in medical imaging, leveraging the capabilities of machine learning (ML) and deep learning (DL). While DL models, particularly CNNs, have shown substantial promise, persistent challenges and limitations have been identified. This observation prompts the introduction of attention mechanisms, such as CBAM, in our approach. Existing studies, including models like U-Net, have demonstrated success in brain ischemic lesion segmentation. However, issues like class balance, false positives, and effective 3D data processing persist. Noteworthy models like Res-FCN, Res-CNN, and innovative approaches like DRANet with attention modules

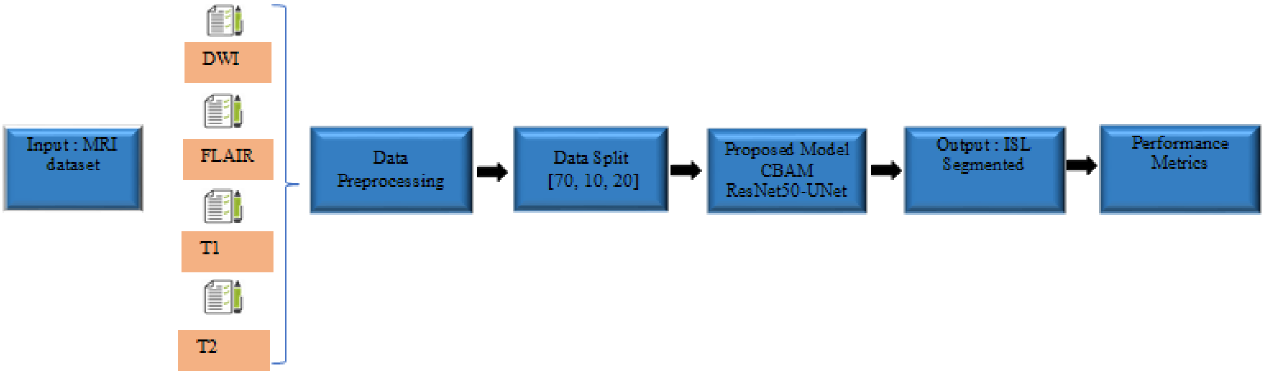

Fig. 1. Flowchart of the proposed approach.

have showcased impressive results. The summary Table I of existing methods highlights diverse approaches and metrics like Dice coefficient, precision, and accuracy. Despite these advancements, limitations in terms of precision and sensitivity justify the need for our CBAM-based approach and attention mechanism to address persistent challenges in accurate brain ischemic lesion segmentation. In essence, the analysis of past works underscores progress but emphasizes the ongoing need for improvements, justifying the introduction of attention mechanisms in our proposed approach.

III. Motivations and Contributions

In this research, we propose an attention model to enhance the performance of ISL segmentation. Only a handful of publications have explored the integration of attention block in segmentation models. Many researchers focus on improving the segmentation outcome without considering task efficiency. Thus, the most crucial aspect in any ML or DL models is to extract minimal yet valuable features. To address this issue, we will apply an attention-based mechanism to select relevant features from the entire MRI and use them for segmentation. Additionally, to minimize the algorithmic and computational complexity of the task, we will employ transfer learning instead of training a complete neural network from scratch, pre-trained with ResNet-50. This technique helps us improve segmentation performance while maintaining task accuracy. Therefore, we summarise our main contributions in this research paper as follows:

- An advanced CAD system for ischemic stroke brain segmentation based on CBAM and a hybrid ResNet50-Unet model from MRI sequences (DWI, T1, T2, and Flair) was developed.
- CBAM block was integrated after each convolution block into the ResNet50-UNet architecture to enhance the model performance and to enhance feature representation by emphasizing relevant channels and adjusting spatial perception.
- Significance evaluation of predicted ground truth for ISL segmentation in MRI sequences.

IV. Proposed Method

In this section, we provide a detailed explanation of the proposed CAD system for ischemic stroke brain segmentation, which relies on CBAM and a hybrid ResNet50-Unet model applied to MRI sequences (DWI, T1, T2, and Flair). Firstly, we present the dataset description and preprocessing steps. Subsequently, we delve into the detailed information about the architecture of the proposed CBAM ResNet50-Unet model. We also elaborate on the reasons for selecting this specific method. Fig. 1 illustrates an overview of our approach.

A. Dataset Description

The multimodal Ischemic Stroke Lesion Segmentation Challenge (ISLES) 2015, provided by the University Medical Center Schleswig Holstein (UKSH) Germany and the departments of Neuroradiology Hospital Rechts der Isar in Munich was used to perform this research study. The data acquisition parameters encompass a slice thickness of 5 mm, an echo time of 87 ms, and a repetition time of 3200 ms. ISLES 2015 dataset is reorganized as follows: SISS, which was employed in our work and involved segmenting sub-acute ischemic stroke lesions, and SPES, which involves estimating the stroke penumbra. This work uses a training dataset supplied by SISS that consists of 28 subject cases and a manually segmented and annotated ground truth. This dataset was acquired from 3T Philips systems and arranged into weighted-T1(T1), weighted-T2(T2), FLAIR, and DWI(b=1000) sequences with 57 to 154 slices. We have obtained a total of 4312 images. Fig. 2 illustrates an example of the four methods of MRI images. Each subject's data is represented in NIFTI(.nii) format, featuring an image shape of 240x240x155x3.

B. Preprocessing

The raw MRI images underwent preprocessing before being employed as input in our proposed approach. Each pixel from the original 3D images is converted into a series of 2D images. To enhance the dataset, non-relevant black images are removed, as they do not fall within the brain tumor category, and utilizing the entire image is unnecessary for medical image analysis. During the preprocessing step, images with black slices lacking information are excluded. Our focus centers on eight slices, commencing from slice 22, where

we define our Regions of Interest (ROIs). Additionally, all images undergo resizing to 128x128x3, ensuring uniformity in dimensionality. The dataset is partitioned into distinct subsets: 70% for training, 20% for validation, and 10% for testing.

C. CBAM Model

CBAM, introduced by Woo et al., serves as an attention module designed to facilitate channel size and spatial operations within CNN architectures. This module comprises two blocks(modules): the channel attention module and the spatial attention module. Fig. 3 describes the CBAM block architecture.

1) Channel Attention Module: Channel attention focuses on discerning the meaningful content within an input image, determining 'what' features are significant. This is achieved by analyzing inter-channel relationships to enhance feature selection and extraction while minimizing loss values. The calculation of channel attention involves compressing the spatial dimension of the input feature map. To aggregate spatial information, Global Average Pooling (GAP) and max-pooling layers are employed. GAP obtained the aggregate information(calculating the average for each patch of the feature map) when the max-pooling layer reached the differences of features(calculates the maximum). The fusion of the GAP layer and max-pooling layer performed better than using a single layer to produce a weighted channel descriptor (Fig. 5). Channel attention is calculated as follows:
$M_c(F) = \sigma(MLP(AvgPool(F)) + MLP(MaxPool(F)))$

$$= \sigma(W_1(W_0(F_c^{avp})) + W_1(W_0(F_c^{max})))$$

where F_c^{avp} and F_c^{max} denote the squeezed feature maps of the two pooling layers, σ represents the sigmoid function, $W_0 \in R^{r/C*C}$ and $W_1 \in R^{C*C/r}$ represent the weights of MLP.

2) Spatial Attention Module: It is based on 'where' is a relevant part. This module used the inter-spatial relationship between features to calculate the spatial attention map. Firstly, GAP and max-pooling functions are applied on the feature maps generated during the previous step (channel attention module) and squeezed into 2D features maps: $F_{avg}^s \in R^{1*H*W}$ and $F_{max}^s \in R^{1*H*W}$. After that, a convolution layer is added on the recombined two 2D feature maps to generate an efficiency feature maps. Then, a sigmoid function is used to calcule the spatial attention map $M_s(F) \in R^{H*W}$. Spatial attention is calculated as follows:
$M_s(F) = \sigma(f^{7x7}([AvpPool(F); MaxPool(F)]))$

$$= \sigma(f^{7x7}([F_{avg}^s; F_{max}^s]))$$

when σ is a sigmoid function and f^{7x7} denotes une convolution function with filter size of $7x7$.

In Spatial Attention Module, GAP and max pooling functions are used to generate spatial feature descriptor then a $7x7$ convolution filter used to emphasize a spatial information.

D. Pre-trained ResNet50 Model

ResNet50 stands as a prominent member of the Residual Network family architecture and is currently among the most widely utilized models in the field of image recognition. It was introduced by Kaiming He et al.[22] in their influential paper "Deep Residual Learning for Image Recognition. ResNet50 has demonstrated exceptional performance across diverse vision applications, encompassing tasks such as classification, object detection, and semantic segmentation. Fig. 4 illustrates the ResNet50 architecture. It comprises 48 convolutional layers organized into four stages, featuring residual blocks with shortcut connections to address the challenges of training very deep. ResNet50 effectively addresses the vanishing gradient problem. The architecture's bottleneck design optimizes computational efficiency, incorporating 1x1 convolutions for feature map dimensionality reduction. With Global Average Pooling (GAP) as a concluding layer and pre-trained weights often obtained from datasets like ImageNet, ResNet50 stands out for its ability to provide compact representations and serve as a robust foundation for transfer learning. This model's advantages encompass its proficiency in mitigating training challenges, its adaptability to diverse computer vision tasks, and its consistent delivery of state-of-the-art performance in image classification and segmentation.

The pre-trained ResNet50 model comprises four key blocks, each referred to as a stage. The initial block involves data preprocessing and feature extraction, followed by three residual blocks within different stages. These residual blocks, incorporating multiple convolutional layers, contribute to the network's depth and capacity to capture intricate features. This architecture, known for its efficacy in image recognition, has achieved state-of-the-art results in various visual tasks due to its depth, skip connections, and the ability to train deep networks effectively.

E. Unet Model

UNet model stands as the common model choice for segmentation tasks in the medical imaging domain, such as segmenting organs or tumors in medical scans. It was developed by Olaf Ronneberger, Philipp Fischer, and Thomas Brox, U-Net is characterized by a U-shaped architecture, featuring an encoder pathway and a symmetric decoder pathway. It adeptly gathers low-level features that encapsulate information about the shapes of different classes, alongside high-level features that leverage this information to discern the class to which each position belongs. The architecture seamlessly integrates both low-level and high-level features to reconstruct the original input's spatial dimensions, ensuring precise classification for each location. UNet architecture is comprised of two fundamental blocks: the encoder and the decoder. The encoder captures contextual information through downsampling, while the decoder reconstructs the segmented image with fine-grained details using upsampling. The unique aspect of U-Net is the incorporation of skip connections that connect corresponding layers between the encoder and decoder, aiding in the precise localization of segmented objects. U-Net's ability to handle limited labeled data and its effectiveness in preserving spatial information makes it a popular choice for image segmentation tasks.

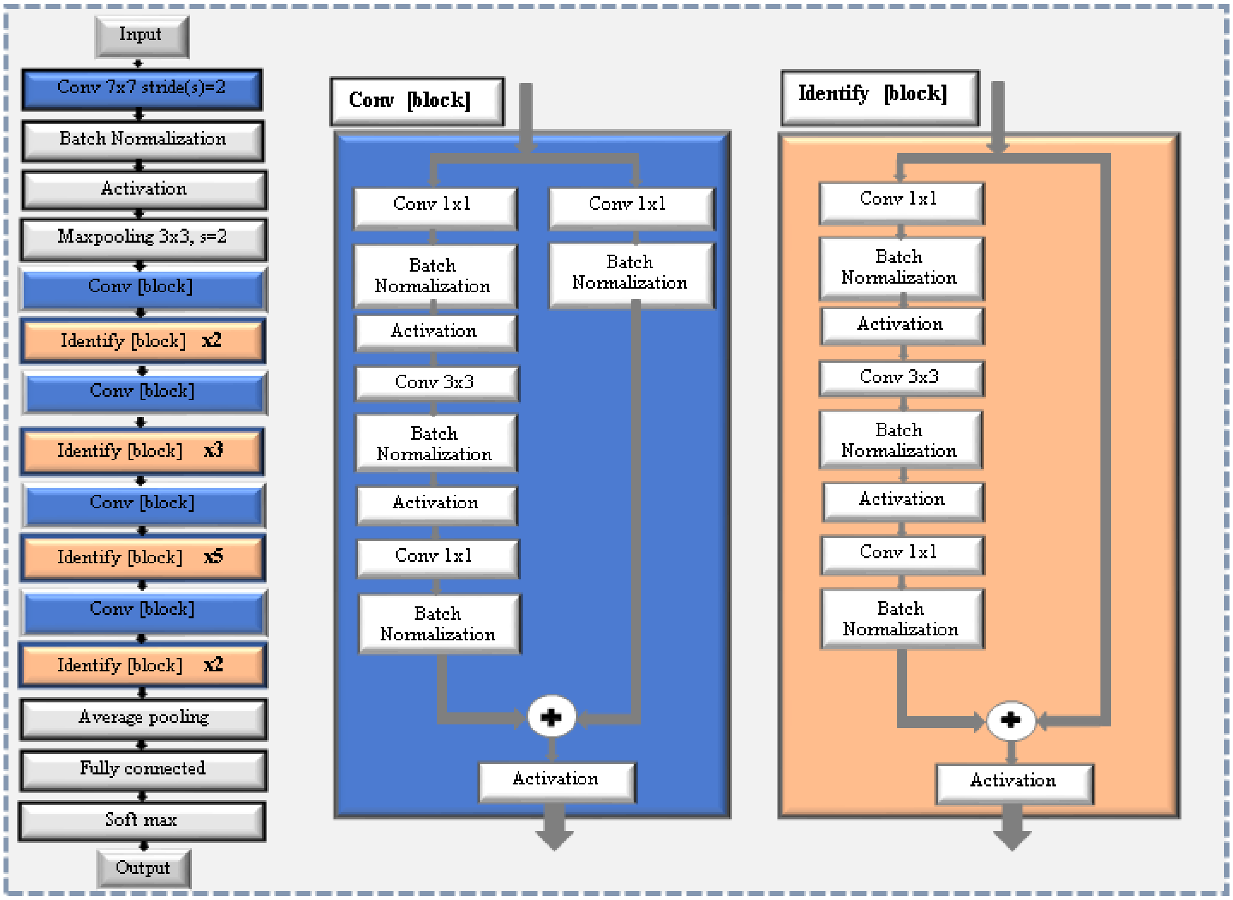

Fig. 4. The architecture of the pre-trained ResNet50 model.

F. Proposed Hybrid CBAM ResNet50-Unet Model

The UNet model architecture is organized into two primary blocks: the encoder and the decoder. In the encoder network, the input is processed through successive convolutional blocks, each succeeded by max-pooling layers for downsampling. These blocks progressively extract hierarchical features, capturing both low-level and high-level representations of the input. Subsequently, the decoder network begins with upsampling operations using transposed convolutions (Conv2DTranspose). Each upsampling step is accompanied by concatenation with the corresponding feature maps from the encoder, creating skip connections. Convolutional blocks in the decoder then process this concatenated information, gradually restoring the spatial dimensions of the original input. The final layer, utilizes a 1x1 convolution with softmax activation, producing a pixel-wise classification map. This architecture seamlessly integrates the encoding of input features and the decoding of spatial information, making it well-suited for segmentation tasks.

The backbone of the ResNet50 model is added into the encoder bloc only. We freeze the encoder layer using fine-tuning and transfer learning in the pre-trained ResNet50 model, entrain the absence of an update of weighted layer during the execution of training data. Instead, the weight of the convolutional layer off ResNet50 will be used. First, we modified the architecture of the ResNet50 to be similar to UNet, adding an expanding layer composed of multiple up-sampling layers and convolution layers at the end of her structure. Second, this is carried out up until the model's overall architecture is symmetric and takes the form shape of a U-Net. Such as this combination the trainable parameters models will be reduced. After, we train the input data MRI using the two proposed hybrid models with a transfer learning method.

In this approach, CBAM block has been thoughtfully incorporated after each convolutional block in the model. Each convolutional block consists of a sequence of convolutional layers, followed by a dropout operation, and finally, batch normalization. The novelty lies in adding the CBAM module after this layer sequence, designed to enhance feature representation by emphasizing relevant channels and adjusting spatial perception. This approach strengthens the model's ability to capture meaningful information while preserving spatial coherence. The addition of the CBAM module after each convolutional block contributes to enhancing the model's performance, especially in image segmentation tasks where the accuracy of representations is crucial. The method allows for the selective integration of attention mechanisms throughout the network, which can be beneficial for the model's prediction quality.

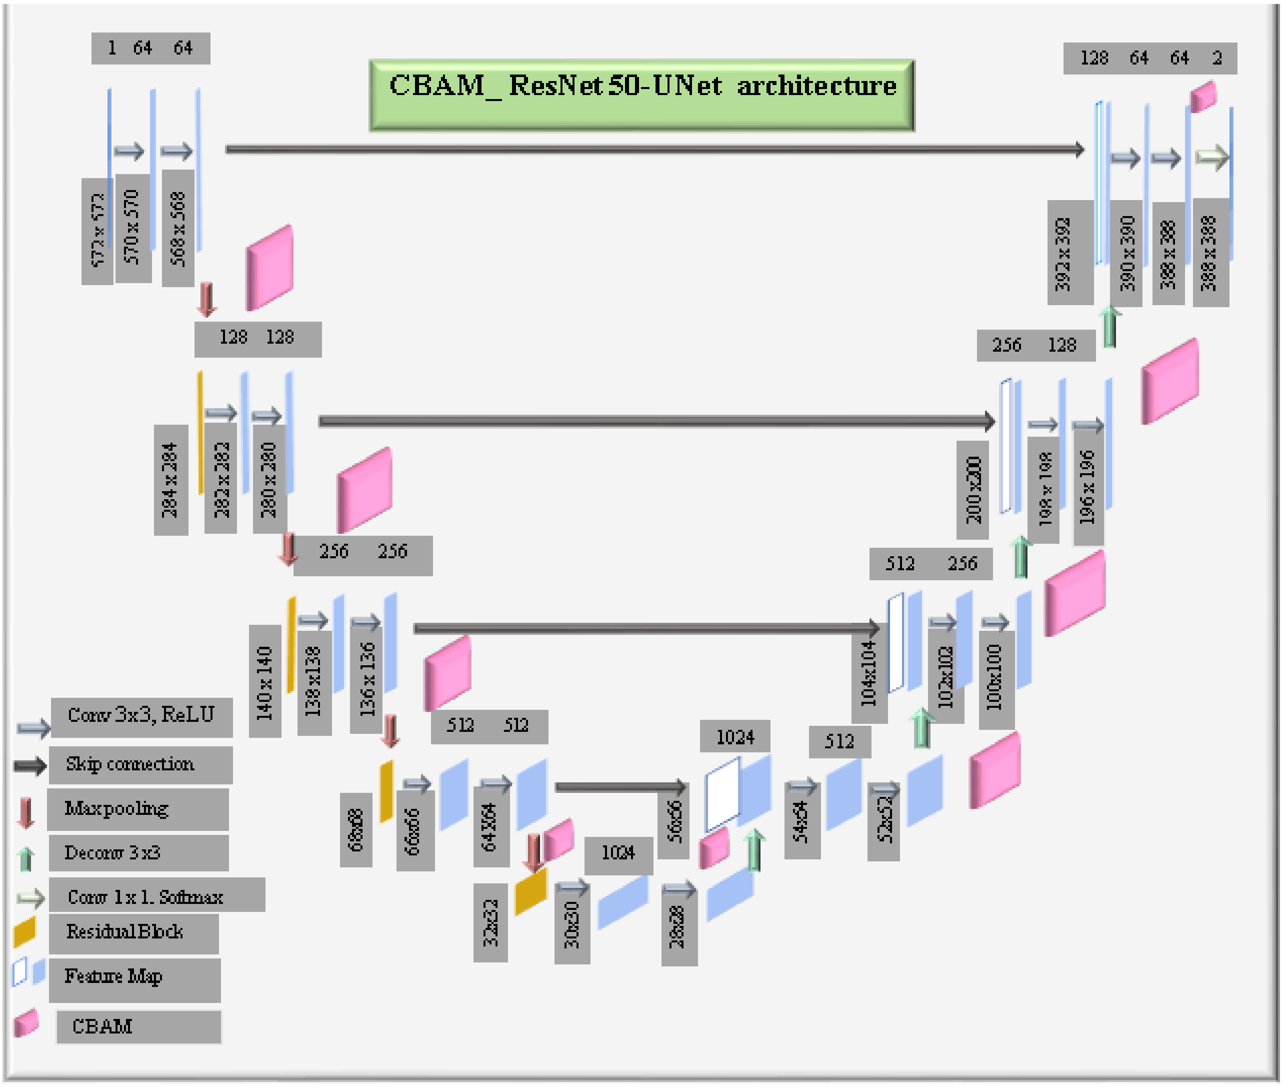

Fig. 5. The detailed architecture of the CBAM ResNet50-Unet model.

V. Experimental Results and Discussion

This section highlights the obtained experimental findings using our model based on CBAM ResNet50-Unet to segment the Ischemic Stroke Lesion tested on the ISLES 2015 MRI images.

A. Implementation Details

The experiments were conducted using the Python language in the Ubuntu environment on a Dell computer equipped with an Intel Core i5 8th generation processor and 8 GB of RAM. The system also featured an NVIDIA GeForce GTX 1050 graphics card with NVIDIA Driver Version 440.59, and the Kaggle framework was utilized. Keras and TensorFlow served as the primary frameworks for implementing the architecture.

To create the optimal model, various variables have been tested and the most effective parameters are chosen. The proposed CBAM ResNet50-UNet architecture was trained with the following parameters: a batch size of 32, 100 epochs, stochastic gradient descent (SGD) optimizer with a learning rate of 0.00001, momentum set to 0.9, and number of epochs of 100. The binary cross-entropy loss function was plotted against the epoch number, and a categorical cross-entropy loss function was also employed.

B. Evaluation Metrics

To assess the efficacy of our approach, the Dice Coefficient (DC) was employed as the primary metric, as well as specificity, sensitivity, precision, and recall. DC quantifies the spatial overlap between the automatically generated segmentation output and the ground truth. Specificity gauges the network's proficiency in predicting healthy tissues, while sensitivity evaluates its ability to identify lesions accurately. Precision, also known as positive predictive value, measures the proportion of relevant outcomes among the predicted positive instances. Accuracy serves as a measure of the overall effectiveness of the proposed approach, capturing the ratio of correct predictions to the total instances. Additionally, recall assesses the model's capability to correctly classify the total

relevant results. This comprehensive set of metrics provides a thorough evaluation of the performance of the proposed approach across various aspects of segmentation quality and predictive accuracy. These metrics are defined as [23]:

$$DC = \frac{2TP}{2TP+FP+FN},$$

$$Accuracy = \frac{TP+FP}{TP+FP+TN+FN},$$

$$Precision = \frac{TP}{TP+FP},$$

where : TP = True Positive , FP = False Positive, FN = False Negative, and TN = True Negative

C. Experimental Results

The proposed hybrid model, CBAM ResNet50-UNet, leverages the advantages of transfer learning with a ResNet50 model to enhance performance, particularly in overcoming the challenges associated with a small dataset. The use of a pretrained ResNet50 model allows for the transfer of knowledge from a large dataset to our specific problem domain, aiding in faster convergence and improved accuracy. Moreover, to further boost the model's capabilities, CBAM is incorporated after each convolutional block. CBAM enhances feature discriminability by capturing both spatial and channel-wise attention. This addition helps the model focus on important features, promoting better segmentation results. UNet being a complex architecture, typically demands a substantial amount of training time, and its performance can be influenced by computer specifications. The integration of CBAM aims to address these challenges, making the proposed hybrid model more efficient in handling segmentation tasks. During experimentation, various scenarios were tested to identify the optimal model based on loss and accuracy metrics. Additionally, we calculated DC, precision, and accuracy values to comprehensively compare the segmentation results of the model with the ground truth values, demonstrating the effectiveness of the proposed approach.

Our proposed approach, CBAM ResNet50-UNet is tested on the ISLES 2015 dataset. Fig. 7 and 8 illustrated an example of prediction outputs and ground truth comparisons for the CBAM ResNet50-Unet model applied to the DWI and T2 sequences. These figures provide a comprehensive visual representation of the model's performance in accurately delineating lesions in each sequence, highlighting the efficacy of our segmentation approach.

Fig. 6 visually presents the performance metrics, including accuracy and loss, to provide a comprehensive evaluation of the proposed method. These curves offer a detailed insight into

how the model evolves over iterations, illustrating its capability to achieve accurate predictions, minimize loss, and optimize segmentation quality, thereby supporting the effectiveness and robustness of our proposed approach.

D. Comparison with State of the Art Studies

Table II compares the proposed model with state-of-the-art models that were trained on the ISLES 2015 dataset. Our CBAM ResNet50-Unet model stands out with a Dice Coefficient of 79.6%, an accuracy of 99.56%, and a precision of 97.12%. These results surpass the performance of numerous state-of-the-art approaches, highlighting the effectiveness of our model in predicting ISL MRI sequence outputs.

E. Discussion

This study presents our new approach CBAM ResNet50-UNet model for the segmentation of medical images, particularly focusing on lesions in the context of ISL segmentation. Through extensive experimentation and evaluation on the ISLES 2015 dataset, our proposed model has demonstrated remarkable performance, outperforming four state-of-the-art models in terms of accuracy, loss, and DC.

The integration of transfer learning with a pre-trained ResNet50 model, coupled with the incorporation of CBAM after each convolution block, has proven to be pivotal in enhancing the model's ability to discern intricate features and optimize segmentation accuracy. The visual representation in Fig. 10 and 9 showcases the model's efficacy in accurately delineating lesions across multiple sequences.

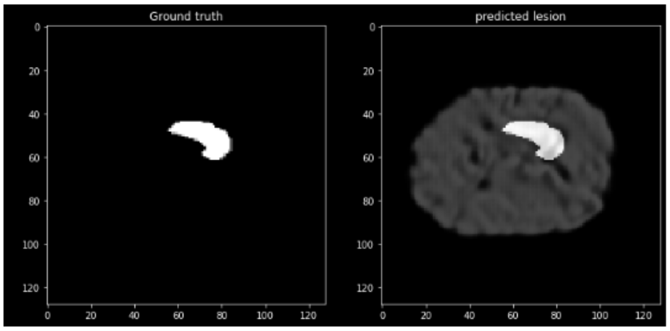

Fig. 9. Example 1 of prediction outputs and ground truth comparisons for the CBAM ResNet50-Unet model.

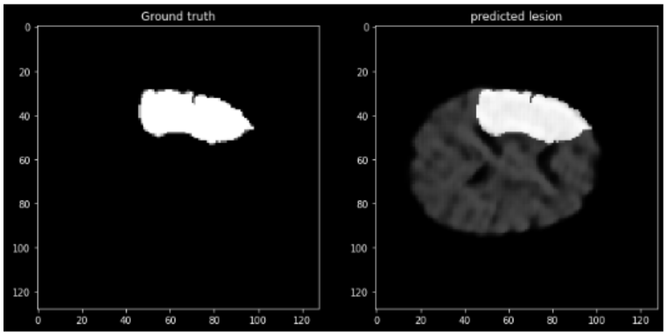

Fig. 10. Example 2 of prediction outputs and ground truth comparisons for the CBAM ResNet50-Unet model.

Moreover, the comprehensive analysis presented in Table II underscores the superiority of our proposed model in comparison to existing approaches. The achieved results not only validate the effectiveness of our methodology but also signify its potential for real-world applications in ischemic stroke lesions detection.

As illustrated in Fig. 11, our proposed CBAM Resnet50-UNet model, when evaluated on the ISLES 2015 dataset, demonstrated notable performance metrics. Specifically, it achieved a Dice coefficient of 79.6 %, an accuracy of 99.6 %, and a precision value of 97.1 %. Comparing these results to existing methods incorporating CRF, 3D CNN, MK-DCNN, UNet with multi-patch network, DRANet, Unet, and Hybrid ResNet50-Unet, our model outperformed them with Dice coefficients of 69 %, 79.1 %, 57 %, 70.7 %, 62.2 %, 76 %, 55.8 %, and 64.1 %, respectively. In terms of accuracy, our model achieved a significantly higher value of 99.9 %, surpassing all previous related works. Notably, Aboudi et al. reported an accuracy of 99.9 % in 2022, whereas their earlier works in the same year recorded values of 99.4 % and 99.7 %. Additionally, while the precision in model [14] reached 98.7 %, our CBAM ResNet50-Unet demonstrated a commendable precision value of 97.1 %

VI. Conclusion

In conclusion, this research paper introduces a novel CAD system for ischemic stroke brain segmentation in MRI sequences, integrating CBAM and a hybrid ResNet50-Unet model. Our motivation stems from the need to enhance both segmentation outcomes and task efficiency. The developed CAD system demonstrates promising results on the multimodal ISLES 2015 dataset, achieving a Dice Coefficient of 79.6% and a precision value of 97.12%. The integration of the CBAM block into the ResNet50-Unet architecture gives our model greater spatial awareness and adaptability to complex anatomical structures, enhances feature selection and extraction, and improves feature representation and segmentation accuracy. These findings contribute significantly to the field of ischemic stroke brain segmentation, laying the foundation for future work in unsupervised segmentation models and further refinement of attention mechanisms within our system.

Optimizing Bandwidth Reservation Decision Time in Vehicular Networks using Batched LSTM

Abdullah Al-khatib[1], Klaus Moessner[2], Holger Timinger[3]
Institute for Data and Process Science, Landshut University of Applied Sciences, Germany[1,3]
Professorship for Communications Engineering, Technical University Chemnitz, Germany[2]

***Abstract*—Time-sensitive and safety-critical networked vehicular applications, such as autonomous driving, require deterministic guaranteed resources. This is achieved through advanced individual bandwidth reservations. The efficient timing of a vehicle decision to place a cost-efficient reservation request is crucial, as vehicles typically lack sufficient information about future bandwidth resource availability and costs. Predicting bandwidth costs often using time-series machine learning models like Long Short-Term Memory (LSTM). However, standard LSTM models typically require longer durations of multiple input data sets to achieve high accuracy. In certain scenarios, quick decisions must be made, even if the vehicle means sacrificing some accuracy. We propose a batched LSTM model to assist vehicles in placing bandwidth reservation requests within a limited data for an upcoming driving path. The model divides data during training to enhance computational efficiency and model performance. We validated our model using historical Amazon price data, providing a real-world scenario for experiment. The results demonstrate that the batched LSTM model not only achieves higher accuracy within a short input data duration but also significantly reduces bandwidth costs by up to 27% compared to traditional time-series machine learning models.**

***Keywords*—Networked vehicular application; time-sensitive networking; network reservation; batched LSTM**

I. Introduction

In recent years, significant efforts have been made by academia and industry to leverage powerful onboard computing resources for applications such as self-driving [1], [2]. These applications are typically computation-intensive, safety-critical, and time-sensitive, requiring immediate action and reaction to ensure safety. However, the limited onboard computing resources of a single vehicle may not be sufficient to handle the demands of these applications. To address this, application data can be offloaded to cloud servers or edge cloud servers via 5G Vehicle-to-Infrastructure (V2I) connections [3], [4]. A prominent challenge is the execution of computation-intensive tasks within strict time constraints, often with a maximum latency threshold of 100 ms $\sim 1s$ [5].

To ensure the essential network resource requirements (i.e., bandwidth) between vehicles and fog/edge networks for safety, a reservation approach is employed. This approach guarantees timely access to scarce bandwidth resources. The conventional approach, network-side reservation [6], [7], [8], involves the MNO allocating bandwidth for various Quality of Service (QoS) classes. However, this approach provides probabilistic rather than deterministic guarantees for individual vehicles accessing network bandwidth. Vehicle-side and individual bandwidth reservation has proven to be a more efficient solution, where vehicles reserve the necessary resources in advance and make reservations based on their specific requirements and resource costs rather than relying on the MNO to allocate resources on their behalf [9], [10], [11], [12], [13]. Another focus of this approach is the economical aspect, which is being minimized by the expenditure for guaranteed access to the network upon reservation.

From the viewpoint of business, MNOs have various traditional pricing options for allocating resources. These involve network service reservation (i.e., subscription) [14] and the Pay-As-You-Go (PAYG) option [15]. However, these pricing strategies may not always effectively manage peak-time and real-time network conditions while ensuring sufficient QoS. Recently, dynamic pricing has emerged as a promising solution for resource management in edge computing [16], [17]. This method dynamically adjusts prices based on network conditions, aiding in managing congestion and ensuring QoS. However, many individual reservation methods overlook dynamic pricing set by MNOs [9], [10], [11], leading to overpriced reservations or insufficient resources.

As a result, vehicles face various challenges, such as the timing of place reservation requests, leading to higher costs or missed opportunities for cost savings in this dynamic environment. Companies like Amazon Web Services (AWS), MTN, China Telecom, and Uninor utilize this method, adjusting prices in response to supply and demand [18], [19], [20]. In a prior study [12], we introduced a concept called a smart request, which is a strategically placed reservation request that allows vehicles to optimize bandwidth costs and mitigate potential risks associated with dynamic pricing and resource unavailability from MNOs. We employed machine learning techniques, specifically LSTM and Transformers, which have proven effective in temporal prediction tasks. However, the conventional LSTM model required a long time interval of input data to achieve high precision, which is not always feasible in some scenarios where vehicles often need to make quick decisions, even if it means sacrificing some accuracy.

To address this, we proposed the batched LSTM model. This model divides data into batches during the training process, which can help improve computational efficiency and model performance. It optimizes the decision time for bandwidth reservation requests within a multiple time interval for predicting bandwidth costs for an upcoming driving path. The major contributions of our article can be summarized as follows:

- We formulate the optimization problem for bandwidth reservation with the primary objective of minimizing the comprehensive cost over a specified time interval.

- We propose a batched LSTM model, which is utilized to optimize decision time by efficiently handling multiple requests concurrently within a short time.
- Through simulations based on the historical dataset of Amazon [18], we show that the proposed model achieves higher accuracy for a given time interval of data and also reduces bandwidth costs compared to traditional models.

The remaining sections of the paper have been arranged as follows: Section II reviews relevant work on cost-effective resource reservation. Section III covers the system model. Section IV provides a formulation for the bandwidth reservation problem. In Section V, we propose to optimize bandwidth reservation decision time and the implementation of the batched LSTM model in this work. In Section VI, we carry out a comparison of the performance of the proposed model with state-of-the-art methods. Section VII concludes the article.

II. Related Work

Many studies have explored problems in resource reservation, focusing on network-side resource reservation in mobile networks[6], [7]. However, few studies have considered the economic implications of vehicle-side reservations with a focus on minimizing resource consumer expenditure. This is becoming a growing area of interest in edge computing [9], [10], [11], [12], [13].

Generally, most studies related to reservation requests mainly put emphasis on the onsite competition [21],[22] or immediate request mode. The main difference between those two types of requests is that in competition requests, users compete for the resource through various game theoretic ways, such as auctions, Stackelberg game, etc. [21], [23], [22]. This results in only a limited number of winners acquiring the resources, leading to a risk of failure for some users and a violation of QoS. Furthermore, onsite requests frequently exhibit volatile pricing and inherent inequity due to the stochastic nature of resource availability and demand. In contrast, immediate requests, as discussed in [10], the authors developed an approach based on meta-learning to assist in reserving resources for computing with the goal of minimizing the cost of using edge services. Zang et al. proposed a smart online reservation framework to minimize the cost of reserving resources for an individual user [9] or multiple users [11]. Based upon their settings, the approaches discussed above for reservations mainly operate on an immediate request basis. As a result of limited resources, the corresponding vehicles need to carry out the schedule reservation well in advance in order to ensure they are able to acquire the necessary resources on time. As a consequence, the immediate requests entail high costs and low guarantees. Planning reservations efficiently is a challenge as users lack knowledge about cost trends and available resources, making it difficult to ensure cost-effectiveness.

Motivated by challenges incurred by competition and immediate requests, an advanced reservation solution [12] has been introduced. This solution enables the advanced reservation of mobility locations at specific time intervals, achieving commendable cost-effectiveness and time efficiency. However, this study lacks an in-depth discussion of the challenges and complexities associated with making reservation decisions within short time intervals. To enhance the reservation decision time, we leverage batched LSTM, which is often more effective for quick decisions with limited data than standard LSTM due to its ability to process multiple input sequences concurrently.

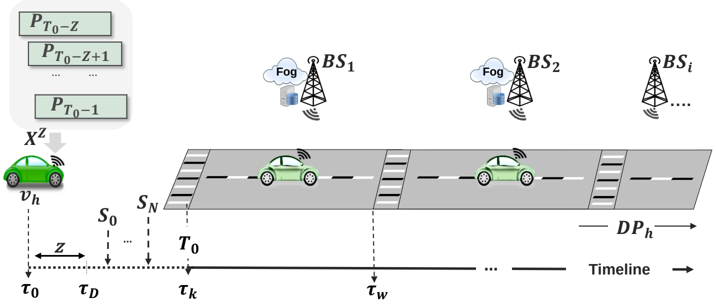

Fig. 1. System model.

III. System Model and Formulation Problem

A. System Model

In this paper, the urban vehicular network is composed of vehicles and Base Stations (BSs), which include Macro Base Stations (MBSs) and Road Side Units (RSUs). The driving path (DP) is partitioned into road segments (RS), each BS associated with a single MNO. This MNO establishes wireless connections between edge routers and participating vehicles within the core network. In each segment of the road, a BS is strategically located (Fig. 1).

In order to meet the strict latency demands of vehicular applications, a Fog/Edge server node is intricately integrated into the infrastructure of each BS. At the initial time τ_0, vehicle v_h $(h = 1, 2, ..., V)$ initiates a reservation request to the MNO for a specific RS along the DP_h. This request provides detailed information about the bandwidth time period Δt_h required to successfully traverse the intended DP_h.

The specified time duration, denoted as Δt_h, is carefully divided into reservation time intervals represented by the range $[\tau_k, \tau_w]$. Each of these intervals corresponds to a specific RS_i, which is entirely covered by a BS_i and the i^{th} road segment. τ_k denotes the entry time into the designated RS_i, while τ_w marks the exit time from that specific RS_i. The determination of these intervals depends on the length of DP_h and the speed of the vehicle v_h, both of which are computed based on data obtained from the navigation system.

Vehicle v_h divides its desired departure interval $[T_0, T_R]$ into $|St|$ small intervals, each representing a discrete time step. For each time step, vehicle v_h requests the cost associated with its designated route DP_h. The resulting list of costs, p_{T_0},..., p_{T_R}, forms a session (S_0). This process is repeated at regular intervals of Δt_{s_v}, up to a maximum of N times, resulting in a sequence of pricing sessions (S_0, S_1,..., S_N), as illustrated in Fig. 1. The session validity time (Δt_{s_v}) is the duration for which the pricing sessions remain valid. This is a predetermined parameter set by the MNO.

B. Formulation Problem

The optimization problem for bandwidth reservation aims to minimize the comprehensive cost associated with reserving bandwidth over the time interval $[\tau_k, \tau_w]$ for all RS_i in D_h. In this approach, the RS_i is transformed into discrete cost areas using a function φ. Each cost area, denoted as A, is associated with a time interval $[\tau_k, \tau_w]$.

$$\varphi : R_+^2 \to R_+^{N \times R} : (\tau_k, \tau_w) \mapsto A \tag{1}$$

where $R = T_R - T_0$ and A is a matrix holding the information about the prices:

$$A = \left[\begin{pmatrix} p_{11} & \cdots & p_{1R} \\ \vdots & \ddots & \vdots \\ p_{N1} & \cdots & p_{NR} \end{pmatrix} \right] \tag{2}$$

This matrix has S_N rows (representing sessions) and T_R columns (representing the desired time departure $[T_0, T_R]$), where $p_{n,r}$ denotes the price corresponding to the n-th session and the r-th desired departure time. The θ function is utilized to establish a relationship between a designated area A and its comprehensive reservation cost:

$$\theta : R_+^{N \times R} \to R_+ \tag{3}$$

Additionally, the function $\omega = \theta \circ \varphi$, where θ and φ are distinct functions, is used to map:

$$\omega : R_+^2 \to R_+ \tag{4}$$

Ultimately, the objective function J is formulated as follows:

$$J = \sum_{\tau_k, \tau_w} \omega(\tau_k, \tau_w) \tag{5}$$

The sum operates over all pairs (τ_k, τ_w) of start and end times. The function ω assigns these time intervals to an overall reservation cost based on the previously defined composite function, incorporating both φ and θ. The objective is to minimize this overarching objective function.

$$\min_{\tau_k, \tau_w} J(\tau_k, \tau_w) \tag{6}$$

The implementation of an optimization technique requires a sophisticated prediction model for accurate decision-making. The process begins with a proficient time-series model, ensuring high prediction accuracy. This forms the basis for effectively applying the optimization technique, using the insights from the prediction model to guide decisions. The model uses historical average prices, X^Z, from the interval $[T_0 - Z, T_0 - 1]$ (as per Eq. 7) to predict the price at time t. Here, Z is the number of time steps before the first price request (τ_D). Optimal Z values can be found by searching for a δt that yields satisfactory accuracy. Hence, the prediction model can be expressed as:

$$(\widehat{x}_{Z+1} = f\left(X^Z; \theta\right)) \tag{7}$$

where,

$$X^Z = [P_{T_0 - Z},\ P_{T_0 - Z + 1},\ \cdots\ P_{T_0 - 1}]$$

f is the model with trainable parameters θ, which returns the expected future price, $\widehat{P}_{T_0}$, for reserving in the following t time steps. The expected price $\widehat{P}_{T_0}$ is then pushed into X^Z, forming a constant size buffer as follows: $X^Z = \left[P_{T_0 - Z + 1}\ \cdots\ \widehat{P}_{T_0}\right]$. Subsequently, the value $\widehat{P}_{T_0+1}$ is obtained by repeating the process of predicting and updating the buffer. This process continues until the expected future price $\widehat{P}_{T_R}$ is obtained, as shown in Fig. 2. The method for finding the minimum expected price is as follows:

$$(\widetilde{p} = min(\widehat{P}_{T_0},\ \widehat{P}_{T_0+1},\ \cdots\ \widehat{P}_{T_R})) \tag{8}$$

In order to calculate the optimal reservation time, we introduce the concept of a decision threshold function, denoted as DE. This function uses the output (the expected minimum future price) to advise a vehicle on its reservation strategy. Specifically, it determines whether the vehicle should reserve at the minimum price in the current session (reserve) or consider postponing the reservation by requesting a new session (wait). The decision action is computed using Eq. (9):

$$DE = \begin{cases} reserve: & \widetilde{p}_{S_n} \leq \widetilde{p} - \varepsilon(n) \\ wait: & \text{otherwise} \end{cases} \tag{9}$$

where,

$$\varepsilon(n) = \frac{c}{n}\ ,\ n \in [1,\ N]$$

In our model, N represents the maximum number of sessions that can be requested. The hyper-parameter c should be tuned to maximize benefits. The expected minimum future price, denoted as $\widetilde{p}$, is derived from Eq. (8). Our model anticipates session prices for the time interval $[T_0, T_R]$. The term $\widetilde{p}_{S_n}$ represents the lowest price at the current requested session, which includes prices $\widetilde{p}^{S_n}_{T_0}, \widetilde{p}^{S_n}_{T_0+1}, \ldots, \widetilde{p}^{S_n}_{T_R}$ in the time interval $[T_0, T_R]$. This is defined in Equation (10):

$$(\widetilde{p}_{S_n} = min(\widetilde{p}^{S_n}_{T_0},\ \widetilde{p}^{S_n}_{T_0+1},\ \ \cdots\ \widetilde{p}^{S_n}_{T_R})) \tag{10}$$

The proposed model suggests the optimal reservation time for the vehicle by returning the time associated with the lowest price. The steps of this algorithm are detailed in Algorithm 1. In the context of Formula 9, determining the optimal risk level is of substantial importance. This is because the proposed strategy aims to minimize overall costs while reducing the risk of rejecting valid sessions. The goal is to find an optimal balance that maximizes efficiency and minimizes negative outcomes. This strategy is based on the concept that the risk is lower at the beginning, but as the maximum number of sessions is approached, the risk begins to increase. The

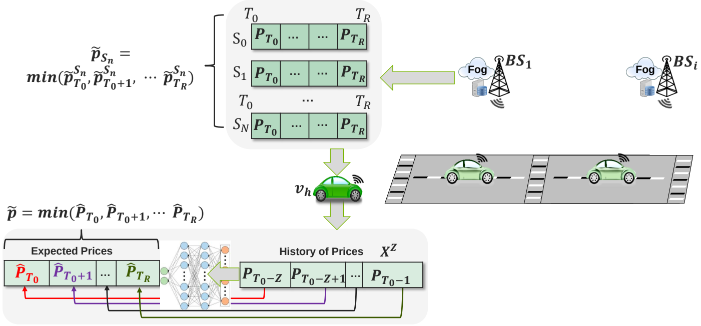

Fig. 2. Prediction model bandwidth reservation request timing.

decision function uses $\varepsilon(n)$ because the model predicts the expected price of reserving in the next time step δt, not the minimum price. Statistically, if the vehicle waits, it will receive a price that is at least equal to the expected price. However, there is a high chance of getting a lower price, and the amount of reduction depends on the variance in the prices. Therefore, the constant c should be proportional to the variance in the prices of DP_h. As the value of N is approached, $\varepsilon(n)$ should decrease. Here, N represents the maximum number of sessions that can be requested per time step δt, which is determined by the MNO. The value of $\varepsilon(n)$ also depends on the time the vehicle started searching for the minimum price prior to takeoff.

In our model, the constant c is crucial. Its optimal values are determined empirically, balancing cost savings and risk reduction. The choice of c also prevents failing to reserve resources due to reaching the maximum number of sessions. Further investigation of these values is conducted in our experiments.

IV. Bandwidth Reservation Decision Time

First, a brief overview of the approach is provided. Following that, appropriate time series prediction models are selected and applied. This enables vehicles to reserve bandwidth on a specific future path at a designated time, thereby minimizing costs. Subsequently, the prediction model, which utilizes the batched LSTM algorithm, is explained in detail.

A. *Overview on the Proposed Approach*

From the vehicle's perspective, the challenge lies in efficiently timing decisions for bandwidth reservation requests due to insufficient future price prediction data. The proposed approach involves vehicle v_h dividing its desired departure interval $[T_0, T_R]$ into Q small δt intervals. It then requests the cost for each area A of DP_h at each future time.

The proposed method uses a time-series deep neural network to predict future costs and continues to request pricing sessions until the minimum price surpasses a dynamic threshold. This threshold, determined by a parameter c, adjusts with each new session to balance risk. The prediction model, trained on models like LSTM and Transformers, leverages recurrent load patterns along DP_h. Despite the high computational cost of training, it's infrequent and can be offloaded to an external server for efficient onboard cost prediction. Retraining is only necessary if major road events significantly alter local traffic.

B. *Machine Learning Model*

In this section, the details of the primary families of candidate time-series deep neural network models (LSTM, batched LSTM, and Mix) are explored to assess their suitability for the prediction task.

1) LSTM: The LSTM model is the classical LSTM architecture without batches. LSTM is an artificial recurrent neural network (RNN) architecture extensively used for sequence modeling and prediction tasks. LSTM networks excel at handling problems where inputs possess long-term dependencies or temporal relationships. Traditional RNNs are susceptible to the "vanishing gradient" problem, which impedes their ability to capture extended dependencies in sequences. LSTM networks tackle this challenge by introducing memory cells and gating mechanisms that control the information flow within the network. The key components of an LSTM network are:

- Cell State: It serves as the memory of the network and is responsible for capturing long-term dependencies. The cell state C can selectively forget or store information using gate units.
- Forget Gate: It decides which information in the cell state should be forgotten or discarded. In the time step t, the decision is made using a sigmoid function σ of the current input vector x_t and the current hidden state h_t. The output, called f_t, is a weight value between 0 and 1: 0 means "let nothing through", 1 means "let everything through".
- Input Gate: It determines which information from the input should be stored in the cell state. In the time step t, using always a sigmoid function σ, it is decided which values will be updated (i_t). A tahn layer creates a vector of new candidate values $\tilde{C}_t$ and, combing i_t with $\tilde{C}_t$, an update C_t is created.
- Output Gate: It controls the output of the LSTM unit and determines what information should be output based on the current input and the previous cell state. In time step t, a sigmoid layer decides what parts of the cell state will go to output. This part is called o_t. The output h_t is obtained by multiplying o_t with the cell state C_t transformed by the $tanh$ function. The formulas outlined within it are:

$$f_t = \sigma(W_f(h_{t-1}, x_t) + b_f) \tag{11}$$

$$i_t = \sigma(W_i(h_{t-1}, x_t) + b_i) \tag{12}$$

$$\tilde{C}_t = tanh(W_C(h_{t-1}, x_t) + b_C) \tag{13}$$

$$C_t = f_t C_t + i_t \tilde{C}_t \tag{14}$$

$$o_t = \sigma(W_o(h_{t-1}, x_t) + b_o) \tag{15}$$

$$h_t = o_t tanh(C_t) \tag{16}$$

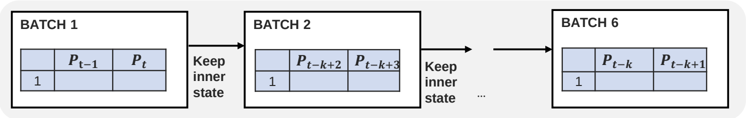

Fig. 3. Structure of batch step

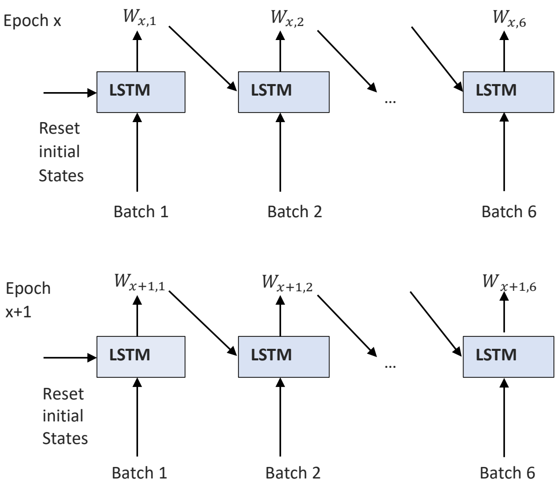

Fig. 4. The structure of a stacked batched LSTM network.

2) Batched LSTM: Batched LSTM is an LSTM model with batches. In LSTM networks, the data is typically processed in batches during training and inference. Let's discuss LSTM with different batches:

- Batch Processing: In LSTM, batch processing refers to dividing the input data into multiple batches. Each batch consists of a subset of the training or test dataset. Batch processing offers several benefits, including improved computational efficiency, parallel processing, and better generalization.
- Variable Batch Sizes: LSTM networks can handle variable batch sizes. It means that each batch can have a different number of sequences or time steps. This flexibility allows for processing sequences of varying lengths within the same batch, which is particularly useful when working with time series data of different lengths.
- Training with Different Batch Sizes: During training, LSTM networks are typically trained on multiple batches, where each batch contains a fixed number of sequences or time steps. The batch size can be chosen based on factors such as computational resources, memory constraints, and the specific characteristics of the dataset. Common batch sizes range from a few samples to several hundreds or even thousands.
- Impact on Training: The choice of batch size can influence the training process. Smaller batch sizes provide more frequent weight updates, which can lead to faster convergence but may result in noisy gradients due to a smaller sample size. Larger batch sizes, on the other hand, offer better gradient estimation but may slow down the training process and require more memory.
- Testing and Inference with Batches: During testing or inference, LSTM networks can process input data in batches as well. This allows for efficient evaluation of multiple samples simultaneously. The batch size for testing can be different from the batch size used during training.
- Handling Remaining Data: When the total number of samples is not divisible by the chosen batch size, there may be a smaller ”remainder” batch at the end of each epoch. Some approaches include discarding the remaining data, padding it to match the batch size, or using dynamic batching techniques that can handle variable batch sizes more gracefully.

Overall, LSTM networks can handle different batch sizes, allowing for efficient processing of time series data in parallel. The choice of batch size depends on various factors, such as computational resources, memory constraints, and the characteristics of the dataset. Careful consideration should be given to selecting an appropriate batch size to balance computational efficiency and model performance. Two types of LSTM with batches exist:

- Stateless batches LSTM: In a stateless LSTM with batches, the internal states of the LSTM cells are reset at the beginning of each batch. This means that the LSTM does not retain any memory of the previous batch when processing the next batch. The LSTM treats each batch as an independent entity.
- Stateful LSTM with batches: In a stateful LSTM with batches, the internal states of the LSTM cells are preserved between batches. The LSTM maintains the hidden states and memory states from the previous batch and uses them as the initial states for processing the next batch. The LSTM carries information from one batch to another within a sequence.

Stateless LSTM with batches is suitable for independent sequences, while stateful LSTM with batches is useful for capturing sequential dependencies and handling variable-length sequences within a batch. For this reason, batched LSTM is a stateful model.

The structure of LSTM with 6 batches is similar to that of LSTM, but the parts of the batches are described in Fig. 3 and 4. While in LSTM in each epoch, only 1 set W is obtained, in batched LSTM in each epoch, 6 sets W are obtained. During each epoch, both LSTM models update their internal parameters (weights and biases) based on the training data and the computed gradients. This parameter update aims to minimize the difference between the model's predictions and the actual targets, effectively improving the model's ability to capture patterns and make accurate predictions. The relationship between different epochs is that each epoch builds upon the progress made by the previous epochs. As the training progresses through multiple epochs, the model's performance typically improves, and the learned representations become more refined. However, it's important to note that the relationship between epochs is not strictly linear or guaranteed to continually improve.

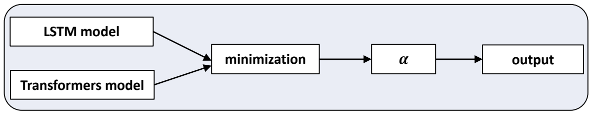

Fig. 5. Structure of mix model.

3) Mixed model: The mixed model, where transformers [24] and LSTMs are run separately, is considered. The key components of a mixed model are:

- Transformer Model: Start by training a transformer model on the time series data. The transformer model captures global dependencies and long-range patterns effectively by utilizing self-attention mechanisms.
- LSTM Model: Train a separate LSTM model on the same time series data. The LSTM model focuses on capturing local dependencies and temporal patterns within the time series.
- Prediction Combination: Once both the transformer and LSTM models are trained, combine their predictions to obtain the final output. This combination is a weighted average, where the weights are calculated to minimize the MSE of the prediction.

Overall, this mixed model combining transformer and LSTM models separately provides a way to leverage the strengths of each architecture and capture both global and local dependencies in the time series. However, it comes with increased complexity and potential challenges in integrating the two models effectively. The structure of the Mix model is described in Fig. 5.

C. Prediction Model Algorithm with Batched LSTM

The algorithm presented is a predictive model that employs a batched LSTM technique to forecast future prices within a time series. Its main goal is to estimate the upcoming price ($\hat{P}_{T_0+1}$), determine the minimum expected price ($\widetilde{p}$) over a specified time interval, and make a decision based on a predefined criterion. To initiate the process, the algorithm takes into account the average prices (X^Z) within a specified time range, namely $[T_0 - Z, T_0 - 1]$. It requires certain parameters, Z, and operates on a model with trainable parameters (θ). The algorithm unfolds in multiple steps. Step 1 represents the initialization and the model training. The algorithm commences by initializing the sequence of average prices (X^Z) and configuring a batched LSTM model with parameters (θ). A crucial step involves defining a batch size, and subsequently, X^Z is reshaped into batches for streamlined processing. The training of the model takes place within a loop, persisting until the successful prediction of $\hat{P}_{T_0+1}$. This training iteration involves updating the LSTM with batches, and the trainable parameters (θ) undergo adjustments as dictated by the model's training procedure. Simultaneously, X^Z is continually updated to incorporate the newly predicted values. The steps from 11 to 18 represent the decision making. Moving forward, the algorithm proceeds to calculate the minimum expected price ($\widetilde{p}$) over the predefined time interval. The decision-making process ensues, determining whether to reserve or wait. This decision hinges on a condition integrating $\widetilde{p}_{S_n}$ and a decreasing function $\epsilon(n)$. The culmination of this phase involves the algorithm providing as output the determined minimum expected price ($\widetilde{p}$) and the corresponding time. Utilizing LSTM for time series prediction ensures the algorithm's ability to capture intricate temporal dependencies. The incorporation of batch processing in the model training phase enhances computational efficiency. Decision making involves a dynamic strategy, employing a threshold ($\epsilon(n)$) and the minimum expected price, guiding the choice between reserving or waiting.

Algorithm 1 Prediction Model Algorithm with Batched LSTM

Input:

- Average prices, X^Z, between time interval $[T_0 - Z, T_0 - 1]$
- Parameters Z
- Model with trainable parameters θ

Output:

- Expected future price, $\widehat{P}_{T_0+1}$, of reserving in the following t
- Minimum expected price, $\widetilde{p}$, for the time interval $[T_0, T_R]$
- Time associated with the lowest price

```
1: procedure PREDICTION MODEL BATCHED LSTM($X^Z, Z, \theta$)
2:     $X^Z \leftarrow [P_{T_0-Z}, P_{T_0-Z+1}, ..., P_{T_0-1}]$
3:     Initialize batched LSTM model with parameters $\theta$
4:     $batch\_size \leftarrow b$                ▷ Set your desired batch size
5:     $X^Z\_batches \leftarrow$ reshape_into_batches($X^Z, batch\_size$)
6:     while $\widehat{P}_{T_0+1}$ not obtained do
7:         for $batch$ in $X^Z\_batches$ do
8:             $\widehat{P}_{T_0+1} \leftarrow$ LSTM_Model($\theta, batch$)
9:             Update $\theta$ using the model's training procedure
10:            $X^Z \leftarrow [P_{T_0-Z+2}, ..., \widehat{P}_{T_0+1}]$
11:        end for
12:    end while
13:    $\widetilde{p} \leftarrow \min(\widehat{P}_{T_0}, \widehat{P}_{T_0+1}, ..., \widehat{P}_{T_R})$
14:    if $\widetilde{p}_{S_n} \leq \widetilde{p} - \varepsilon(n)$ then
15:        $DE \leftarrow$ "reserve"

18:    end if
19:    $\varepsilon(n) \leftarrow \frac{c}{n}$ for $n \in [1, N]$
20:    $\widetilde{p}_{S_n} \leftarrow \min(\widetilde{p}^{S_n}_{T_0}, \widetilde{p}^{S_n}_{T_0+1}, ..., \widetilde{p}^{S_n}_{T_R})$
21:    Return $\widetilde{p}$ and associated time
22: end procedure
```

V. Performance Evaluation

A. Dataset Description

To assess the effectiveness of our methodology, we utilized a historical dataset of Amazon spot prices, which are subject to fluctuations influenced by factors such as capacity, demand, geographic location, and specific instance types [18]. Given the time-sensitive nature of various applications, vehicles require both computing instances and communication links, i.e., bandwidth. Our assumptions are that the pricing for setting up computing and communication resources aligns with the Amazon spot pricing model, as previously referenced in [11],

[9]. For this study, we collected pricing data from all available instances and two specific regions, namely us-west-1b and us-west-1c. This data was collected from April 17, 2021, to May 2, 2021, for training purposes, and from May 3, 2021, to May 8, 2021, for the testing phase of the model.

B. Experimental Results

In this section, the experimental results of the study are presented, encompassing model evaluation and metrics, a comparison of prediction errors among different models, an analysis of the level of risk, and the performance evaluation of cost. The study includes four models: LSTM, batched LSTM, Transformers, and Mix. The experiments were conducted using the PyTorch framework in Python and trained on an NVIDIA GeForce RTX 2080 Ti GPU.

1) Model evaluation and metrics: Mean Absolute Percentage Error (MAPE), Mean Absolute Error (MAE), and Root Mean Squared Error (RMSE) are three commonly used metrics for evaluating the performance of prediction models and assessing their forecasting accuracy. These metrics provide valuable insights into the effectiveness and reliability of the models in capturing the underlying patterns and making accurate predictions.

Table I presents a comparison of the time consumption among four models, measured in seconds. Batched LSTM and Transformer models demonstrate significantly shorter processing times compared to LSTM and the mix model, thanks to their ability to leverage parallel processing. It is noteworthy that the mix model is the most time-consuming, which is a recognized drawback of this particular approach due to its hybrid nature. Additionally, the table includes a comparison of the time taken for a single forward pass among the three models. Batched LSTM takes advantage of parallel processing by batching sequences together, resulting in improved performance during a forward pass. This parallelization allows for more efficient utilization of hardware resources like GPUs, enabling batched LSTM to achieve faster forward pass times compared to processing each sequence individually, as in LSTM. Transformers are known for their exceptional parallel processing capabilities. By employing self-attention mechanisms, Transformers can simultaneously process all positions in the input sequence, enabling parallelization across different positions. Consequently, Transformers achieve fast forward pass times, especially for long sequences. Interestingly, Transformers and batched LSTM show similar forward pass times, which is advantageous for resource-constrained environments like vehicles, where computational resources are limited and model training need not be performed onboard. The mix model is not considered in this comparison due to its hybrid nature, which makes it challenging to fit into the batch processing paradigm. As a result, the focus is on analyzing the performance of models that fully embrace parallel processing for more efficient and faster computations. In addition, the parameters settings of models are as shown in Table II.

TABLE I. Time Consumption of Training Per Epoch and Per Single Forward Pass Time on the Amazon Spot Pricing Dataset

Training Time per epoch [s]				Time Single Forward-Pass [ms]		
LSTM	Tranf.	Mix	B.LSTM	LSTM	Tranf.	B.LSTM
0.034	0.025	0.188	0.025	2.412	1.889	1.886

TABLE II. Parameters Settings

Model	Layer	Hidden layers	Dropout percentage
LSTM	1	100	
Transformers	2	10	0.2
Mix model	3	110	0.2
Batched LSTM	1	100	

2) Model prediction error comparison: In this section, the error analysis provides valuable insights into the strengths and weaknesses of each model in capturing different aspects of prediction accuracy. The three error metrics, MAE, MAPE, and RMSE, play distinct roles in assessing prediction accuracy. MAE emphasizes the magnitude of errors; MAPE provides a relative measure of the prediction error as a percentage; and RMSE takes both the magnitude and direction of errors into account, giving more weight to larger errors. The choice of which metric to use depends on the specific context and requirements of the problem at hand. Based on these metrics, the batched LSTM model emerges as the top performer, achieving a lower error rate as demonstrated in Fig. 6. However, for a more comprehensive evaluation, the errors of other models are compared as well. At epoch 140, the Transformers and Mix models show similar errors to the LSTM model when considering MAE and RMSE. On the other hand, taking MAPE into account, the LSTM model exhibits a smaller error compared to Transformers and Mix, though still higher than the Batched model. The lower error rate with MAPE for the LSTM model can be attributed to its effective handling of outliers, as MAPE is less influenced by extreme values compared to RMSE and MAE. Consequently, the LSTM model demonstrates superior robustness in producing predictions when faced with extreme data points.

Fig. 7 clearly shows that the accuracy of the model improves with a longer time interval provided as input. The length of time (in the analyzed case, an hour) that the vehicle has to determine the input's duration directly affects the model's accuracy, with longer input intervals leading to better performance and a lower MAE. Consistently, the LSTM models outperform the Transformer model. They demonstrate better performance in capturing temporal dependencies and patterns in the time series data, consistently yielding lower MAE values compared to the Transformer model across different input matrix lengths. This indicates that the LSTM models are more effective in modeling the sequential nature and capturing relevant information for accurate predictions.

On the other hand, the Transformer model benefits from longer sequences, exhibiting a larger reduction in MAE as the length of the input matrix increases. Although the Transformer model has a higher MAE than the LSTM models at all input lengths, it shows a more significant reduction in MAE with longer sequences. This suggests that the Transformer model can leverage the additional information present in longer sequences to learn more complex patterns. While the MAE remains higher than that of the LSTM models, the relative improvement in performance for the Transformer model is substantial. Based on these observations, it can be concluded that the LSTM models consistently outperform the Transformer model in terms of MAE. The LSTM models'

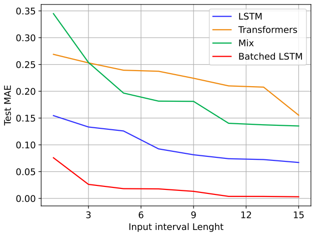

Fig. 7. Input request price time interval.

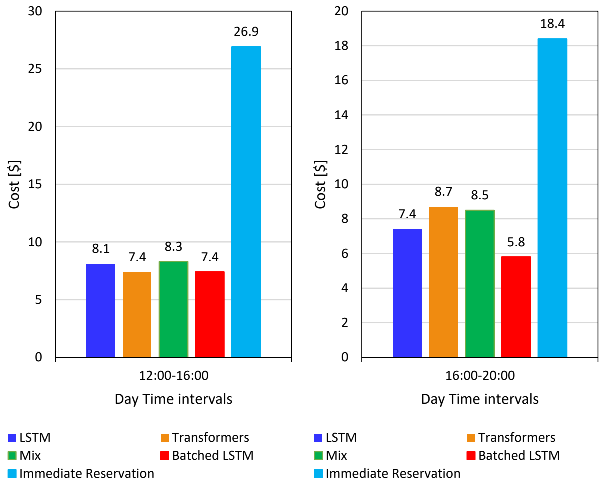
ability to model sequential dependencies and capture relevant information gives them an advantage over the Transformer model. However, the Transformer model shows promise in handling longer sequences and exhibits a larger reduction in MAE, indicating its potential for capturing more complex patterns and dependencies. In the context of the mix model, if either the transformer or LSTM model poorly estimates the true price, the decision threshold step in the bandwidth cost problem may lead to worse performance of the mix model compared to both the transformer and LSTM models, even if it outperforms them in the estimation step.

Finally, the batched LSTM outperforms the standard LSTM due to its consideration of batches, enabling it to produce more generalized results. LSTM models trained with batches tend to exhibit improved generalization performance. By exposing the model to multiple sequences within each batch, it gains exposure to a diverse range of patterns and can capture broader temporal dependencies. This increased variety of examples enhances the model's ability to make predictions on unseen data, resulting in improved generalization and more accurate forecasts, even with shorter input to the model. As observed in Fig. 7, the vehicle only needs a small number of hours (i.e., 1-3 hours) as input to the model to achieve better and more accurate predictions of bandwidth cost. This indicates that the model's performance remains consistent even with limited input, closely resembling real-world scenarios. The advantage of using a shorter input interval is that the vehicle does not need to wait for an extended period to find the best price for bandwidth.

3) Level of risk analysis: The analysis of risk levels among different models sheds light on their precision and helps identify the best c values for optimizing prediction accuracy. When comparing the optimal value of risk achieved by various models in Fig. 8, the batched LSTM demonstrates the lowest value of c, indicating higher precision, while Transformers exhibit the highest value of c. It's important to note that as c increases, precision decreases. For instance, when $\tilde{p}^{S_n} = 1$ and $\tilde{p}$ equals 1.1, the algorithm reserves with a c of 0, whereas a c of 0.2 would prompt the algorithm to wait wrongly. Consequently, batched LSTM, being the most precise algorithm, has the lowest MAE associated with the smallest c, and the change in MAE associated with varying c is minimal. However, all the best c are very small.

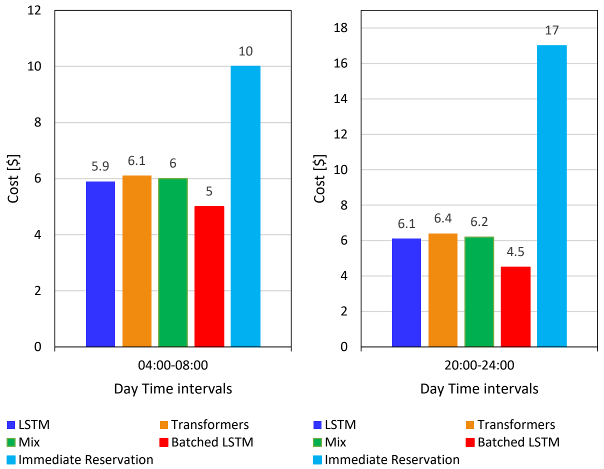
4) Cost performance: In this subsection, a comprehensive evaluation of the cost performance of the prediction models is conducted by comparing them with the benchmark immediate reservation request scheme. Three distinct benchmark scenarios are explored, each characterized by different time intervals during which the vehicle searches for the most cost-effective option. As mentioned earlier, the time interval represents the desired departure time for the vehicle. Furthermore, time steps are utilized to divide the aforementioned time interval into smaller segments, such as hours or half-hours.



(a)

(b)

Fig. 9. Comparison of cost performance across benchmark with time intervals $[T_0\ , T_R\ ] = 4$ hr and time steps $\delta t = 1$ hr.



(a)

(b)

Fig. 10. Comparison of cost performance across benchmark with time intervals $[T_0\ , T_R\ ] = 4$ hr and time steps $\delta t = 0.5$ hr.

Subsequently, the total cost is calculated by determining the number of BSs that the vehicle reserves along its driving path to reach the final destination. The calculation enables an effective assessment of the performance of prediction models in comparison to the established benchmark. The analysis of cost performance highlights the effectiveness of the proposed method in securing reservations at lower prices. Fig. 9 and Fig. 10 illustrate the comparison between the costs of various approaches and immediate reservations. In all cases, the prediction methods derived from the different approaches outperform the immediate reservation scheme in obtaining a better price. This is due to the fact that the proposed approach identifies the optimal price, which may differ significantly from the immediate reservation price.

Among the estimation methods, batched LSTM exhibits the smallest Mean Absolute Error (MAE), resulting in an estimated value that closely approximates the true best price, deviating distinctly from the immediate price. Nevertheless, all four estimation methods capture this difference, making the proposed method valuable for securing reservations at lower prices.

Comparing Fig. 9 with Fig. 10, it is evident that as the time steps (δt) increase from 0.5 hr to 1 hr, the price of immediate reservations may rise, while the cost savings from employing the proposed approach increase. For example, comparing the savings obtained using the estimated price from batched LSTM with the immediate reservation for the interval 12.00-16.00, the saving is 72.49% for 1 hr (Fig. 9.a) and time interval 20.00-24.00 for 0.5 hr (Fig. 10.b) is 73.52%.

VI. Conclusions

In conclusion, this research effectively addresses the challenges in decision time for bandwidth reservation, particularly within the context of safety-critical vehicular applications. The paper introduces an optimized approach using batched LSTM to predict bandwidth costs within a short duration. By organizing data into batches during the training phase, the model enhances both computational efficiency and prediction accuracy. This approach has proven highly effective, through the utilization of real price data, resulting in significant cost reductions by 27% compared to traditional time-series machine learning models, as we have provided in the experimental results. In future work, we aim to explore dynamic BS ranges and varying MNO numbers for more realistic and intelligent reservation request strategies.

***Abstract*—This research investigates the problem of assigning pre-scheduled trips to multiple drones to collect hazardous waste from different sites in the minimum time. Each drone is subject to essential restrictions: maximum flying capacity and recharge operation. The goal is to assign the trips to the drones so that the waste is collected in the minimum time. This is done if the total flying time is equally distributed among the drones. An algorithm was developed to solve the problem. The algorithm is based on two main ideas: sort the trips according to a given priority rule and assign the current trip to the first available drone. Three different priority rules have been tested: Shortest Flying Time, Longest Flying Time, and Median Flying Time. Two recharging conditions are maintained: recharging needed time and recharging full duration. By applying each priority rule and each recharging condition, we generate a six versions of the algorithm. The six versions of the proposed algorithm were implemented in Java programming language.The results were analyzed and compared proving that the Longest Flying Time priority rule surpasses the other two rules. Moreover, recharging a drone just enough for taking the next trip proved to be better than fully recharging it.**

***Keywords*—Drones; trip assignment; priority rules; flying capacity; load balance**

I. Introduction

The Vehicle Routing Problem (VRP) is an important problem discussing the process of finding the optimal routes for a single or multiple vehicles, to perform a certain task or service. VRPs have been extended for numerous of problems. Most recently, VRPs using a single or multiple drones also called Unmanned Aerial Vehicles (UAVs) have spread widely. Those varied to truck-drone, truck-multi-drone, and multi-truck-multi-drone problems to achieve precise goals and maintaining a set of constraints. The author in [1] presented the vehicle routing problem with drones (VRPD) as a design of the combination of truck-drone routes and timetables to serve a group of customers with specific requirements and time limitations. The applications of VRPD or as called, Drone Routing Problems (DRPs) received a massive amount of attention from different fields and concerned parties. Media has shown interest in drones equipped with cameras to cover stories in different areas [2], commerce companies have been intrigued with last-Mile delivery using UAVs for speeding the process and lowering shipping costs [3], scientists for great discoveries [4], medical staff for urgent transportation of equipment [5], program developers and even the entertainment sector for mesmerizing drones shows. Environmentalists have utilized drones for addressing great problems threatening our earth, affecting humans and all living creatures [6]. Specialized VRPs regarding critical environmental issues such as CO2e emission, air pollution and global warming are called Green Vehicle Routing Problems (G-VRPs). Hazardous waste is another serious problem that puts us in danger by the minute. Taking advantage of the VRPD and G-VRP, our study highlights the formation of a hazardous waste collection plan, where waste is collected in the minimum time possible using multiple drones (MTMD). The authors in [7] proved the strongly NP-hardness of the problem and proposed a 2-phase approach and a linear program to solve it using a single Unmanned Aerial Vehicle. In their research, a set of efficient trips have been produced for each solved instance. Each trip is a path that starts from a depot site, visits some other sites to collect the maximum waste in the minimum time, respecting the drone flying and waste capacities before returning back to the depot for charging and some minor maintenance. In the current research, we adopt those datasets of generated trips and extend the study using multiple drones. The motivation behind this research was mainly to propose efficient algorithms that will allow an optimal or near-optimal use of the flying and weight capacities of a fleet of drones in order to collect hazardous waste in a shortest time from many sites. This research studies a new Drone Routing Problem (DRP) using m drones. Constraints related to the flying capacity and recharge duration of each drone are set. The aim of the study is to assign pre-generated tours in [7] so that completion time of the last drone is minimum. To solve this problem, the authors proposed priority rules-based algorithm. These rules have the purpose of sorting the trips prior distribution among the drones. The algorithm allows a maximum use of each drone's charge without exceeding the flying capacity. An experimental study using benchmarks was conducted to compare the efficiency of the proposed algorithm for each priority rule.

The remaining of the paper is structured as follows. In Section II, the literature review highlights the related and relevant areas of the research. The methodology used for conducting the research is detailed in Section III. Next, the experimental results and discussion are explained in Section IV followed by the conclusion and future work.

II. Literature Review

New Vehicle Routing Problems (VRPs) studies have been intensively emerging in the last few decades, especially those using Unmanned Aerial Vehicles (UAVs). The author in [8] acknowledged that the interest in the use of drones in various applications has grown significantly in recent years. Accompanied with specific constraints, limitations and several goals, VRPs are becoming progressively challenging. Most commonly, Different approaches to solve Drone Routing Problems (DRPs) have been proposed for last-Mile delivery. Moreover, transportation of medical equipment as in [9], collection of waste, surveillance, search and rescue missions and even forest monitoring to detect fire as presented in [10]. The author in [11] stated that similar to the traditional vehicle routing problem, the vehicle routing problem with drones (VRPD) involves the use of drones in addition to trucks for delivery. When trucks and drones are routed together, the challenge is substantially more complex and distinct from traditional vehicle routing problems.

Most DRPs were organized to truck-drone routing problems, as [12] demonstrated how incorporating truck-drone tandems into transportation systems can enhance delivery speed while also allowing the fleet size to be reduced without impacting delivery times or adding to truck drivers' workload. The author in [13] presented and solved a truck-drone hybrid routing problem with time-dependent road travel time (TDHRP-TDRTT) to resolve the truck-drone cooperative issue. TDHRP-TDRTT was solved using an iterative local search heuristic method. Whereas, in [14], they thought of several drones, each with a different set of capabilities, such as speed and battery life, are transported by and sent out from the truck, working together to satisfy customers. The truck must wait until each drone returns and numerous drones can all be dispatched at once. The proposed model was given the name heterogeneous drone-truck routing problem (HDTRP), and a formulation of the problem using mixed-integer programming was provided.

Likewise, A parallel Drone Scheduling Traveling Salesman Problem was solved in [15]. In this approach, deliveries are divided between a truck and one or more drones. The truck goes on a tour from the depot, but the drones can only go back and forth. The goal is to finish as soon as possible. The problem was expanded by taking into account many vehicles. A hybrid metaheuristic, as well as a Mixed Integer Linear Programming formulation and a simple branch-and-cut algorithm, were also presented as solutions. In addition, A mixed-integer linear programming (MILP) model for the multi-trip Capacitated Arc Routing Problem was proposed in [16] to reduce the overall cost of waste collection (CARP).

Logically, the algorithms developed in solving the problems varied. A widely known algorithm is the neighborhood search. In [17], an Adaptive Large Neighborhood Search metaheuristic for the vehicle routing problem with drones (VRPD) was proposed, following minimum time and cost constraints, using multiple trucks. They developed a mathematical model to create a problem close to the Flying Sidekick Traveling Salesman Problem to optimize huge instances. Nevertheless, a tabu search heuristic algorithm in [18] proposed a new neighborhood generation process for a distribution company, to transport commodities from a single depot to multiple dealers. And a hybrid genetic algorithm was studied in [19] combining sweep and genetic algorithms in an enhanced approach. Both are recognized algorithms to solve the VRPD in the literature.

Other important algorithms are those whose called nature based. An ant colony optimization (ACO) technique was developed to solve the NP-hard VRPs with drones in [20]. The studies showed that the suggested ACO algorithm can solve the VRDP efficiently for diverse size instances and area distributions. Similarly, a novel dynamical artificial bee colony (DABC) was used in [21] to reduce operating costs. To identify employed bee swarm and onlooker bee swarm, two bee swarms were formed. Also, variable neighborhood descent was used in employed bee phase and onlooker bee phase in varying methods. An artificial bee colony-based hybrid approach was developed to solve the waste collecting problem while taking the halfway disposal pattern into account in [22]. Moreover, [23] suggested a Particle Swarm Optimization (PSO) algorithm to solve uncertain VRP, alongside a decoding scheme to improve its efficiency. According to [24], a simulated annealing heuristic algorithm was proposed to solve one of the Green Vehicle Routing Problems (G-VRPs), which is the Hybrid Vehicle Routing Problem (HVRP).

The clustering algorithms are majorly common. The author in [25] proposed two different hybrid metaheuristic algorithms in regards of the Clustered Vehicle Routing Problem (Clu-VRP). The first algorithm relies on an Iterated Local Search algorithm, in which only possible solutions are searched. The second one is a hybrid genetic search where the shortest Hamiltonian path between every set of vertices inside each cluster is precomputed.

The Location-Routing Problem for delivering orders to a group of clients was discussed in [26]. They attempted to reduce the overall CO_2 emissions using trucks and drones for last-mile deliveries. The problem was resolved using a mathematical model. Their findings focused on how adopting greener transportation technology can be a start to the substantial contribution that UAVs make to problems with parcel delivery routing. Hence, it is considered one of the G-VRPs, which highlight serious environmental issues like high CO_{2e} emission, pollution, global warming, low sustainability lifestyle and many others, as clearly stated in [27]. Waste collection problem is another example of the G-VRPs. Conveniently, [28] introduced a particle swarm optimization (PSO) approach in a capacitated vehicle-routing problem (CVRP) model to establish the optimal waste collection and route optimization solutions. The PSO-based CVRP model included threshold waste level (TWL) and scheduling approaches. Solomon's insertion algorithm was developed to solve a real-world waste collection vehicle routing problem with time windows (VRPTW) in [29].

This research investigates the process of collecting hazardous waste from different sites using constrained drones (UAVs), proposing priority rules-based algorithm to help efficiently collect the waste in the minimum time using multiple drones (MTMD). Using the outcomes of [7] as the base of the study, extending it by assigning the trips to multiple drones instead of a single drone.

Despite the magnitude of research conducted on VRPs following versatile approaches and proposing applicable solutions, shedding lights on such problem with this significance and effect on the daily life and unknown future of livings on the face of earth is crucial and deserving. Also, employing the latest modern technology like drones to accomplish the desired goal efficiently makes a distinctive difference. On that account, presenting an algorithm maintaining sensitive constraints and imposing priority rules as a solution would narrow the gap and expedite the plan to a safer, healthier and waste free planet.

To the best of our knowledge, there is no existing literature that addresses the specific challenges associated with using drones in hazardous waste collection. Therefore, we are unable to compare the proposed algorithm with existing solutions in this context.

III. Research Methodology

To assign the trips to the drones in an efficient way so that the total waste will be collected from all sites in the minimum time, we developed an algorithm that is mainly based on three principles:

- Order the trips to be traveled according to their flying times. The trips are then executed according to either an increasing order of their flying times: Shortest Flying Time (SFT), a decreasing order of their flying times: Longest Flying Time (LFT), or alternatively from the median time: Median Flying Time (MFT).
- Assign the current trip to the first available drone. This principle will guarantee an efficient use of the drones, balance distributing the flying times between the drones, and collect the waste in a minimum time.
- When the current charge of a given drone is less than the flying duration of the next trip, then charge it according to two principles. The first is fully recharge the drone before taking the next trip. The second is to recharge the drone just enough for it to take the next trip.

The suggested algorithm enables multiple drones to access the list of trips at the same time, where each drone has a maximum flying and weight capacity, as well as a recharging duration. The flying capacity and drone's recharge are the two key constraints defined. The algorithm's two primary tasks are: parallel assignment of trips to multiple drones and recharging of drones. The trips are assigned to the drones as long as the list of trips is not empty, employing one of three proposed priority rules and following one of the charging principles. As a result, six versions of the main algorithm are proposed. The details of these algorithms are illustrated in Algorithms 1 to 4. Note that Algorithms 1 and 2 each has two versions. A version uses the SFT rule and another version uses the LFT rule. The notations used to develop the algorithm are summarized in Table I.

TABLE I. Problem Notations

n	Number of trips in an instance
m	Number of drones
T	Maximum flying time of a drone if fully charged
r	Time needed to fully recharge a drone
c_j	Completion time of the last trip assigned to drone $j, 1 \leq j \leq m$
t_i	Flying duration of trip $i, 1 \leq i \leq n$
q_j	Remaining flying capacity of drone j

Algorithm 1 Assignment of trips to drones using SFT/LFT rule and charging drones when needed

```
 1: input: $m, n, T, r, t_i$
    output: $C_{max}$: The completion time of the last trip.
 2: Sort $t_i$ in increasing/decreasing order
 3: for $j \leftarrow 0$ to $m - 1$ do
 4:     $c_j \leftarrow 0$
 5:     $q_j \leftarrow T$
 6: end for
 7: $i \leftarrow 0$
 8: while $(i < n)$ do
 9:     $a \leftarrow\ index\ of \min c_j$
10:     if $(q_a < t_i)$ then
11:         $c_a \leftarrow \frac{t_i - q_a}{T} \times r + t_i$
12:         $q_a \leftarrow 0$
13:     else
14:         $c_a \leftarrow c_a + t_i$
15:         $q_a \leftarrow q_a - t_i$
16:     end if
17:     $i \leftarrow i + 1$
18: end while
19: return $\max c_j$
```

Algorithm 2 Assignment of trips to drones using SFT/LFT rule and charging drones fully

```
 1: input: $m, n, T, r, t_i$
    output: $C_{max}$: The completion time of the last trip.
 2: Sort $t_i$ in increasing/decreasing order
 3: for $j \leftarrow 0$ to $m - 1$ do
 4:     $c_j \leftarrow 0$
 5:     $q_j \leftarrow T$
 6: end for
 7: $i \leftarrow 0$
 8: while $(i < n)$ do
 9:     $a \leftarrow index\ of\ \min c_j$
10:     if $(q_a < t_i)$ then
11:         $c_a \leftarrow \frac{T - q_a}{T} \times r + t_i$
12:     else
13:         $c_a \leftarrow c_a + t_i$
14:     end if
15:     $q_a \leftarrow q_a - t_i$
16:     $i \leftarrow i + 1$
17: end while
18: return $\max c_j$
```

Note that steps 3 to 5 in all algorithms have the purpose of initializing the completion times of the drones to zeros and set their initial charge to full so that they can fly for T unites of time. Step 9 assigns the next trip to the first free drone. Step 10 in Algorithms 1 and 2 and 17 in Algorithms 3 and 4 means that the drone does not have enough charge to fly the next trip. For that reason, the drone needs either to be partially enough charged to fly the next trip (as in algorithms 1 and 3) or fully charged up to its maximum flying capacity T (as in algorithms 2 and 4). The last statement in all algorithms returns the maximum completion flying time of the last trip for all drones. The six proposed algorithms ensure an early completion time of the waste collection by assigning the next trip to the first available drone. This method maintains also an equilibrium between the total flying time between the drones.

Algorithm 3 Assignment of trips to drones using MFT rule and charging drones when needed

```
input: $m, n, T, r, t_i$
output: $C_{max}$: The completion time of the last trip.
Sort $t_i$ in increasing order
for $j \leftarrow 0$ to $m-1$ do
    $c_j \leftarrow 0$
    $q_j \leftarrow T$
end for
$left \leftarrow \lfloor \frac{n}{2} \rfloor,\ right \leftarrow \lfloor \frac{n}{2} \rfloor + 1,\ k \leftarrow 0$
while ($k < n$) do
    $a \leftarrow index\ of\ \min c_j$
    if ($k \mod 2 = 0$) then
        $i \leftarrow left$
        $left \leftarrow left - 1$
    else
        $i \leftarrow right$
        $right \leftarrow right + 1$
    end if
    if ($q_a < t_i$) then
        $c_a \leftarrow \frac{t_i - q_a}{T} \times r + t_i$
        $q_a \leftarrow 0$
    else
        $c_a \leftarrow c_a + t_i$
        $q_a \leftarrow q_a - t_i$
    end if
    $k \leftarrow k + 1$
end while
return $\max c_j$
```

Algorithm 4 Assignment of trips to drones using MFT rule and and charging drones fully

```
input: $m, n, T, r, t_i$
output: $C_{max}$: The completion time of the last trip.
Sort $t_i$ in increasing order
for $j \leftarrow 0$ to $m-1$ do
    $c_j \leftarrow 0$
    $q_j \leftarrow T$
end for
$left \leftarrow \lfloor \frac{n}{2} \rfloor,\ right \leftarrow \lfloor \frac{n}{2} \rfloor + 1,\ k \leftarrow 0$
while ($k < n$) do
    $a \leftarrow index\ of\ \min c_j$
    if ($k \mod 2 = 0$) then
        $i \leftarrow left$
        $left \leftarrow left - 1$
    else
        $i \leftarrow right$
        $right \leftarrow right + 1$
    end if
    if ($q_a < t_i$) then
        $c_a \leftarrow \frac{T - q_a}{T} \times r + t_i$
    else
        $c_a \leftarrow c_a + t_i$
    end if
    $q_a \leftarrow q_a - t_i$
    $k \leftarrow k + 1$
end while
return $\max c_j$
```

IV. Experimental Study

The six versions of the proposed algorithms were implemented in Java. Distributing the number of trips among multiple drones grants completing all the trips in a sooner time than assigning all the trips to a single drone, because all the drones are flying simultaneously; whenever a drone completes a trip and it is available in the depot, the program assigns another trip to it, not taking into account the status of the other drones.

Testing the program using the three priority rules: SFT, LFT and MFT while recharging only for the time needed once, and again recharging the drones till they are full, generated six distinctive cases. Twenty instances varying from 101 to 941 sites, with a number of trips in the range $[23, 249]$, have been used for validation of the proposed algorithms. A summary of results is shown in Tables II, III, IV, and V. For the six algorithms, the time each drone takes to complete the trips assigned to it was compared; the longest time means that it is the last drone to finish. As observed, the last drone finishing time of the cases that follow the LFT rule and recharge only for the time needed, is mostly the shortest, which means the LFT rule frequently guarantees a faster execution of the routing process. However, in some cases, multiple drones finish on the same time.

TABLE II. Values of C_{max} for Different Instances when $m = 2$

		Needed charge			**Full charge**		
Instance	n	SFT	LFT	MFT	SFT	LFT	MFT
I_{101}	23	294	289	**284**	296	293	**284**
I_{121}	28	392	**384**	392	393	388	393

I_{661}	143	1847	**1840**	**1840**	1847	1841	1841
I_{701}	156	1519	**1511**	1519	1519	1512	1519
I_{721}	162	1662	**1652**	1662	1662	1658	1662
I_{741}	183	1493	**1487**	1489	1493	1488	1489
I_{861}	194	2188	**2182**	2188	2188	2184	2188
I_{901}	207	2158	**2151**	2153	2158	2152	2153
I_{941}	249	2159	**2151**	2154	2159	2152	2154

Moreover, the three cases where the drones are fully recharged every time the battery ran out, took a slightly longer total time to complete all the trips, regardless of the number of drones used, than those three cases which the drones are recharged for only the time needed to be assigned the next suitable trip. Table VI confirms this result for instance I_{101}.

Although, the recharge count could be the same for both recharging conditions, the remaining charge in the cases that recharge only the needed duration is always zero. Whereas the cases that recharge fully, have useless remaining charge; that adds extra period of time, which increases the completion time of all the trips. Therefore, it is better to consider the cases that will reduce the total time by charging the drones only for the time needed.

TABLE VI. TOTAL TIME COMPARISON FOR INSTANCE I_{101}

	Needed charge			Full charge		
m	SFT	LFT	MFT	SFT	LFT	MFT
2	562	563	562	566	569	568
3	556	557	556	561	566	559
4	549	550	550	557	557	556
5	544	543	544	553	558	553

In addition, the average of the time each drone took to complete the assigned trips was calculated. The difference between the time each drone took, and the average was also calculated, to illustrate how balanced the assigning of trips among the drones was. The total difference of those differences was then summed up to accentuate the exact gap between the time all the drones took to complete the trips and the average of it. It is noticeable that the total difference generated by SFT rule is always the biggest compared to the LFT and MFT rules. Whilst, the MFT cases often have smaller total difference than the SFT cases and a few of them have the same total difference as the LFT or SFT cases. In numerous instances, the MFT cases have the smallest total difference out of all three rules. Furthermore, a decreasing pattern in the number of those instances was noticeable, where the number of instances and the number of drones used have an inverse relationship; whenever the number of drones used increases, the number of the instances having the smallest total difference in the MFT cases decreases. However, the LFT cases mostly have the smallest total difference amongst all three. Additionally, in some LFT cases the total time of all the drones is the same as the average time, which means the total difference is zero. This comparison truly demonstrated how the LFT rule performs best in regards of the assignment of trips among the drones, despite their number, which ensures that all the drones take up nearly the same time to complete the trips. Moreover, it is an indication that the drones visit approximately the same number of trips. As a resultant, sorting the trips from the longest flying time to the shortest flying time (LFT) almost equally assigns the trips to the drones, which executes a more efficient program, effectively fulfilling the objective of the proposed algorithm MTMD.

"Fig. 1, "Fig. 2", "Fig. 3" and "Fig. 4" below, clarify the contrast between the total differences in each rule (SFT, LFT and MFT) for all 20 instances using 2, 3, 4 and 5 drones.

V. CONCLUSION AND FUTURE WORK

A. Conclusion

In conclusion, studying the Vehicle Routing Problem using Drones (VRPD) and how it can be applied to help finding a solution to the accumulated hazardous waste problem was the first step. The diversified literature of VRPs gave the proper background and knowledge to investigate this major problem and propose an algorithm to resolve it.

Adopting the outcomes of an existent research as a dataset, six versions of a proposed algorithm were brought forward that allow multiple drones to access the list of trips at the same time, where the drones have maximum flying and weight capacities and a recharge duration. Concentrating on the flying capacity and the recharging of drones as constraints, the

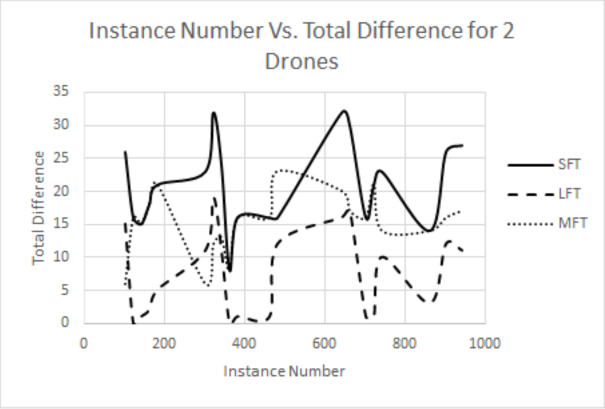

Fig. 1. Total differences for each rule using 2 drones.

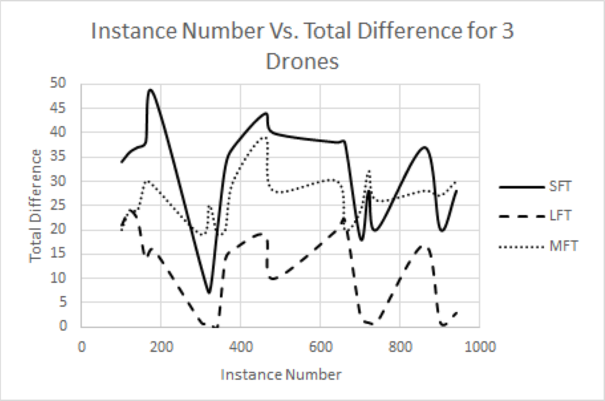

Fig. 2. Total differences for each rule using 3 drones.

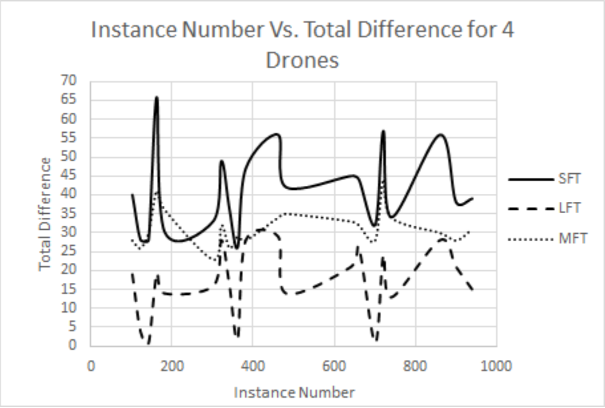

Fig. 3. Total differences for each rule using 4 drones.

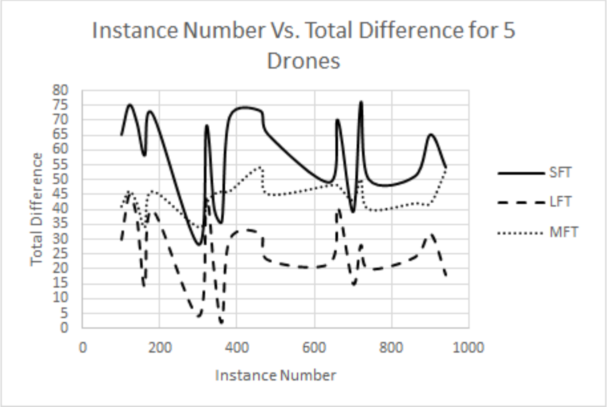

Fig. 4. Total differences for each rule using 5 drones.

presented algorithms handle the routing through two main tasks: the assignment of trips to multiple drones and recharging of drones. It suggested three priority rules in sorting the flying times before assigning them to the drones. The first rule is sorting from the shortest to the longest flying time (SFT) in ascending order. The second rule is sorting from the longest to the shortest flying time (LFT) in descending order. The third rule is sorting the flying times in ascending or descending order first and then starting from the median trip time (MFT). Following each rule, whenever the drones need recharging, two conditions were taken into consideration: recharging the drones just for the time needed to be assigned the next adequate trip or recharging the drones fully, taking their total recharge duration. Hence, the algorithms map routes in minimum time using multiple drones (MTMD).

Moreover, the algorithm's versions were implemented using Java to program was developed validating the algorithm, which produced six cases that test each individual rule (SFT, LFT and MFT) with both recharging conditions (needed and full).

After various testing of the six cases, the output of the program resulted in valuable findings. The LFT rule was proven the current best in assignment of trips to the multiple drones. It almost distributes the trips equally, which means approximately the same total flying time, recharge count and trip count of the drones. The program was tested using common several testing types as well, to assure its effectiveness in following the MTMD algorithm.

B. Future Work

Aggregating the work done, positive improvements are expected to better the research, starting from developing a program with higher performance and dedicating enough time to test all the instances of the dataset using a greater number of drones.

In addition, the Drone Routing Problem (DRP) is progressing continuously; researchers are studying new challenging extensions of it momentarily. Consequently, proposing a better algorithm to develop an enhanced program as a solution to this substantial problem is an aspiration kept in mind. An existing similar problem called the Subset-Sum problem could be beneficial for evolving the rules the MTMD algorithm proposed.

Acknowledgment

The authors would like to thank the deanship of graduate studies and scientific research at the University of Bahrain for supporting the current research with a grant number 2019/8. A special thank also goes to Dakota State University, USA for supporting the publication of this paper.

The Management System of IoT Informatization Training Room Based on Improved YOLOV4 Detection and Recognition Algorithm

Huiling Hu
School of Economic Management, Nanjing Vocational University of Industry Technology, Nanjing, 210023, China

Abstract—**In response to the problems of low recognition rate and long system operation time in equipment detection management in the existing IoT information training room management system. A research has proposed an IoT information training room equipment detection management system on the ground of an improved YOLOV4 detection and recognition algorithm to solve the above problems. Firstly, it used the YOLOV algorithm to detect and identify equipment in the IoT information training room. Then, it used clustering methods to improve the YOLOV algorithm, thereby enhancing the detection accuracy and robustness of the algorithm, and thereby enhancing the performance of the equipment management system in the equipment management process of the training room. Finally, performance validation of the training room management system was conducted using datasets and simulation experiments. The results showed that the loss value of the training room equipment management system constructed using the improved YOLOv4 algorithm during the training process was 0.16. The accuracy and recall rates of device recognition were 95.71% and 92.83%, respectively. And the detection false alarm rate during the device detection and recognition process was only 2.15%, with a mAP value of 91.66%, and the detection and recognition indicators are higher than those of the comparison method. This indicates that the training room equipment management system constructed in the study has good adaptability in equipment detection and recognition in IoT information training rooms. The research aims to provide effective technical support for the management system of IoT training room equipment.**

Keywords—YOLOV4 algorithm; Internet of Things informatization; training room; management system; detection and recognition

I. Introduction

As the boost of Internet of Things (IoT) technology, IoT information training rooms, as a new type of teaching and practical environment, are widely used in various universities. Çobanoğlu et al. investigated the laboratory operation needs of K-12 teachers and students using a survey method [1]. Automated detection and identification of equipment can improve the efficiency and accuracy of equipment management, Kan et al. conducted a study on the management of training in basic operating rooms using new evaluation criteria [2]. However, due to the diverse types, shapes, and sizes of equipment in the training room, traditional detection and identification management systems are difficult to meet practical needs, Sturt et al. conducted a study on effective review of managers of practical training rooms using a supervisory framework [3]. Therefore, a device detection management system for IoT information training rooms on the ground of an improved YOLOV algorithm has been proposed in the study. The YOLOV algorithm is an extensively utilized algorithm in the object detection (OD) and recognition. It transforms the OD and recognition problem into a regression problem and directly forecasts the category and position of the target through a neural network. Majeed et al. conducted an in-depth study on Facial Recognition and Attendance system for monitoring system in practical training room through YOLOv5 model [4]. However, the YOLO algorithm suffers from inaccurate positioning and missed detections in some complex scenarios, thus requiring improvement Hasanvand et al. explored vehicle recognition technology using specific image processing techniques [5]. Meanwhile and other scholars conducted an optimization study on the process of detecting small targets by target detector using improved YOLOv4 network [6]. The study first uses the YOLOV algorithm to detect equipment in the IoT information training room, and then improves the YOLOV algorithm using clustering methods to enhance its detection accuracy and robustness. The IoT information training room equipment management system (TREMS) not only accurately monitors and identifies the status of the training room equipment, but also manages the reasonable utilization of equipment. This can enhance the overall effectiveness of the management system. The research aims to construct a device detection management system model that can provide effective technical support for device management in IoT training rooms. Meanwhile, it also provides new research ideas for OD and classification in other similar scenarios.

In summary, Section I and Section II of the study analyzes the training room equipment management now while summarizing the research of YOLOV algorithm in equipment detection and identification; Section III firstly improves the YOLOV algorithm by using the method of clustering, and constructs the equipment management system system model of the IoT informatized training room on the basis of the improved algorithm; the third part is to verify the performance of constructing the equipment management system model of the IoT informatized It is to verify the performance of constructing the model of equipment management system system of IOT informationization training room, and the verification of the performance is carried out with simulation experiments and practical applications; Section IV is to analyze and summarize the obtained experimental results, and to get the advantages and shortcomings of the model constructed by the research. Finally Section VI concluded the paper.

II. Related Works

The management system of training room equipment is one of the key factors in maintaining the stable and reliable development of IoT information technology training rooms. It can enhance the effective management ability of equipment in the training room. But currently, the management system of the training room still has problems such as low efficiency and longtime consumption in equipment identification. To promote the scientific development of IoT information technology training rooms, many experts and scholars have conducted in-depth research on the detection and recognition of equipment in the training rooms. To improve the detection performance of training models on device images, scholars such as Obaid I proposed a device detection and recognition method on the ground of Tiny YoloV3. This method can detect and recognize devices on the ground of the performance and execution time of the training model. The outcomes showcased that the recognition probability of large objects increased from 75% to 90%, and the detection and recognition of small objects increased by 20% [7]. Zhao J et al. proposed a data adaptive amplitude method on the ground of spatial and channel attention to enhance the utilization of priority devices in two-level neural networks. This study utilizes feature approximation to generate adaptive amplitudes and minimizes the difference between real values and 1-bit convolutions. The results showed that a 64.0% efficiency was achieved on the Pascal VOC dataset, with storage and computation savings of 18.62 times and 15.77 times, respectively. On ImageNet, storage space savings of 11.04 times and 10.80 times were achieved compared to fully accurate counterparts [8]. Chinta R et al. proposed a visual framework to improve the performance of object recognition technology. This framework can utilize novel and fast algorithms to construct frameworks for objects, and then perform deep recognition on these frameworks. The outcomes showcased that the proposed framework can be executed on a humanoid robot and also extends its self-sufficiency in learning and communicating with humans [9]. Jiaxu L and other scholars proposed a bidirectional feature fusion method for enhancing the detection performance of small targets. This method can improve the performance of small OD and recognition from different aspects such as feature fusion, context learning, and attention mechanism. The results indicate that research on feature fusion, context utilization, and attention mechanisms is of great value in improving small OD in complex scenes. The detection accuracy of small target objects was enhanced by 10.3% [10].

F Li et al. proposed a deep convolutional recognition algorithm for small targets on the ground of an improved YOLOv4 network for addressing the issue of inaccurate detection of small targets in mainstream OD. This study requires obtaining more target feature information and introducing spatial pyramid pools with different pool kernel sizes. The outcomes showcased that compared to the original YOLOv4, the improved network has increased the average detection speed and accuracy by about 30% and 7%, respectively [11]. Scholars such as S Lu proposed a real-time video OD algorithm on the ground of YOLO network to apply deep learning technology to OD and recognition. This study eliminates the influence of image background through image preprocessing, and then trains a fast YOLO model for OD for getting target information. The results indicate that the YOLO network has been improved by replacing the original convolution operation with a small one, reducing the quantity of parameters and greatly shortening the time for OD [12]. Wang K proposed a high-precision remote sensing detection method on the ground of the advanced YOLOv4 framework for enhancing the detection performance of large-scale targets. A clustering algorithm that combines object scale knowledge is studied for generating a prior anchor box with high matching degree. The feature extension module is designed for expanding the receptive domain of the backbone network and getting essential contextual information. The results indicate that the feature extension module is designed for extending the receptive domain of the backbone network and getting essential contextual information [13]. To improve the detection performance of small objects and objects with varying scales, Y Ma et al. introduced a densely connected feature pyramid strategy and constructed a scale aware attention module. The study utilizes dense network blocks and median frequency balancing mechanism to process data, and then utilizes OD algorithms for detection. The results showed that AP increased by 6.22% and 5.09%, respectively. AP is 1.82% higher than YOLOv4 [14].

In summary, the design and research of the IoT TREMS model on the ground of the improved YOLOV4 algorithm is of great significance. It uses clustering algorithm to improve YOLOV4 algorithm, analyzes the detection and recognition of equipment in the training room, and obtains the specific situation of the equipment, providing more effective information for the equipment management system. The research aims to provide effective technical support for device detection and classification in IoT training rooms.

III. Design of IoT TREMS on the Ground of Improved YOLOV4 Algorithm

The design of an IoT TREMS on the ground of the improved YOLOV4 algorithm is a comprehensive solution that combines deep learning, IoT technology, and information management technology. Its main goal is to improve the detection and recognition accuracy and efficiency of IoT training room equipment by improving the YOLOV4 algorithm, thereby providing reliable support for the management system.

A. *Research on IoT Training Room Equipment Detection and Recognition on the Ground of YOLOV4 Algorithm*

In the equipment management system of the IoT training room, equipment detection and identification are important links. In the process of device detection, the collected video and image information, as well as their clarity and resolution, will affect the judgment of device detection and recognition results. Therefore, it is necessary to increase the accuracy of data collection for IoT training room equipment. The YOLOv4 algorithm is a deep learning based image recognition technology mainly used for OD. It can recognize targets in the images of IoT training room equipment and detect whether the equipment in the training room is working properly or missing, Lou completed a study on the counting of non-contact surveillance area based on YOLOv4-tiny algorithm [15]. By detecting and identifying the equipment in the IoT training room, it is possible for ensuring the safe operation of the equipment and prevent it from being left vacant or damaged or stolen. Dewi et al. conducted an in-depth analytical study on the performance of video vehicle recognition using Yolo V4 algorithm [16]. Through research on the detection and recognition of IoT training room equipment, it has been found that if intelligent detection of equipment is carried out using images, it is necessary to collect, analyze, and calculate the detected dataset and images. To better collect equipment related data, a YOLOv4 algorithm was used to construct an IoT training room equipment detection and recognition model. The network structure diagram of YOLOv4 is showcased in Fig. 1.

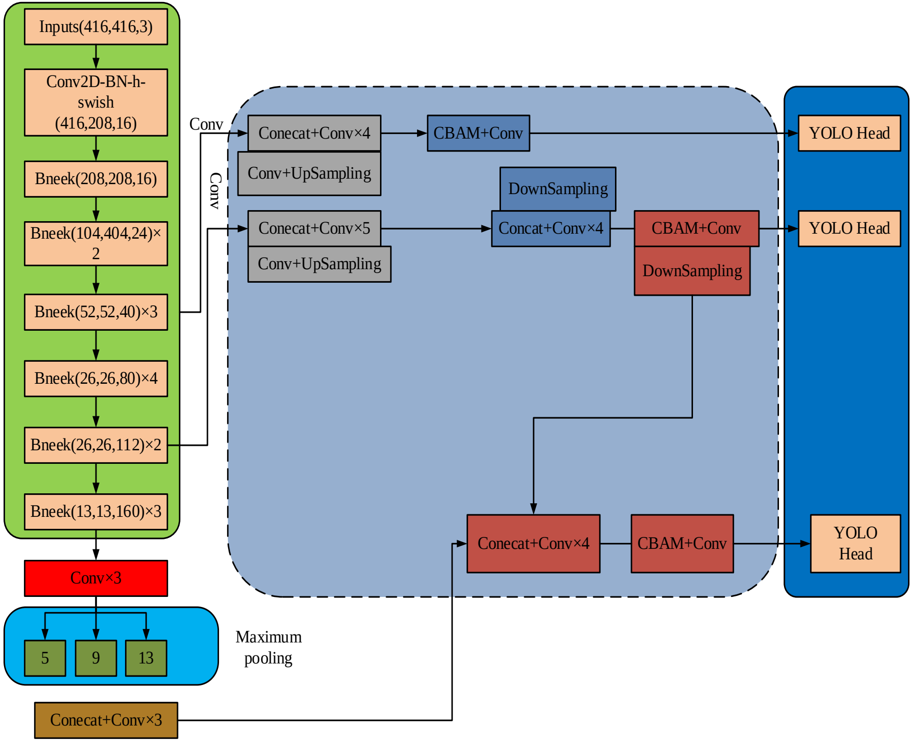

Fig. 1. Network structure diagram of YOLOv4.

When using the YOLOv4 algorithm for OD, for ensuring the accuracy of the data, it is necessary to pay attention to the convergence speed. The convergence speed refers to the speed at which a model gradually approaches the optimal solution during the training process. This speed is affected by the loss function. To improve convergence speed, research needs to consider the boundary values and confidence coefficients of the data. The boundary value of data refers to the minimum and maximum size of the target object in the dataset, which can help the model learn the size range of the target object. The confidence coefficient is used to measure the model's level of confidence in each target object. By setting reasonable boundary values and confidence coefficients, the convergence speed of the model can be accelerated, thereby improving the accuracy of the data. When traditional algorithms perform regression on bounding boxes, the coordinates of the center point and the width and height data are used as independent variables for calculation, Li and other scholars combined YOLOv4 with attention mechanism for the study of traffic sign detection in clothing context [17]. To reduce this part of the error, the study abandoned the least squares method and used the Jaccard index to solve the variable relationship between the parameters and the center coordinate. And on the ground of the problems with the Jaccard index, corresponding optimizations were made to the target detection loss function, the distance loss function between the predicted box and the true box in the target detection model, the target detection loss function, and the confidence loss function. The Jaccard index can be expressed using Formula (1).

$$L_{Jaccard} = 1 - Jaccard(A, B) \qquad (1)$$

In Formula (1), A, B respectively represent the difference in IOU in the predicted box and the true box. The improved OD loss function incorporates a penalty term, which can prevent gradient problems during data detection and can be represented by Formula (2).

$$L_{GIOU} = 1 - IOU + \frac{\left|C - B \cap B^{gt}\right|}{|C|} \qquad (2)$$

In Formula (2), B represents the true box value. C is the minimum bounding box generated by the intersection of A, B. B^{gt} represents the center point of the true box value. Due to the insufficient calculation of area in the process of OD loss function, it is necessary to use the loss function of the distance in the predicted box and the actual box in the OD model for representing the relationship in the predicted value and the actual value. This can also increase the convergence process of the loss function. Formula (3) can be used to represent the loss function of the distance in the predicted box and the true box in the OD model.

$$L_{DIOU} = 1 - IOU + \frac{\rho^2(b, b^{gt})}{c^2} \tag{3}$$

In Formula (3), c represents the diagonal length that covers the minimum range in the true value and the predicted value. ρ is a constant. b^{gt} represents the coordinates of the center point. The improvement of the target detection loss function mainly involves optimizing the overlap area, spacing at the center position, and the ratio of length and width in the coverage area. It can be represented by Formula (4).

$$\begin{cases} LCIOU = 1 - IOU + \frac{\rho^2(b, b^{gt})}{c^2} + \alpha v \\ \alpha = \frac{v}{(1 - IOU) + v} \\ v = \frac{4}{\pi}(\arctan\frac{\omega^{gt}}{h^{gt}} - \arctan\frac{\omega}{h})^2 \end{cases} \tag{4}$$

In Formula (4), ω^{gt} serves as the width of the true value. h^{gt} serves as the height of the true value. b^{gt} serves as the coordinates of the center point. ω represents the width of the predicted value. α represents the trade-off parameter. v represents the consistency between the candidate value and the aspect ratio of the target object. ρ is a constant, representing the Euclidean distance. The confidence loss function can be calculated using Formula (5).

$$\begin{cases} L_{cla}(O, C) = -\sum_{i\in Pos}\sum_{i\in cla}(O_{ij}\ln(\hat{C}_{ij}) + (1 - O_{ij})\ln(1 - \hat{C}_{ij})) \\ \hat{C}_{ij} = Sigmoid(C_{ij}) \end{cases} \tag{5}$$

In Formula (5), O_{ij} represents a constant, with a value of 1 or 0. $\hat{C}_{ij}$ represents the probability that the predicted value i contains the j target. The entire process of detecting equipment in the YOLOv4 IoT training room mainly consists of three parts: creating a dataset, training the dataset, inputting it into the model to calculate the confidence of the results. The entire process is shown in Fig. 2.

B. *Construction of Equipment Management System Model on the Ground of Improved YOLOV4 Algorithm*

Through the study of YOLOv4 algorithm in device detection and recognition, it was found that the backbone network CSPDarknet in YOLOv4 has greatly improved in performance. However, it is still a heavyweight network that cannot meet the requirements of low consumption and high efficiency in the detection and recognition process. Zhang utilized YOLOv4 for the recognition study of the posture of welding studs [18]. Although YOLOv4 has significant advantages in the model of device detection and recognition in IoT training rooms, there is still a problem of excessive training parameters in the actual operation process, Liu and other scholars utilized YOLOv5 algorithm for fast detection study of infrared device images [19]. To solve this problem, the K-means clustering algorithm was applied to the prior boxes of the YOLOv4 algorithm dataset to cluster the data. K-means clustering can first select the center point of the initial cluster in the prior box, and then perform clustering. Meanwhile, due to the uneven scale distribution in the detection image, K-means clustering can forcibly cluster objects of similar sizes, thereby improving the accuracy of detection. The perspective scale for identifying cameras in the IoT training room equipment detection management system is fixed. This study utilizes K-means clustering to cluster different specific sizes, but it still needs to meet the requirements of sample clustering. The requirements for clustering can be expressed using Formula (6).

Fig. 2. Detection flowchart on the ground of YOLOv4 algorithm.

In Formula (6), $D = (d_1, d_2, \cdots, d_n)$ represents the prior box. r represents the image resolution of the clustering input. $u(0, r)$ represents the size range of the recognition device. There are a total of three groups and nine prior boxes in YOLOv4 used in the study. These three sets of prior boxes can detect and recognize devices of different sizes, including large, medium, and small, as set. To avoid the phenomenon of undetectable size, the study only selected one detection head, which means that all devices are placed on a certain layer for detection, to avoid undetectable situations. Meanwhile, to prevent situations where the device volume is too small and cannot be detected, the study added IK-means on the basis of K-means clustering. This enables clustering of all nodes in the network and sets two thresholds, Sun et al. utilized YOLO algorithm for effective detection of targets at multiple scales to improve the accuracy of different picking devices [20]. This allows for scale division of devices of different sizes. Through the detection of three sets of prior boxes, a total of nine prior boxes were obtained. Two threshold values were set to annotate the size of the object boxes, and rectangular annotation boxes were defined. The size of this annotation box is defined using the length of the diagonal, and the specific definition formula can be represented by Formula (7).

$$Diag(j)=\sqrt{(a_j^w)^2+(a_j^h)^2} \tag{7}$$

In Formula (7), $(a_j^w)^2+(a_j^h)^2$ represents a rectangular annotation box. $j=1,2,\cdots,m,$. m represents the total amount of all annotation boxes. $Diag(j)$ represents the diagonal length corresponding to the annotation box. w represents width. h represents height. After obtaining the length of the diagonal, clustering algorithms can be used to cluster the diagonal and obtain different detection box cluster centers. After calculating the cluster center, it can be utilized for determining the threshold that needs to be set for the research. The calculation of threshold can be represented by Formula (8).

$$\begin{cases} Th_1=(C_1+C_2)/2 \\ Th_2=(C_2+C_3)/2 \end{cases} \tag{8}$$

In Formula (8), $C=(C_1,C_2,C_3)$ represents the cluster center. Th_1 and Th_2 represent threshold 1 and threshold 2. The flowchart of using K-means combined with IK-means clustering is shown in Fig. 3.

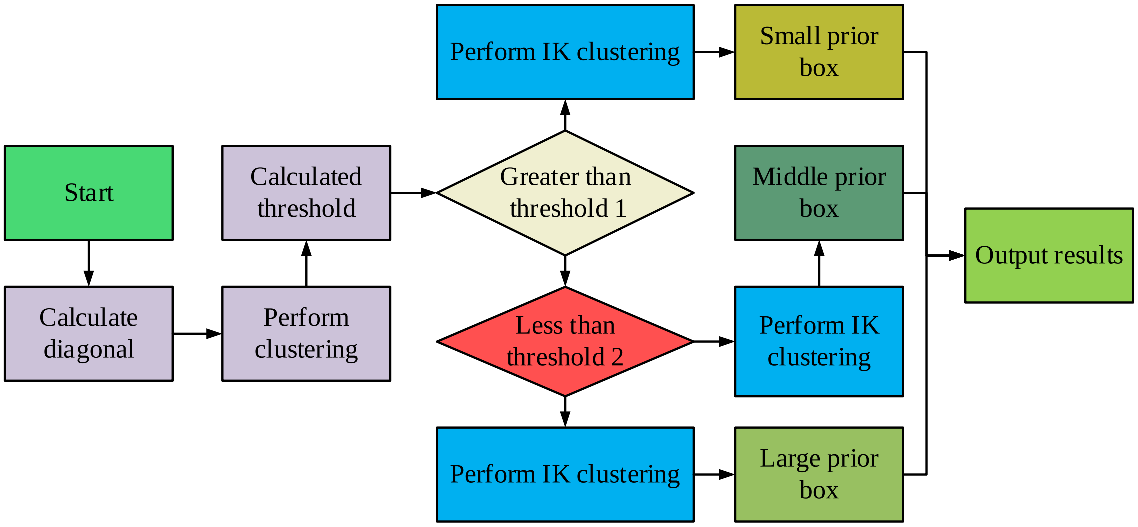

Fig. 3. Flowchart of K-means combined with IK-means clustering.

To further ensure the high detection accuracy of the model, attention modules were introduced into the backbone network of the model. The addition of attention modules could enhance the learning efficiency and detection and recognition accuracy of the model for data information. Meanwhile, to reduce the impact of dimensionality reduction on the attention module channels, the study eliminated the dimensionality reduction effect by performing lightweight operations on the attention module. The attention module at this point can be represented by Formula (9).

$$W(k)=\begin{bmatrix} w^{1,1} & \cdots & w^{1,k} & 0 & \cdots & 0 \\ 0 & w^{2,2} & \cdots & 0 & \cdots & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & \cdots & w^{C,C-k+1} & \cdots & 0 & w^{c,c} \end{bmatrix} \tag{9}$$

In Formula (9), k serves as the size of the convolution kernel in the module. C represents the number of channels for inputting feature maps in the module. At this point, the shared weight values of all channels can be represented by Formula (10).

$$w_i=\sigma(\sum_{j=1}^{k} w_i^j y_i^j),y_i^j\in\Omega_i^k \tag{10}$$

In Formula (10), σ represents the activation function. y_i represents weight. Ω_i^k represents the k domain channels in the y_i weight. The schematic diagram of the attention module structure is showcased in Fig. 4.

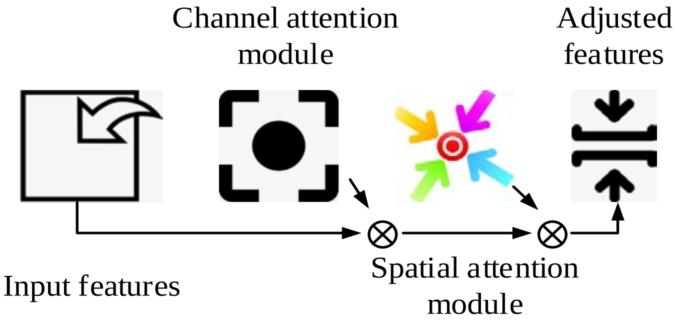

Fig. 4. Schematic diagram of the structure of the attention module.

In summary, the IoT information training room equipment detection on the ground of the improved YOLOV4 algorithm first improved the prior boxes using K-means clustering, then added attention modules to the backbone network and removed the SPP structure in the YOLOV4 network. The flowchart of the device detection and recognition system in the improved YOLOV4 algorithm device management system is shown in Fig. 5.

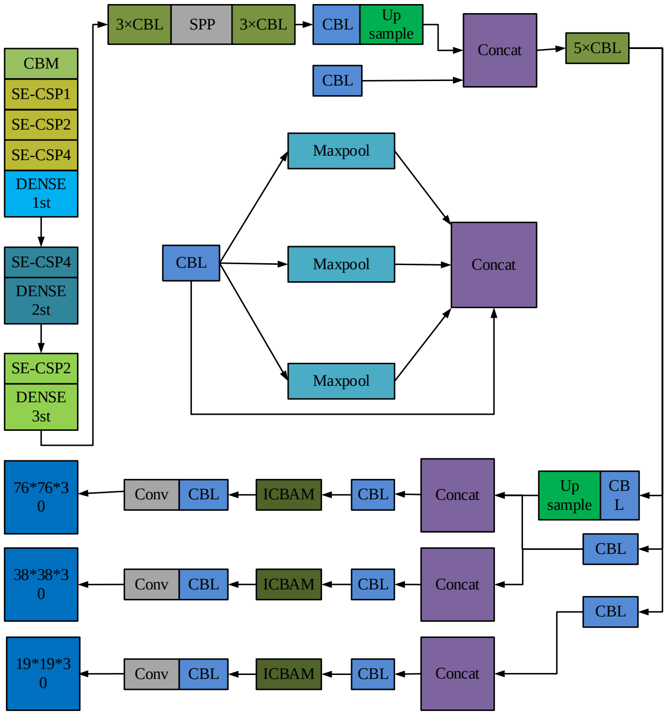

Fig. 5. Flowchart of equipment detection and identification system in equipment management system with improved YOLOV4 algorithm.

On the ground of the analysis in Fig. 5, after the model training is completed, it is necessary to use mAP in the target domain as an evaluation indicator. mAP can be represented by Formula (11).

$$mAP = \frac{1}{N}\sum_{i=0}^{N-1} AP_i \tag{11}$$

In Formula (11), N represents the category of the detected target, with a value of 3. AP_i represents the AP value corresponding to the three types of detection targets.

IV. Performance Analysis of Equipment Management System Model on the Ground of Improved YOLOV4 Algorithm

To verify the performance of the IoT information training room equipment detection management system model on the ground of the improved YOLOV4 algorithm, this study compared the YOLOV4 algorithm and Single Shot Multibox Detector (SSD) with the improved YOLOV4 algorithm as comparative methods. This is to verify the performance of the IoT information TREMS on the ground of the improved YOLOV4 algorithm in equipment detection and recognition.

A. *Performance Analysis of Equipment Inspection Management System Model*

To verify the performance of the equipment management system model in the IoT information training room in equipment detection and recognition, the performance of the model was analyzed. It takes the loss value during the training process of the system model as one of the indicators to judge the performance of the model. The comparison results of function loss values for three methods in device detection and recognition are shown in Fig. 6.

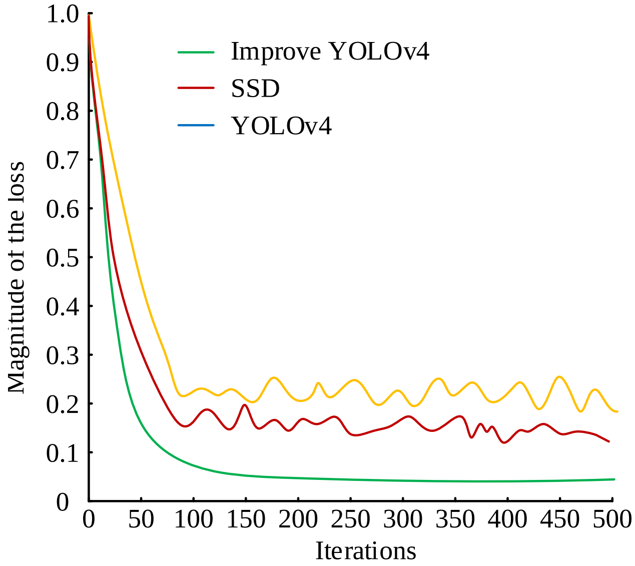

Fig. 6. Comparison results of function loss values among three methods for device detection and recognition.

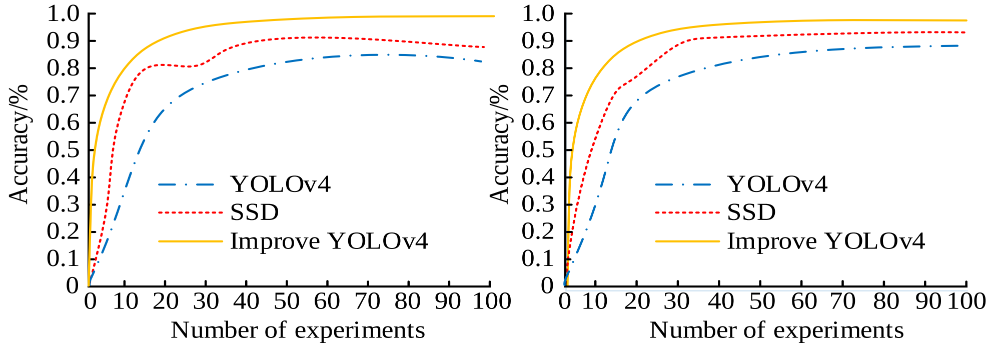
Fig. 6 showcases that the loss value of improved YOLOv4 tends to stabilize after 146 iterations, with a loss value of 0.16. The loss value of SSD slows down after 98 iterations, but does not tend to stabilize. Instead, it remains fluctuating, with a loss value of 0.25. The loss value of YOLOv4 slows down after 95 iterations, but does not tend to stabilize, with a loss value of 0.31. This indicates that the smaller the difference between the predicted and actual values in the processing of device data, the more accurate the predicted results of the device management system model constructed in the study. To verify the performance of the model in device image detection and recognition, the accuracy and recall of recognition were studied as validation indicators. The comparison results of recognition accuracy and recall of the three methods are showcased in Fig. 7.

Fig. 7(a) shows that there is a certain difference in the accuracy of device recognition among the three methods. The improved YOLOv4 has a device recognition accuracy of 95.71%, SSD has a device recognition accuracy of 88.64%, and YOLOv4 has a device recognition accuracy of 81.52%. Fig. 7(b) shows that among the three methods, the improved YOLOv4 has the highest recall rate for device recognition data, which is 92.83%. The recall rate of SSD is 88.31%, and the recall rate of YOLOv4 is 82.9%. This indicates that the improved YOLOv4 system model constructed in the study has stronger robustness in data detection. To verify the recognition performance of the system model on devices, the study used device recognition false alarm rate and mAP as indicators. The comparison results of the false alarm rate and mAP for device recognition using three methods are shown in Fig. 8.

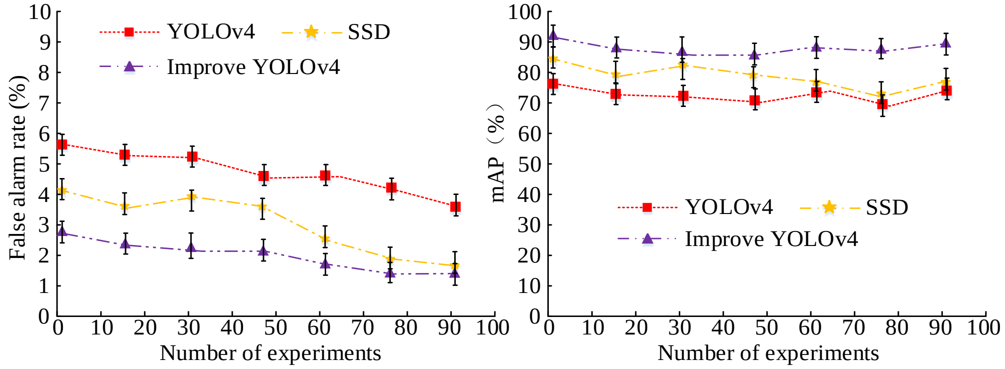
Fig. 8(a) shows that during the equipment detection and recognition process in the IoT information training room, the improved YOLOv4 has a false alarm rate of 2.15%. The device detection and recognition false alarm rate of SSD is 3.95%, and the device detection and recognition false alarm rate of YOLOv4 is 5.26%. Fig. 8(b) shows that the improved device detection and recognition mAP for YOLOv4, SSD, and YOLOv4 are 91.66%, 82.39%, and 78.24%, respectively. This indicates that the system model constructed in the study can significantly reduce errors in equipment detection and recognition processes, and improve detection performance. To further validate the system model, the quantity of floating-point operations per second and the number of frames transmitted per second of the image were used as indicators for performance validation. As shown in Fig. 9, the comparison results of three methods on the quantity of operations and the quantity of transmitted frames are presented.



(a) Accuracy of different methods

(b) Recall rates for different methods

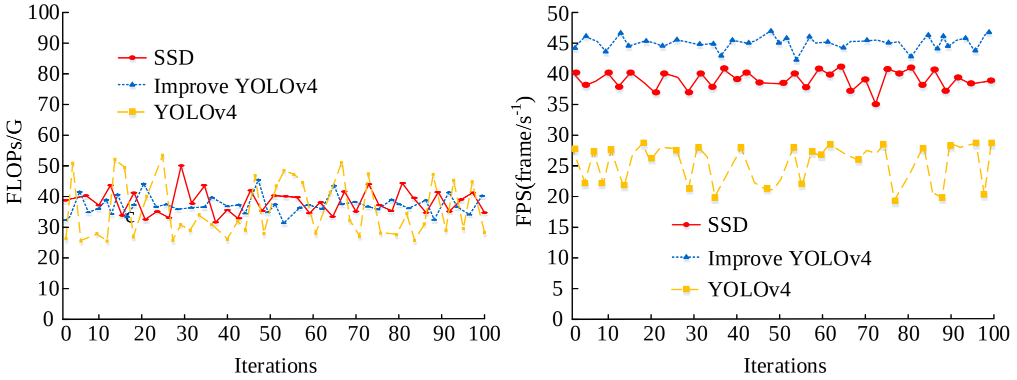
Fig. 7. Comparison results of recognition accuracy and recall of three methods.



(a) Device recognition false alarm rate using different methods

(b) Comparison results of mAP using different methods

Fig. 8. Comparison of false alarm rates and mAP results of three methods for device recognition.



(a) Comparison results of floating-point operations for device detection and recognition using different methods

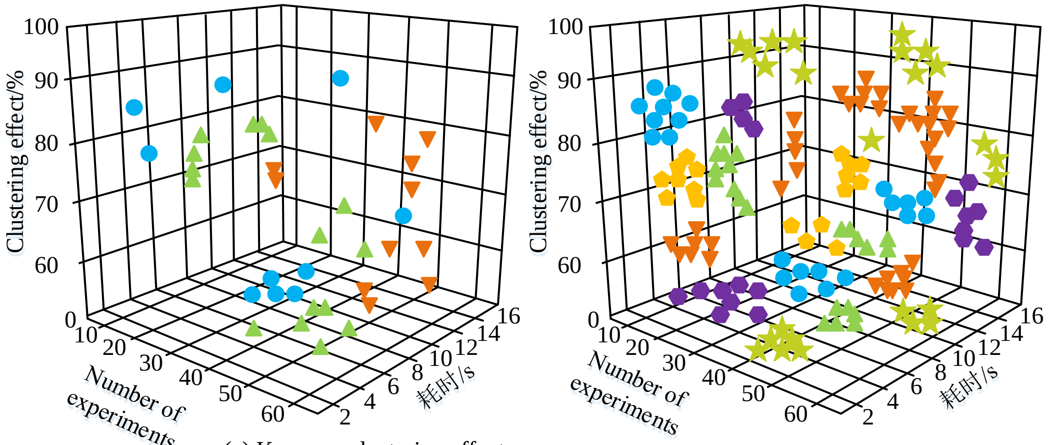
(b) Comparison results of transmission frame rates for device detection and recognition using different methods

Fig. 9. Comparison results of three methods on the number of operations and transmission frame rate.

Fig. 9(a) shows that there is a certain difference in the number of floating-point operations per second among the three methods when detecting devices in the IoT information training room. The budget for improving YOLOv4, SSD, and YOLOv4 is 42.36, 36.25, and 31.83, respectively. Fig. 9(b) shows that the transmission frame rate plays a crucial role in image monitoring and recognition. The improved YOLOv4 has a detection and recognition transmission frame rate of 43.59 for device images, while SSD and YOLOv4 have a detection and recognition transmission frame rate of 38.17 and 24.93 for device images, respectively. This indicates that the management system model has better performance and stronger adaptability in the recognition process of device images.

B. *Application Performance Analysis of Equipment Inspection Management System Model*

To verify the application performance of the IoT information technology TREMS in equipment detection, a study was conducted to compare the clustering results of equipment detection and recognition data, and the clustering effect was used as the validation indicator. The comparison results of K-means and system model clustering performance are shown in Fig. 10.



(a) K-means clustering effect

(b) Detection and recognition system model clustering effect

Fig. 10. Comparison of clustering performance between K-means method and system model.

Fig. 10(a) shows that in the K-means clustering results, a total of three types of device information were found, taking a total of 12.8 seconds. Through analysis, it was found that the clustering method did not have a good overall recognition effect on the equipment in the IoT information training room. Fig. 10(b) shows that during the detection and recognition process of IoT information training room equipment in the system model, a total of 6 types of equipment were identified, which is much higher than the clustering results of K-means. Simultaneously detecting and recognizing takes 9.5 seconds. This indicates that the IoT information training room equipment detection management system constructed through research has a better effect on data clustering and can improve the performance of equipment detection and recognition. To further validate the performance of the system model, environmental conditions were studied as validation indicators. The device detection and recognition performance of the system model was validated in bright and dim environments, as showcased in Fig. 11, which showcases the detection and recognition outcomes of three methods in two different environments.

Fig. 11(a) shows that in a brightly lit environment, all three methods have good performance in detecting and recognizing devices. The improved YOLOv4 achieved a recognition result of 97.05%, SSD achieved a recognition result of 92.46%, while YOLOv4 achieved a relatively poor recognition result of 87.69%. Fig. 11(b) shows that in a dim environment, the detection and recognition outcomes of the three methods on the device are significantly affected. The recognition results of improved YOLOv4, SSD, and YOLOv4 were 46.95%, 38.31%, and 31.28%, respectively. Through comparison, it was found that the detection capability of the equipment management system model has significant advantages compared to the comparative methods. For further verifying the application performance of the system model, the recognition scalability of the system model was analyzed. As shown in Fig. 12, three methods were applied to analyze the clustering ability in device detection and recognition. The curve in the figure represents the iterative process of clustering, the graph on the right shows the clustering model, and the orange in the figure represents the clustering center.

Fig. 12(a) shows that the YOLOv4 method stopped clustering analysis of the data after 31 iterations, and the entire clustering process was relatively scattered, with fewer trajectory points in the orange position. Fig. 12(b) shows that the SSD method stopped analyzing the clustering data after 52 iterations. Fig. 12(c) shows that the improved YOLOv4 method stopped analyzing clustering data at 49 iterations, but it had the most trajectories in the orange region, with only four trajectories outside the orange region. This indicates that the improved YOLOv4 method has a more stable applicability performance in clustering data.

V. Discussion

In the research on the management system of the IoT information technology training room based on the improved YOLOV4 detection and recognition algorithm, there may be challenges such as difficulties in data collection, algorithm optimization, hardware and equipment limitations, data security and privacy issues, and difficulties in verifying practical application scenarios. These challenges may affect the progress of the research and the accuracy of the results, which requires researchers to continuously improve and optimize the research methodology to ensure that the final research results can be effectively applied and verified. Through related research, it is found that the potential future directions of research mainly include algorithm optimization, multi-target detection, behavior recognition, multi-sensor fusion, scenario-oriented optimization, system integration and deployment, and privacy protection and data security. These directions will help to further enhance the intelligence level of the management system of the IoT informatized training room and improve the management efficiency and security.

VI. Conclusion

To enhance the management ability of the IoT information training room management system, a study was conducted on the equipment management system of the training room. It proposed a system model for equipment detection and management in IoT information training rooms on the ground of an improved YOLOV4 algorithm. The results showed that the system model identified a total of six types of devices in the detection and recognition process of IoT information training room equipment, with a detection and recognition time of 9.5 seconds. In bright environments, the improved YOLOv4 achieved a recognition result of 97.05%, while in dim environments, the improved YOLOv4 achieved recognition results of 46.95%, and its adaptability was significantly better than the comparison method. This indicates that the system has high accuracy and robustness in device detection and recognition, and can meet the needs of users for device management. Meanwhile, the system can perform real-time detection and identification of equipment in the training room, thereby improving the ability of equipment management and effective utilization. However, there are still certain shortcomings in the research, and there is still room for optimization of equipment detection and recognition algorithms in the IoT information training room. By optimizing the algorithm, the performance of detection and recognition could be further enhanced, providing more data support for training room managers.

***Abstract*—Autism Spectrum Disorder (ASD) is a permanent neurological maturation condition that impacts communication, social interaction, and behavior. It is also associated with atypical walking patterns. This study aims to create an automated classification model to distinguish ASD children during walking based on the muscles Electromyography (EMG) signals. The study involved 35 children diagnosed with ASD and an equal number of typically developing (TD) children, all aged between 6 and 13 years. The Trigno Wireless EMG System was used to collect EMG signals from specific muscles in the lower limb (Biceps Femoris - BF, Rectus Femoris - RF, Tibialis Anterior - TA, Gastrocnemius - GAS) and the arm (Biceps Brachii - BB, Triceps Brachii - TB) on the left side. To identify the most significant features influencing walking in ASD children, a statistical analysis using the Mann-Whitney Test was conducted. The dataset contained 42 features derived from the analysis of six muscles across seven distinct walking phases throughout a single gait cycle. Following this, the Mann-Whitney Test was utilized for feature selection, uncovering five significantly distinctive features within the EMG signals between children with ASD and those who were typically developing. The most notable EMG features were subsequently employed in constructing classification models, namely an Artificial Neural Network (ANN) and a Support Vector Machine (SVM), aimed at distinguishing between children with ASD and those who were typically developing. The results indicated that the SVM classifier outperformed the ANN classifier, achieving an accuracy rate of 75%. This discovery shows potential for employing EMG signal analysis and classification model algorithms in diagnosing autism, thereby advancing precision health.**

Keywords—Autism Spectrum Disorder; Electromyography signals; Artificial Neural Network; Support Vector Machine; precision health

I. INTRODUCTION

Autism Spectrum Disorder (ASD) is a lifelong neurodevelopmental condition distinguished by speech impairments, atypical behaviors, and difficulties in social communication. Certain children diagnosed with ASD may display motor-related challenges concerning gross motor skills, encompassing issues with motor coordination, muscle tone, arm movement, postural stability and gait. These motor difficulties are linked to the intricate interplay between the neurotransmitter system and specific brain structures, which influence both basic motor skills and sensory-motor performance [1]. Typically, children with ASD display distinct gait patterns, often characterized by clumsiness [2], subtlety, and a wide base [3-4]. In some cases, children with ASD may exhibit toe-walking tendencies, which are more closely associated with motor behavior than language development. Therefore, early detection of ASD can rely on motor indicators [5-6]. Children with ASD may experience motor delays in gross and fine motor skills, affecting their locomotion [2, 7].

Electromyography (EMG) is an experimental methodology employed in the development, recording, and analysis of myoelectric signals. Its application, particularly in the biomedical field, has grown significantly. EMG-based models have provided accurate results in adjusting musculoskeletal geometry, such as muscle-tendon lengths, velocities, and arm moments for individuals with high-functioning hemiparesis during walking [8]. EMG signal analysis can also measure variations in EMG waveforms during different walking conditions, contributing to human-machine interactions and the adaptability of locomotion activities [9]. Research indicates a notable decrease in the activity of hip adductors and hamstring muscles during walking among individuals with wider pelvises [10].

Gait, the method by which walking occurs, can undergo clinical assessment through various means, such as laboratory tests like surface EMG, force plates, and kinematic assessments. The central nervous system plays a pivotal role in transmitting commands that activate the muscular system, ultimately facilitating movement. Measuring muscular activity through non-invasive EMG is a suitable method for characterizing motor activity [11]. The application of EMG in the rehabilitation of central neurological disorders, including autism and cerebral palsy, has demonstrated successful outcomes [12-13].

The perceptron-based technique employs algorithms rooted in the perceptron concept, encompassing single-layered perceptrons, multi-layered perceptrons, and Radial Basis Function (RBF) networks [14]. Between these, Artificial Neural Networks (ANN), a subtype of multi-layered perceptrons, has gained prominence in the analysis of EMG signals in various applications related to human gait, including classification [15, 16], prediction of gait angles [17, 18], and

*Corresponding Author.

muscle activation [15, 19]. ANN algorithms have been developed to bridge the gap between kinematic movement planning and human muscle activation for normal locomotion. These algorithms adjust parameters such as stance width, stride length, cadence and foot clearance [20]. Wang [15] developed an ANN-based model to address the challenge of accurate muscle activation prediction, showing a strong relationship between EMG signals and joint moments [15]. ANN has been widely used for gait pattern classification [17, 21-22]. Jung [22], for example, applied neural networks to classify gait phases for controlling exoskeleton robots, demonstrating superior performance compared to traditional gait classification methods using foot sensors. ANN has also proven effective in distinguishing between healthy individuals and those with pathological gait, as it can identify relevant parameters specific to classification tasks [17]. Thus, ANN is a valuable tool for gait classification.

The Support Vector Machine (SVM) is a widely employed machine learning technique utilized for data analysis, classification and pattern recognition. SVM algorithms have been applied in numerous studies involving EMG signal analysis [23-26]. SVM has shown potential as a classifier for developing fully automatic EMG signal analysis systems for clinical use. It has successfully identified neuromuscular diseases with a classification accuracy of 100% by combining multi-class SVM algorithms with autoregressive (AR) features [24]. SVM algorithms have also excelled in distinguishing various human activities based on EMG signal data. An SVM classifier utilizing AR-based features attained a recognition rate more than 90% for activities like standing still, walking, running and jumping, and surpassing the performance of conventional SVM classifiers [26]. EMG signals have even been used for hand gesture recognition, with bend resistive sensors and SVM classifiers achieving a classification accuracy of 93.33%, making it suitable for communication by soldiers [27].

Notably, there has been limited attention given to the automated classification of ASD children based on EMG signals. Therefore, this study aims to differentiate between ASD and typically developing (TD) children using EMG signal analysis during walking. The lower limb and arm muscles examined in this study include Biceps Femoris (BF), Rectus Femoris (RF), Tibialis Anterior (TA), Gastrocnemius (GAS), Biceps Brachii (BB), and Triceps Brachii (TB). At the conclusion of this study, two classification models, namely ANN and SVM, were trained to distinguish EMG signals between children with ASD and typically developing children. The research seeks to assist medical practitioners in diagnosing ASD in children based on EMG signals from lower limb and arm muscles during walking, as there is currently no definitive medical test for ASD diagnosis [19].

II. Methodology

This section provides an in-depth explanation of the proposed classification system illustrated in Fig. 1. The system comprises four key stages: EMG data acquisition, pre-processing techniques, data selection and extraction methods, and the development of the classification model.

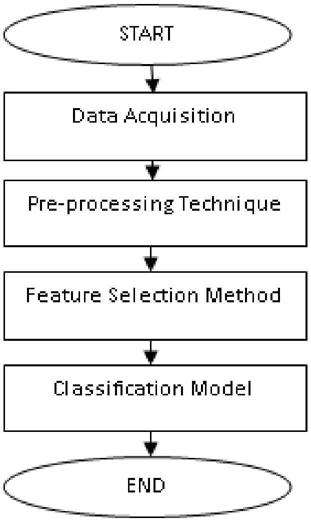

Fig. 1. Overall flowchart.

A. Data Acquisition

In this study, 35 children diagnosed with ASD and 35 typically developing children, aged between 6 and 13 years, with no history of orthopedic surgery, participated. All participants, both ASD and TD, displayed the capability to follow oral guidance given by the researcher. The ASD children were recruited from the National Autism Society of Malaysia (NASOM) center, local kindergarten and primary school in Selangor. The research procedures received ethical approval from the local ethics committee of Universiti Teknologi MARA (UiTM) in Shah Alam, Selangor, Malaysia, from May 29, 2015, to 2023 with updated database. Additionally, all participants were provided with written informed consent forms before participating.

EMG data were collected while the subjects walked naturally at a normal pace. The EMG signals were recorded using the Trigno Wireless EMG System, a product of Delsys Inc. This system is specifically designed for reliable and consistent detection of EMG signals while minimizing noise interference. Each EMG sensor in the system is equipped with a built-in triaxial accelerometer, has a communication radius of 40 meters, and features a rechargeable battery with a minimum runtime of seven hours. The system can transmit data to EMG Works Acquisition and Analysis software and supports up to 16 EMG sensors (measuring 37mm x 26mm x 15mm) and 48 accelerometer analog channels, facilitating integration with Vicon motion capture and data acquisition systems. Furthermore, the system offers full triggering capabilities, expanding the potential for integration with additional measurement technologies.

During data collection, surface electrodes were used, and their placement followed the SENIAM convention system, ensuring that the distance between electrodes did not exceed one-fourth of the muscle fiber length [28]. Specifically, 12 EMG sensors were affixed to the subjects' skin to capture EMG signals from the muscles of BF, RF, TA, GAS, BB, and TB. To secure the electrodes during the experiments, self-adhesive tapes were applied to the skin above the selected muscles, as depicted in Fig. 2.

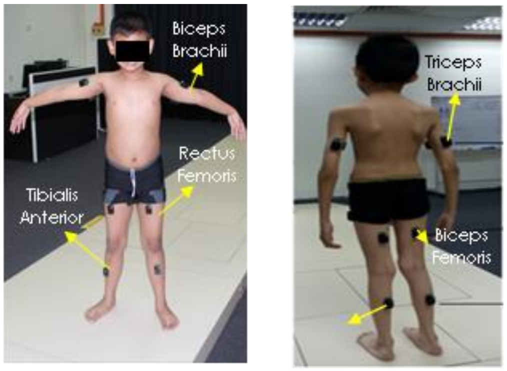

Fig. 2. Electrode placement on subject.

A securely positioned video camera was synchronized with the EMGWorks 4 Acquisition software to allow simultaneous recording of both movement and EMG data. This ensured synchronization in timing between the video camera and the software. To maintain consistency, a sample rate of 2000 Hz was chosen for recording, a rate achievable by all devices in this setup. EMG data for a single gait cycle was extracted and normalized as a percentage of the entire gait cycle duration. In this study, a gait cycle was defined as the duration between two consecutive heel strikes of the same leg. It's important to note that only EMG signals from the left lower limbs and arm muscles were considered for analysis in this study.

B. *Pre-processing Techniques*

At this stage, the raw EMG signals were normalized to a single complete gait cycle to minimize the influence of environmental noise that might have been present during data collection. Time normalization was selected as the most reliable method to enhance the quality of gait cycle analysis for EMG signal data [29]. It's important to note that each subject had varying time frames due to differences in walking speed and step length. To address this, EMG signal data for each muscle was controlled to fit within one gait cycle, ensuring consistency and obtaining standardized EMG signals for gait analysis.

In this study, a complete gait cycle was defined as the duration from the left foot's initial contact to its terminal swing. This definition was applied due to the generally insignificant differences in gait parameters between the left and right legs during normal walking [30]. The EMG signals obtained via the EMG Works Acquisition software and the duration of one gait cycle from the video camera were synchronized.

Fig. 3 and Fig. 4 illustrate the phases of the gait cycle and arm movements during normal walking, respectively. During walking, the ipsilateral arm and leg exhibit an anti-phase relationship, with the left leg in flexion and external rotation while the left arm is in internal rotation and extension. When one arm moves forward, the corresponding leg and torso move forward, and this relationship alternates between the left and right sides [31]. As walking speed increases, the contribution of active muscles to arm movements increases, while the total energy consumption decreases [31]. A previous study [32] has demonstrated that arm swinging during walking contributes to the stability of human gait.

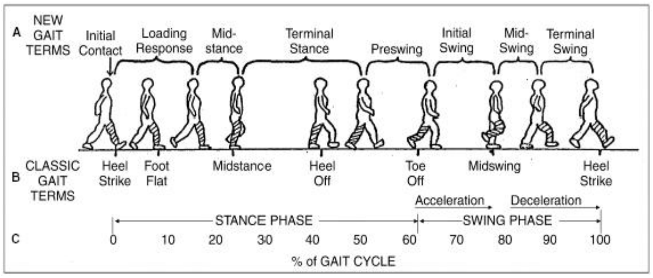

Fig. 3. Phases of one gait cycle.

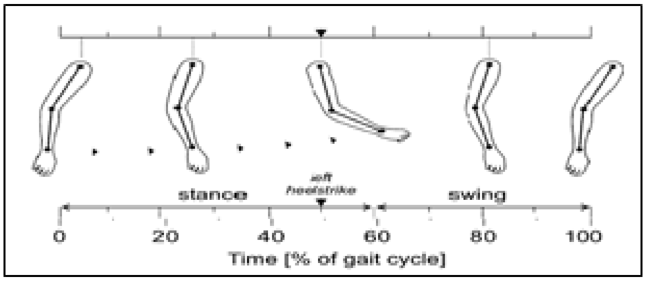

Fig. 4. Arms swing during normal walking [34].

The gait cycle normalization in this study involved two steps. The first step was time-normalizing the EMG signal data for the relevant muscles of all subjects to one gait cycle, expressed as a percentage. The time taken to complete one gait cycle in the recorded video was equated with the time frame of the acquired data. The 100% gait cycle represents the time taken for one complete gait cycle [33]. The second step involved averaging the normalized EMG signal data for the same muscle across all subjects. The normalization process for EMG signal analysis was conducted using Microsoft Excel software version 2013 (Microsoft Corp., USA). This study analyzed the tested muscles across seven gait phases: loading response (LR) spanning 0% to 10% of the gait cycle, mid-stance (MST) covering 10% to 30%, terminal stance (TST) ranging from 30% to 50%, pre-swing (PSW) encompassing 50% to 60%, initial swing (ISW) spanning 60% to 70%, mid-swing (MSW) ranging from 70% to 90%, and terminal swing (TSW) from 90% to 100% of the gait cycle.

C. *Feature Selection Method*

The feature selection process involved identifying a new set of muscles comprising the most significant features to differentiate between ASD and TD children [34], subsequently enhancing the classification performance. Initially, the normalized EMG data were subjected to an examination of normality using the Shapiro-Wilk test. This test was employed to assess whether the dataset exhibited a normal distribution or not. Given the relatively small number of subjects, the Shapiro-Wilk test is considered an appropriate method to determine the normality of the data. This test is particularly accurate and reliable in assessing the normality of scores [35]. Subsequently, non-parametric testing was applied since the data distribution in this study was found not to be normally distributed [35]. The study utilized the Mann-Whitney test with a 95% confidence interval to explore significant features within the EMG data of muscles including Biceps Brachii (BB), Rectus Femoris (RF), Gastrocnemius (GAS), Biceps Femoris (BF), Tibialis Anterior

(TA), and Triceps Brachii (TB) during walking, comparing children diagnosed with ASD and typically developing children.

D. Classification Model Development

This research presented two classification models: the Artificial Neural Network (ANN) and the Support Vector Machine (SVM); with the aim of distinguishing between ASD walking patterns and normal walking patterns. The computation of these algorithms was carried out using Matlab software version R2014a for evaluation. The input data for both classification models were derived from the significant muscle features that differed between ASD and TD children. The division of input-output data was based on the cross-validation method, where the output represented the classification group for each condition, with '0' indicating ASD and '1' indicating TD children.

One of the most commonly used techniques to assess the performance of the proposed classifier is stratified k-fold cross-validation. In this study, five-fold cross-validation was conducted. This means that the original sample was randomly divided into five equal-sized subsamples. One of these subsamples was used as the training data, while the remaining four subsamples were retained as validation data to test the model. This process was repeated five times, corresponding to the number of folds. Each observation was used for both training and validation, but only once for validation in each fold [36]. It is worth noting that the use of K-fold cross-validation is a reliable method and has the potential to provide meaningful results for estimating expected utilities [37].

For the ANN classification model, the number of hidden neurons in the hidden layer was set to achieve the best accuracy for adjusting the network weights. Scaled Conjugate Gradient (SCG) training algorithm, the optimum number of 10 neurons are found to be the optimum model accuracy. The selection of the network architecture involved testing the performance of the network by varying the number of hidden neurons from 1 to 11 in two-interval increments. The scaled conjugate gradient method was employed to train the network, which updates weight and bias values.

Regarding the SVM classification model, the input data were trained using name-value pair arguments for the kernel function. In this study, the linear kernel function, also known as the dot product, was used to obtain the best accuracy. Subsequently, each row of the sample data was classified using the information in the SVM classifier structure. The performance of both the ANN and SVM classification models was evaluated using a confusion matrix, which included measures such as accuracy, precision, sensitivity, and specificity.

III. Results and Discussion

In this segment, we will examine the acquired results and initiate a discussion. A total of sixty children took part in this study, with 35 diagnosed with ASD and 35 TD children. The demographic information for both the ASD and TD groups is outlined in Table I. Notably, both groups exhibited a similar mean age, with ASD children having a mean age of 8.10 and TD children having a mean age of 9.40. However, the age variation was slightly wider among TD children, ranging from 6.30 to 11.06 years, compared to ASD children, whose ages ranged from 6.30 to 10.50 years. Correspondingly, TD children had a higher mean height and weight compared to ASD children, with mean heights of 128.5 cm and 124.7 cm and mean weights of 30 kg and 28.8 kg, respectively. The range of heights for TD children was more extensive, spanning from 95 cm to 159.5 cm, resulting in a higher standard deviation (SD) of 18.07, compared to ASD children's SD of 13.26. However, the weight variation among both ASD and TD children exhibited a comparable pattern, with standard deviation (SD) values of 11.14 and 11.60, respectively. It is noteworthy to mention that a substantial proportion of the ASD subjects approached by the researcher were boys, as depicted in Fig. 5. Approximately 60% of the ASD children involved in this study were male. This observation may be attributed to the fact that diagnosing autism in boys is often more straightforward than in girls. This finding aligns with previous research, which has consistently shown that ASD is nearly five times more common in boys than in girls [38].

The outcomes of the Mann-Whitney test unveiled noteworthy distinctions ($p < 0.05$) in muscle activation between these two cohorts of children, as succinctly outlined in Table II. Specifically, five muscles were found to be significantly useful in distinguishing between 'Normal' and 'Autism' categories. The p-value for the TA (30%) muscle was found to be 0.017, whereas for the BB the corresponding p-values were 0.021 (10%) and 0.018 (80%), respectively. Meanwhile, the GAS muscle displayed p-values of 0.049 (50%) and 0.034 (60%) respectively. Drawing from the results detailed in Table II, it can be deduced that there exist notable distinctions (highlighted in gray) in the activation of lower limb and arm muscles between ASD and TD children during walking, particularly in the TA, GAS, and BB muscles.

TABLE I. SUBJECTS DEMOGRAPHIC DATA

Subjects	Age (years)		Height (cm)		Weight (kg)	
	Ave	SD	Ave	SD	Ave	SD
ASD	8.10	2.20	124.5	13.26	27.5	11.14
TD	9.40	2.67	128.5	18.07	30.0	11.60

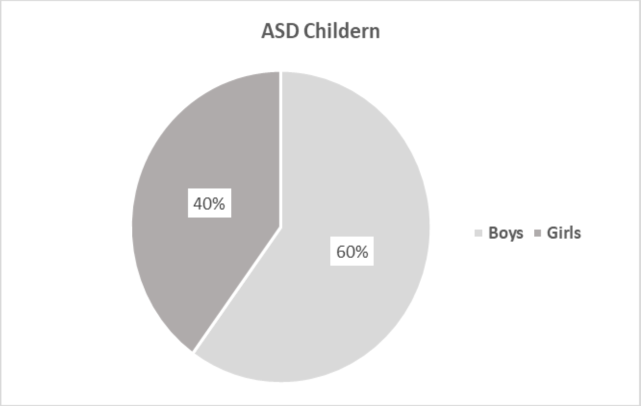

Fig. 5. Gender data for ASD children.

TABLE II. RESULTS FROM MANN-WHITNEY TEST

Gait Cycle	LR 10%	MST 30%	TST 50%	PSW 60%	ISW 80%	MSW 90%	TSW 100%
BF	0.688	0.494	0.495	0.441	0.415	0.321	0.54
RF	0.925	0.803	0.75	1.001	0.651	0.635	0.232
TA	0.974	0.017	0.273	0.534	0.477	0.852	0.69
GAS	0.136	0.162	0.048	0.033	0.305	0.182	0.52
BB	0.02	0.401	0.173	0.864	0.002	0.83	0.491
TB	0.475	0.277	0.964	0.858	0.573	0.682	0.284

The performance of the ANN classifier was assessed using a confusion matrix, as depicted in Table III. The confusion matrix reveals that out of the ASD children group, 3 data points were accurately classified as belonging to the ASD group, and 5 data points from the TD children group were correctly classified as TD. However, there were 3 instances where data from the ASD children group were erroneously classified as TD children, and only 1 data point from the TD children group was incorrectly categorized as ASD children. The accuracy of the SCG ANN classifier is calculated at 66.7%. Additionally, the classifier exhibited a specificity of 91.7%, sensitivity of 79.2%, and precision of 90.5%.

The performance of the SCG ANN classification model was calculated based on the disparity between the actual and predicted gait parameters derived from the EMG signal data. As illustrated in Fig. 6, the x-axis denotes the number of hidden neurons, while the y-axis represents the MSE values. The highest error was observed with four hidden neurons, resulting in an MSE value of 0.9482. In contrast, the lowest error was achieved when using 10 hidden neurons, yielding an MSE value of 0.1542. Notably, in this study, the SCG ANN system with 10 hidden neurons exhibited the most favorable performance among the classification model algorithms. The distribution of error within a neural network serves as a valuable area for exploration and is recommended for determining improved neural network performance criteria and addressing conflicting classification results [39].

TABLE III. CONFUSION MATRIX FOR SCG ANN CLASSIFICATION MODEL

	Positive	Negative
Positive	3 (TP)	1 (FN)
Negative	3 (FP)	5 (TN)

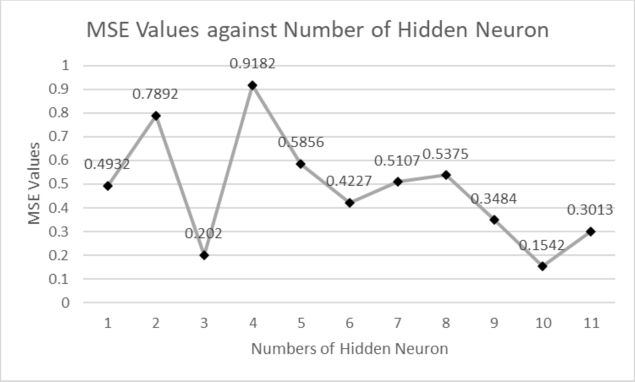

Fig. 6. MSE value in testing performance.

TABLE IV. CONFUSION MATRIX FOR SVM CLASSIFICATION MODEL

	Positive	Negative
Positive	7 (TP)	2 (FN)
Negative	1 (FP)	2 (TN)

The performance of the SVM classifier was assessed using a confusion matrix, as presented in Table IV. The confusion matrix indicates that 7 data points from the ASD children group were accurately classified as belonging to the ASD group, and 2 data points from the TD children group were correctly classified as TD. However, 1 data point from the ASD group was erroneously classified as TD, and 2 data points from the TD group were incorrectly categorized as ASD. With an accuracy of 75%, the SVM classifier demonstrates robust classification capabilities for distinguishing between ASD and TD children. Additionally, the classifier exhibited a specificity of 50%, sensitivity of 87.5%, and precision of 78%.

Fig. 7 provides a comparison of the performance measures of the SCG ANN and SVM classifiers. Notably, the ANN classifier outperformed the SVM classifier in terms of precision and specificity, achieving values of 90.5% and 91.7%, respectively. Conversely, the SVM classifier surpassed the SCG ANN classifier in terms of accuracy and sensitivity, with values of 75% and 87.5%, respectively. It is worth mentioning that specificity is particularly valuable when interpreting positive test results to estimate an individual's probability of having a disease [40]. Overall, both developed classifiers demonstrated impressive performance with consistent rates of accuracy, sensitivity, specificity, and precision.

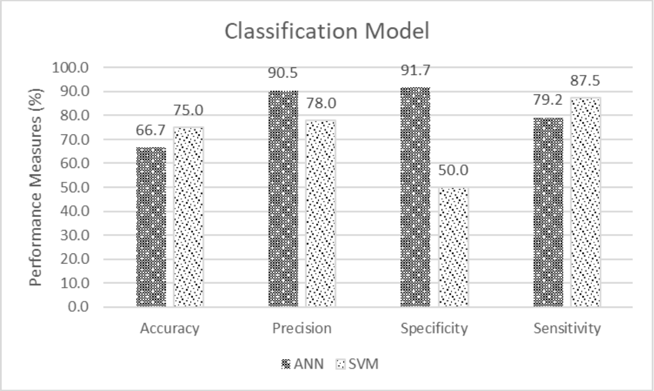

Fig. 7. Comparison of performance measures for ANN and SVM classifier.

As previously mentioned, the primary objective of this investigation was to categorize ASD and TD children by analyzing EMG signals recorded during walking. Despite its inherent challenges, the analysis of EMG data provides valuable insights into diagnosing ASD children through the assessment of muscle activation during walking. In the initial phase of the study, a database of EMG signals for both ASD and TD children during walking was established through the data collection process. The Mann-Whitney test, with a 95% confidence interval, was utilized to scrutinize significant differences in muscle activation among BF, RF, TA, GAS, BB, and TB muscles in both groups of children. The analysis of EMG signals has emerged as a promising diagnostic approach for identifying autism based on muscle activation patterns during walking.

The subtle motor deficits in individuals with autism can manifest as abnormal gait patterns, with variations in muscle extension being a contributing factor [41]. Difficulties in walking among children with ASD may arise due to heightened variability in velocity and the manifestation of irregularities in stride length and duration [42]. Additionally, a study by [43] demonstrated that movement disorders were observable in ASD children, characterized by irregular steps and vigilant gait during normal walking, as observed in video recordings during experiments. This study has revealed that three muscles—TA, GAS, and BB—were affected during walking in ASD children. The TA muscle, in particular, showed significant activation differences between ASD and TD children [44]. This discovery aligns with earlier research indicating that body movement and arm swing during walking can amplify TA muscle activity [45].

Similarly, while the walking patterns of ASD children may appear relatively normal on the surface, many of them exhibit subtle gait abnormalities that can impact lower limb muscle activation [41]. The BB muscle exhibited significant disparities between ASD and TD children during walking, likely attributable to its role as a primary mover during the concentric phase [45]. Consequently, the BB muscle in ASD children was notably affected and distinct from that in TD children during walking. These results substantiate the study's hypothesis, which proposed that EMG data from ASD children during walking could be precisely classified using SCG ANN and SVM classifiers.

As far as we are aware, our study constitutes the initial exploration into the classification of ASD and TD children based on muscle activation in both lower limb and arm muscles during walking. The results demonstrate that the proposed method successfully classifies ASD and TD children, with high accuracy, specificity, sensitivity, and precision. This research has significant implications for both rehabilitation and clinical applications. The experimental results validate the accomplishment of the study's objectives, and the selected parameters for investigating gait in ASD children during walking have been validated by previous researchers.

The developed classification model system exhibits robust performance, achieving high accuracy rates, specificity, sensitivity, and precision. While this study has succeeded in classifying ASD and TD children, future research may consider classifying the severity of ASD conditions, as suggested by [46]. Additionally, expanding the sample size of ASD participants could further validate the EMG signal patterns observed in this study.

IV. Conclusion

In conclusion, this study has revealed significant differences in muscle activation patterns in the lower limbs and arms of individuals with ASD during walking, focusing on muscles including BF, RF, TA, GAS, BB, and TB. Notably, the TA, GAS, and BB muscles exhibited distinctive features between ASD and typically developing individuals. Two classification models, SCG ANN and SVM, were then introduced to discern these features from the EMG signals. Following classifier training, the SVM model emerged as particularly promising for distinguishing between ASD and TD children. These findings underscore the significant characteristics present in EMG signals between ASD and TD individuals, affirming the efficacy of classification model algorithms in differentiation. This discovery holds substantial potential for automating ASD screening and diagnosis, facilitating the design of more effective treatments and rehabilitation strategies by parents and therapists, thus advancing precision health.

Acknowledgment

The authors wish to thank Institute of Research Management Centre (RMC) and College of Engineering, Universiti Teknologi MARA (UiTM) Shah Alam, Malaysia for the financial support, instrumentation and experimental facilities provided. The authors also express gratitude to the National Autism Society of Malaysia (NASOM), all participants, their families and caretakers for their invaluable contributions to the study.

Improving Load Balance in Fog Nodes by Reinforcement Learning Algorithm

Hongwei DING, Ying ZHANG*
Hebei Software Institute, Hebei, Baoding 071000, China

***Abstract*—Fog computing is a distributed computing concept that brings cloud services out to the network's edge. Real-time user queries and data streams are processed by cloud nodes. Tasks should be evenly divided among fog nodes in order to maximize speed and efficiency, optimize resource efficiency, and reaction time. Real-time user requests and data flow processing are done by cloud nodes. Nodes in a network must share responsibilities in a balanced manner in order to maximize speed and efficiency, resource efficiency, and reaction time, hence in this article, a novel approach is presented. When it comes to fog computing, load balancing essential suggested to be improved. According to the suggested algorithm, a task submitted to the fog node via a mobile device would be processed by the fog node using reinforcement learning before being passed on to another fog node. Neighbor or let the cloud handle it. According to the simulation findings, the suggested algorithm has achieved a reduced execution time than other compared approaches by properly allocating the work among the nodes. Consequently, the suggested technique has reduced the chance of incorrect job assignment by 24.02% and the response time to the user by 31.60% when compared to similar methods.**

Keywords—Fog computing; resource allocation; reinforcement learning; delay; load balancing; fog nodes

I. Introduction

Load balancing is a fundamental concept utilized in cloud settings for allocating computing resources among servers and devices [1]. By balancing the use of hardware, network, and software resources, load balancing aims to maximize system performance, increase efficiency, and provide the best possible user experience [2]. Reinforcement learning algorithms are an artificial intelligence approach to load balancing that provides automatic and adaptive performance enhancement [3]. IoT devices usually assign task processing to the nearest fog node. In this case, it's possible that certain fog nodes take on more tasks than others and eventually become overburdened. In order to avoid this, load balancing techniques are used to spread tasks among fog nodes equitably [4]. Fog nodes are distributed throughout the environment [5]. Two distinct forms of load balancing are utilized in dispersed environments: static load balancing and dynamic load balancing. When choosing a load balancer, static load balancing ignores the target fog node's state [6]. On the other hand, dynamic load balancing chooses which fog node to route traffic based on its present status [7]. Dynamic load balancing is applied in this post. Load balancing among fog nodes reduces expenses, latency, and user response times while simultaneously enhancing resource productivity, efficiency, resource conservation, and real-time event detection [8]. Numerous load balancing techniques have been presented recently, and they are all effective in certain system situations. Meta-heuristic or hybrid load balancing algorithms may be taken into consideration, depending on the approach used [9]. There are two types of heuristic algorithms: static and dynamic. Initiatives entail limitations intended to determine the best course of action for a certain problem [10]. These algorithms have an advantage over meta-heuristic algorithms in that they are easily implemented and yield good results. Meta-heuristics require finality because of the enormous immensity of their solution space and the fact that they are completely random processes [11]. The type of problem, how it was initially set up, and the strategy employed to find a solution all have a big impact on how long it takes to resolve. In terms of execution time and cost, coupled algorithms—which are produced by combining numerous meta-heuristic heuristic algorithms—are more efficient than other algorithms [12]. Through the use of reinforcement learning techniques, the fog system can automatically and dynamically adapt to changes in compute load and service requirements [13]. Based on an assessment of the present status of the system and clients, the fog system can determine whether to add or subtract computing resources from a server, shift load from busy servers to freer servers, or assign resources to services and requests according to their importance. The system will be able to use the greatest computing resources and adapt dynamically to the different needs of users and services by employing this technique, which will significantly improve load balancing in fog computing.

Due to the distributed nature and dynamics of fog computing, however, conventional load balancing techniques become less effective, necessitating the development of an algorithm that can change with the context through time. To achieve this goal, a decision-making procedure based on reinforcement learning is suggested in this article to locate sparse fog nodes [14].

The agent chooses the right fog node based on the experiences it obtains from the environment in each scenario, which makes the proposed technique, the delay may be greatly reduced. Additional and time-consuming calculations are also removed in the proposed method of this article. Reinforcement learning for load balancing is superior to conventional approaches in that it not only simplifies the algorithm framework without taking any network model assumptions into account, but also converges to the best policy in polynomial time. The collected findings demonstrate that, when compared to the compared approaches, the suggested load balancing method greatly decreases the lag and reaction time to the consumer. This article's conclusion is structured so that it is discussed in the section of current related research in the area of load balancing in fog computing.

Section III explains the concept of the proposed system, the reinforcement learning technique, and how to find the system's delay. The suggested load balancing strategy is presented in Section IV. The evaluation and comparison of the simulation results with earlier techniques are done in Section V. Section VI will conclude with recommendations for additional research.

II. Related Work

In fog computing, jobs are typically assigned to the nearest fog node by mobile users and IoTs devices. These devices are frequently mobile, therefore depending on where they are in the network, various important nodes may have varying loads. Due to this problem, some fog nodes may be overburdened while others may be idle or underloaded in terms of the distribution of work. Methods to solve the load balancing issue in the fog computing environment have been presented by some authors. These actions can be divided into various categories [15].

Here, prior research on task delegation in which nodes need to be aware of each other's computational capabilities will be examined. To discover the best loading decision in the presence of an uncertain reward model and transition probability, [16]. According to the resource capacity, fog nodes in the presented process can assign an ideal number of incoming jobs to a free neighboring fog node. This is done to cut down on processing time and potential overhead [17]. They looked into load balancing on several kinds of computing nodes before officially presenting the fog computing system's structure. Then, they developed a matching resource allocation strategy for fog environments, which combines static resource allocation with dynamic service transfer, to accomplish load balancing in fog computing systems. The min-min method was developed by [18] to take network resources into account. When sending a job to a cluster node that is overloaded, factors such the distance between the cluster and the node next to it, the amount of tasks that are waiting in each cluster's queue, and the distance between the cluster node and the closest cloud data center are taken into account. Researchers suggested the min-min method in [19] and put it into practice inside each cluster while taking network resources into account. In this method, a neural network is used to evaluate the fog node's current capacity. The Internet of Things gadget transmits its work to the cloud if it doesn't get the necessary resource. In this study, a four-layer architecture for load balancing and task scheduling is proposed. The Internet of Things is a component of the top layer, where a lot of data is generated and sent at once. The jobs are divided into two categories important and less important in the second layer via a dual fuzzy logic method. The user-proximate nodes with the lowest load are given priority for task execution [20].

Other works are predicated on the knowledge of the node's load or the prediction of its future load. This algorithm continuously gathers network traffic, server load information, and control information. By merging fog computing and software-based networks, [21] devised a load balancing technique based on reinforcement learning. In order to offer the greatest amount of access to the resources, this algorithm analyzes the behavior of the network and divides up the work by considering network's current load and forecasting its future load. The network is adaptable thanks to this architecture's dispersed nature. In this article, a threshold limit is taken into consideration to implement the load balancing method, and if the server load exceeds 75%, the load balancing algorithm is called. In order to achieve better load balance, [22]. It also applies reinforcement learning to handle the task loading problem. In this study, Deep Q-Learning is enhanced using an LSTM network. The quantity of input data needed for the sub-task, the downlink bandwidth, the amount of output data generated by the sub-task, and the load on each server make up the state space in this article. The action space is a vector with m + 2 zero- and one-dimensional dimensions. A cloud server and a mobile device are included in the m and 2 edge servers. Any of the same folders can be used to download data to the server. The three variables of load balance, cost, and energy consumption are taken into account by the reward function. In study [23], Berardi and colleagues address the issue of resource management by presenting two distributed load balancing algorithms, Sequential Forwarding and Adaptive Forwarding, which are intended to handle heterogeneity. They do this by assigning jobs to nearby nodes. According to the threshold limit and the maximum number of steps, M, a task is delivered at random to nearby fog nodes using the first approach, known as the Sequential Forwarding method, until it reaches the correct node. The second method, known as the Adaptive Forwarding method, is suggested since it is difficult to define the working parameters and M. This method automatically and conditionally updates these parameters. For a fog computing environment, the research in [24] presented a load balancing method that works well for medical applications.

The techniques described in earlier studies demonstrate that the majority of these techniques require knowledge about the nodes' capacity or load in order to make decisions [25]. This effort necessitates a number of time-consuming computations that add latency and raise network traffic burden shall be. Additionally, in the majority of these approaches, the load balancing operation and load distribution are often performed by a single node. In contrast to other works, this one uses a different decision-making procedure because, according to the suggested method, the fog node decides on processing and task assignment only after gathering information from the delay and reward during the learning period and after taking into account its own capacity and the positions of other nodes [26]. The proposed solution is intended to address a subset of difficulties, although its use is not constrained to a particular scenario. Additionally, the strategy suggested in this article is dynamic and adapts to the circumstances of the agent's goals.

III. System Model

The description of the suggested system and the reinforcement learning algorithm will be covered first in this part. The load balancing problem formulations are then provided using reinforcement learning.

A. System Description

The paper takes into account a four-layer design for the suggested system, which includes Internet of Things, fog nodes, proxy servers, and cloud data centers, as shown in Fig. 1. The Internet of Things layer, which contains various end devices including wireless sensor nodes, mobile devices, etc., is the initial layer in this system. These gadgets can transmit data to nearby fog nodes because they are directly connected to them. The fog layer, which is the second layer, is made up of extremely intelligent equipment like routers, switches, and gateways that take in and process data from endpoints [27]. The cloud data center layer, which consists of numerous computers and data centers, is the fourth tier. This structure eliminates the requirement for data transfers to the central cloud by allowing data and information processing to take place locally in fog nodes [28]. Due of their limited computational power, mobile devices in the proposed system assign fog nodes within their range to process a portion of the work (a virtual reality game). Since there is no master node or controller in this system that keeps track of the fog nodes' status and the external conditions, it is up to the fog nodes to collect data and make decisions [29], [30].

The proposed system operates as follows: On the user's smartphone, an Android application called Tractor Beam2EEG (a type of game where players compete against each other) is running. This application demonstrates how the human brain and the computer interact. Each player must have a headset attached to his smartphone in order to play this game. This application continuously monitors the signals picked up by the headset, the processing, and the mental state of the user. Processing the software can need a lot of processing power. Therefore, in this article, the program is broken into multiple pieces known as subtask 3 in order to enhance the processing time, transfer time, and boost the usage rate of network resources. The following dependencies, depending on virtual reality game tasks, are presented in this article. The software is divided into five subtasks, as illustrated in Fig. 2: EEG, Client, Actuator, Concentration-Calculator, and Connector. These subtasks' data are interdependent.

The major processing modules in this application are the Client, Concentration-Calculator, and Connector modules. In order to receive the EEG signals, the Client module interfaces with the sensor. Once it has received the signals, it checks their levels and, if they are constant, passes them to the Concentration module. Calculator that assesses the user's mental state based on the signal it receives and computes their level of concentration [31]. The Client module is then informed of the computed concentration level by the Concentration-Calculator module. The Connector module connects the game amongst several participants who may be present in geographically dispersed areas by operating on a global scale. The Client module of each connected user receives a constant stream of information from the Connector about the game's current condition [32]. Numerous modules can be kept on mobile devices due to the fact that these sub-tasks require less computational complexity and data transfer, while those that demand greater computing resources can be assigned to the cloud provider's nodes. The loop that transforms the user's mental state into the game's state on the mobile device's screen is the most crucial control loop in this application. The mobile device and the device that houses the user's brain state calculation module must communicate in real-time for this to work. The user experience is significantly impacted by latency in this loop because it affects the entities that the user interacts with directly [33].

The computing modules should be as near the data sources as possible to minimize the latency in data transmission between units. The EEG, Client, and Actuator modules of this article's suggested design, as illustrated in Fig. 3, are connected to mobile devices. Each module in the loop processes the program, forwarding the processed data to the subsequent module, and so on, until the Actuator module in the mobile device receives the program's final results [34]. Each fog node has an unpredictable amount of mobile devices connected to it at any one time given time due to the dynamics of the environment, and it is possible that some fog nodes acquire more subtasks than others and eventually become overloaded. To prevent this, fog nodes are evenly divided into sub-tasks using load balancing techniques.

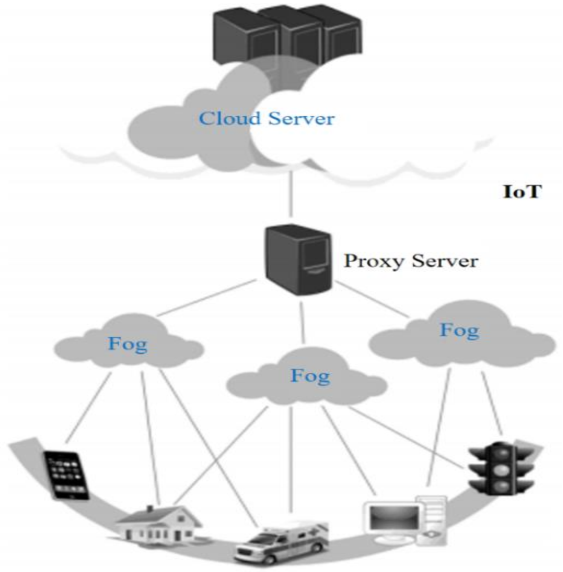

Fig. 1. Architecture of fog computing layers.

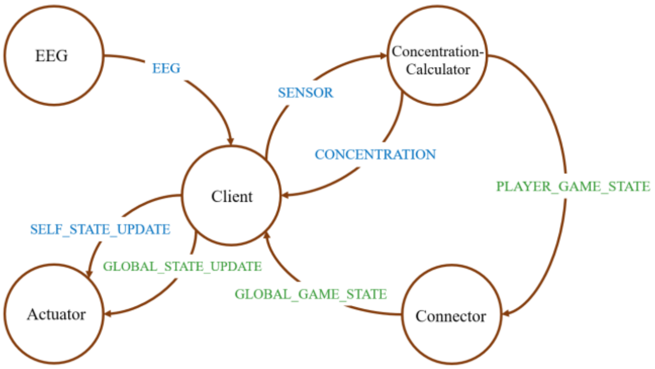

Fig. 2. Subtasks and their dependencies.

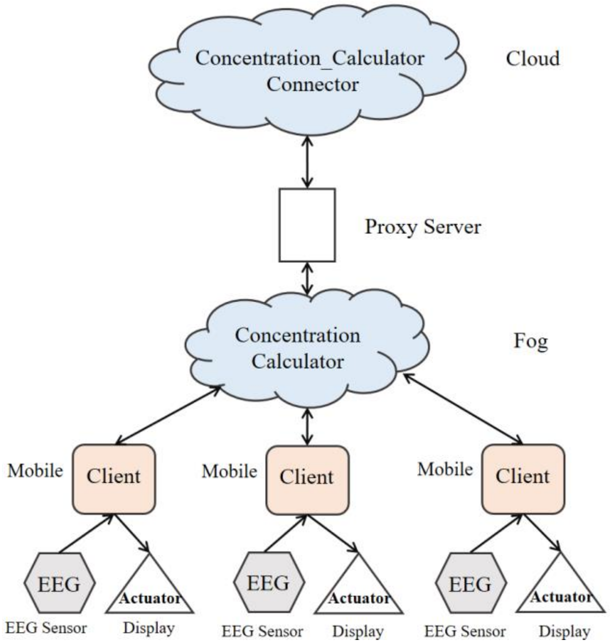

Fig. 3. Module placement in various devices.

The load balancing algorithm's primary goal in a fog computing setting is to increase the user reaction time by dispersing the system's total load so that it can continue to operate at its best under dynamic system settings. This article's goal is to reduce network resource loss, user response time, and delay by applying the reinforcement learning method to the fog nodes. When a fog node receives a subtask, it employs a reinforcement learning algorithm to decide whether to process it independently, pass it on to another node in the area, or send it to the cloud to be processed faster.

B. *Reinforcement Learning Algorithm*

Supervised, unsupervised, semi-supervised, and reinforcement learning are the four main types of machine learning algorithms. Numerous labeled input data are needed for supervised learning in order to train the system. Unsupervised learning, as contrast to supervised learning, involves learning from unlabeled events in order to uncover hidden patterns in the data. Unlabeled data and labeled data are used in supervised fog learning to increase learning accuracy [35]. The agent can learn the best actions from the environment through reinforcement learning. Through environment exploration, trial and error, and use of the incentives provided by the environment, this learning is accomplished [36]. In this article, load balancing is accomplished by Q-L algorithm. The proposed approach formulates the load balancing problem as a Markov decision process (MDP), where the fog node takes a decision after learning the state of its surroundings and is rewarded by it. Experience is the end result of trial and error and is characterized by the four states of the present state, action, reward, and next state [37].

1) Policy: The agent's behavior can take one of two forms when it comes to policy: active policy, in which the agent learns the value function in accordance with the performance that the current policy has caused, or passive policy, in which the agent learns in accordance with the action that the policy has caused [38]. The function learns the value, the other is obtained, and it is defined. The Q-Learning algorithm is a passive algorithm with a greedy learning strategy for the Q value.

2) Value function: The learner function's reward function sets the objective, and the closer it gets to the target, the more reward it receives. The value function in reinforcement learning, on the other hand, derives a value as Eq. (1) for each state and has a long-term perspective. The closer to the objective this value is, the higher it is.

$$v*(s) = max \sum_{s',r} p(s',r|s,a)[r + \gamma v*(s')] \quad (1)$$

The discount factor, often known as $0 < \gamma < 1$, in this context determines the significance of potential benefits in the future and the decision made right now is more important than those made in the future.

In states, the agent takes action (A) to change the environment from its present state to a new state (b) and receives a reward (r) for his efforts; both factors influence his future decision-making.

3) Model: The reinforcement learning problem has a random model with non-deterministic states. Going from one state to another and taking any action are both possibilities [39].

Reinforcement learning has thus found various uses in optimization in the dynamic, unpredictable, and changing environments of fog and clouds. Additionally, it might be a good way to evenly distribute loads among fog nodes [40].

C. *Formulation of the Problem*

Discrete time stochastic control is what the MDP is. One method for solving MDP is reinforcement learning, which in turn makes use of dynamic programming. To achieve the target performance, the suggested load balancing problem is expressed as an MDP. For the suggested load balancing problem, the fours $< S, A, P, R >$ are defined below, which are typically included in MDP:

1) The state space $S = \{s\,(C, Q, N)\}$ represents the relationship between the fog node's capacity (C), the size of its upstream queue (Q), and the number of mobile devices (N) linked to the fog node.

The Q-L algorithm bases decisions on the system's present state. Many of the earlier techniques for defining the state space call for knowledge of the nearby nodes' capacity [41]. However, the state of the system is solely specified in the proposed method based on the state of the decision-making fog node, which forces decisions to be taken without knowledge of the states of the surrounding nodes.

2) In the action space $A = \{a = (n)\}$, n represents the choice of a fog or cloud node to be assigned to the subtask.

3) P: A number between zero and one represents the transition probability. In order to be in state s, the criterion is to have the probability distribution of the transition $P(s'|s, a)$ to the next state s', with the action choice.

4) R: The state's activity is directly linked to the reward. The primary objective is to minimize processing delay and overhead probability while maximizing long-term value in each system by selecting the appropriate action.

As was already noted, there are various subtasks within the task (virtual reality game). The sum of all linked sub-tasks' transmission and processing delays across all relevant devices is the task execution delay and is determined as follows:

$$T_{task} = t_{uot} - t_{in} \tag{2}$$

where, $t_{out} and\ t_{in}$ represent, respectively, the entry time and exit time of a task in the suggested system. Since the processing and transmission delays in mobile devices are relatively constant, this article solely calculates the processing delays of the Concentration-Calculator subtask in fog or cloud nodes and the subtask in the mobile device to compute the delay of task execution [42]. It is seen as having a constant value. The suggested method uses fog nodes to perform the Q-Learning algorithm, Additionally, the subtask's processing delay is equal to the negative of the reward function (R $R(s,a)$), which is allocated to the fog node. The longer the processing delay of the subtask, the better. As a result, $R(s,a)$ will be lower than expected. The calculation looks like this.

$$R(s,a) = -T_{Subtask} \tag{3}$$

This refers to the calculation subtask that the fog node is tasked with performing, where $T_{Subtask}$ is its processing delay. The symbols used to evaluate the system and the delay calculation formulas are listed in Table I.

TABLE I. SYMBOLS USED TO EVALUATE THE SYSTEM AND DELAY CALCULATION FORMULA

Parameters	Description	Value
W	How many smaller jobs ran on the node	-
L	Subtask data size	3500
B	Bandwidth per node	10000
$d_{i,j}$	How far apart are the nodes i and j?	-
β_1	Path loss constant between two nodes	10^{-3}
β_2	path loss power	5
P	Power transfer between nodes	20 dBm
N_0	Spectral density of noise power	175 dBm /Hz
I	Quantity of subtask-specific commands	200×10^{6}
Cycle	The amount of CPU cycles used by each instruction	5
f	Fog node cpu speed, cloud cpu speed	2800 44800
N	Just how many fog nodes	4
n	The frequency with which a state is displayed	-
α	Rate of learning	2/n
y	reduction element	0.8

The subtask's processing lag depends on whether its processing is done in the fog the node that the mobile device sent the subtask to $(FN-I)$ or whether it is handed over to the neighboring fog node $(FN-J)$ or the cloud.

- The following formula determines the execution delay of the subtask, which is equal to Subtask if the subtask is processed by $FN-I$.

$$T_{Subtask} = \frac{I\times Cycle\times W}{f} \tag{4}$$

- If the subtask is delegated to $FN-I$ or Cloud for processing, $T_{Subtask}$ is calculated as follows.

$$T_{subtask} = t_{W_i} + t_{c_{ij}} + t_{E_j} + t_{W_j} + t_{c_{ji}} \tag{5}$$

In this regard, t_{W_i} and t_{W_j} are the waiting delay of the subtask in the I-FN sending queue t and the J-FN sending queue or cloud is affected by the subtask's waiting delay. $t_{c_{ij}}$ denotes the time it takes for the subtask to be transmitted over the communication channel. Moving from I-FN to J-FN or the cloud. The subtask execution delay in J-FN or the cloud is represented by t_{E_j}, whereas the subtask result delay from J-FN or the cloud to I-FN is represented by $t_{c_{ij}}$. A node's (i) or cloud node's (j) waiting delay in the sending queue is determined in the following way.

$$t_w = t_o + t_i \tag{6}$$

where, t_o and t_i are respectively the entry Add the arrival time of subtask m to the node's queue and record the departure time of subtask m from the same queue. The latency of subtask transmission on the communication route between FN-I and FN-J or the cloud, and vice versa, is equivalent to:

$$t_c = \frac{L}{r_{i,j}} \tag{7}$$

where, $r_{i,j}$ The transmission rate between nodes i and j is denoted as.

$$r_{i,j} = Blog(1 + \frac{g_{i,j}\times p}{B\times N}) \tag{8}$$

where, $g_{i,j} = \beta_1 d_{i,j}^{-\beta_2}$ is the gain of the channel between two nodes i and j. The delay of execution of the subtask in J-FN or cloud t_{E_j} is equal to:

$$t_{E_j} = \frac{I \times Cycle \times W}{f} \qquad (9)$$

Each fog node is a learning agent operating in an S-state space environment. Each time a new task is added to the system, the agent performs an action in the surrounding area and chooses one of the nodes to receive the new work. In the event that the environment state is updated, the reward for this allocation will be decided. The agent will receive the reward if the system is now operating with a load balance that is closer to ideal and the subtasks are processed more quickly than they would otherwise [43]. Each node progressively acquires the ability to optimize its decision-making process for handling subtasks based on the rewards it receives. Minimizing the delay of sub-task processing in the fog environment will reduce the overall delay and response time to the user, resulting in the network spending less time on task processing.

IV. The Proposed Load Balancing Method

In order to address the issues with the prior approaches, the load balancing algorithm based on reinforcement learning is presented in this section. It is designed to distribute the load uniformly among the intermediate nodes of the fog. Dynamic programming can solve MDP when the system for every state-action combination has a transition function and a reward function, but typically the system is unable to anticipate the precise value of the transition function and reward for the majority of the states, which is required to solve the problem. It is suggested to use reinforcement learning to solve these issues. The Q-Learning algorithm, one of the reinforcement learning algorithms, is utilized in this article to locate the ideal action mode with the least amount of computing expense, making up for the absence of appropriate data through experimentation. The Q-Learning algorithm's model is a random model.

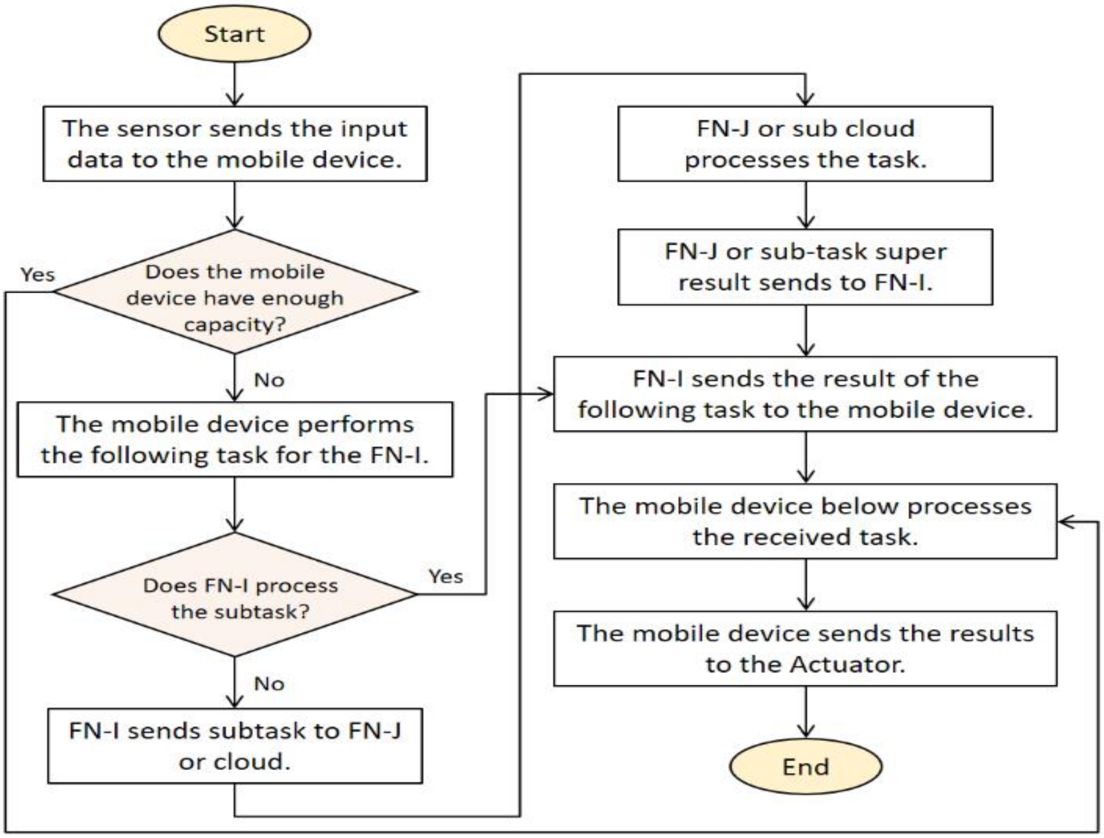
Distributes an agent involved in network learning is referred to as a fog node. The sub-fog node will choose to use reinforcement learning to process a new task after receiving it. Hence, the fog node designated for the Concentration-Calculator task acquires data from the mobile device. The fog node then assesses the environment and, in order to maximize the long-term reward, decides whether to complete the subtask independently or to delegate it to a nearby fog node for quicker completion based on its capacity and past experiences and rewards. If the Concentration-Calculator subtask takes longer to process in the fog nodes than it does in the cloud, the fog node chooses to transfer this subtask's processing to the cloud, which will speed up processing and lighten the load on the fog nodes. According to the system model, each fog node performs a response after observing the current states, a delay is made, and the new state s' is observed, and for that, it receives a reward (R, s, c) from the environment.

$$Q_{new}(s,a) = Q_{old}(s,a) + a[R(s,a) + \gamma \max_{a} Q(s',a') - Q_{old}(s,a)] \qquad (10)$$

The learning rate, 0 $1 < \alpha < 1$, strikes a balance between previously learned material and new observations. Using the available knowledge, the greedy method selects a course of action that yields the greatest reward in a single step. The Learning-Q method uses the likelihood of selecting an action ε, where ε –greedy is the policy with larger reward, in order to maximize the long-term value. The fog node is chosen to complete the subtask in order to maximize long-term value. In this manner, a random action with a fixed probability ε –greedy is chosen in each time step of the algorithm $0 \leq \varepsilon \leq 1$.

The benefit of utilizing 1–ε and the action with the highest value is that as the number of steps rises, every ε –greedy of the Q(s,a) algorithm exhibits an infinite action, ensuring that it will eventually converge to the best value. As a result, using the Learning-Q method, the fog node learns to choose the best node for handling the subtask. The suggested method calculates the suitable reward function using 3.

Since the function of infinity has been observed, it is certain that (Q, s, and a) will eventually converge to the ideal value. Consequently, using the Q-Learning method, the fog node learns to choose the best node for processing subtasks. The load balancing solution that has been suggested calculation of the suitable reward function is shown in Fig. 4 and it is done using Eq. (3). The fog node learns the complete network and the likelihood of loading to each node as it traverses the network using the learning method, enabling it to select the best node to transfer the task to. The algorithm begins by using a greedy approach to explore the network, and once it has a thorough understanding of the network's requirements, it performs optimal load balancing. The state space encompasses the capacity of the fog node, the length of the uplink queue within the fog node, and the quantity of mobile devices linked to the fog node. In order to minimize the processing delay for the subtask, select either a reward eyebrow or a fog node.



Start
The sensor sends the input data to the mobile device.
Does the mobile device have enough capacity?
Yes
No
The mobile device performs the following task for the FN-I.
Does FN-I process the subtask?
Yes
No
FN-I sends subtask to FN-J or cloud.
FN-J or sub cloud processes the task.
FN-J or sub-task super result sends to FN-I.
FN-I sends the result of the following task to the mobile device.
The mobile device below processes the received task.
The mobile device sends the results to the Actuator.

Fig. 4. Block diagram of the implementation steps of the proposed load balancing method.

V. Evaluation and Simulation

This article utilizes the iFogSim simulator [21] to model the load balancing problem using the reinforcement learning technique. This software was executed on a Sous computer equipped with seven Intel Core i processors and eight GB of RAM. The proposed system has N fog nodes and a variable number of mobile devices that establish random connections with neighboring fog nodes to broadcast subtasks. This paper proposes the utilization of the Q-Learning algorithm for load balancing in a fog environment. Initially, the fog node lacks any understanding of the network due to the fact that all the Q-table values in the Q-Learning algorithm are set to zero. The application of the avaricious approach to learning is implemented. Initially, the algorithm conducts an exhaustive search of the network, prioritizing immediate gains, as the number 0 is considered equivalent to 1. Over time, as the fog node's estimation reliability in the Q-table increased, its value changed to 0.3. Additionally, the received reward's value is equal to the concentration-calculator subtask's negative processing delay at the fog or cloud node.

The learning method is applied right away to minimize the generation of overhead in the nodes as it is expected that the task creation and task sending have already been completed in the simulation. The Q-L method allows the fog node to learn the best ways to interact with its surroundings. Through environment exploration, trial and error, and use of the incentives provided by the environment, this learning is accomplished. In general, each fog node assesses the state of the environment, selects a node to assign the work to, and then reaps the benefits. With each iteration of the method, the fog node's network experience grows, and over time it learns to assign the sub-task to a node with a lighter workload and faster processing speed. Contrary to the proposed way, alternative solutions (such as those in sources [6, 8]) conduct the load balancing algorithm before adding overhead to the fog node, which degrades the performance of the aforementioned systems and lengthens their latency. Another benefit is that, in the comparative methods for allocating sub-tasks to surrounding nodes, it is only necessary to be aware of this node's position and capacity, which may be determined by making a few numbers of laborious computations. However, in the suggested system of these computations, time-consuming and redundant tasks are eliminated, and the fog node simply behaves in accordance with the knowledge it has received from its surroundings. By doing this, the proposed system's latency will be as little as possible.

A number of current load balancing techniques have been compared to the performance of the suggested method, and in this simulation, random and proportional SALB load balancing techniques have been employed as benchmarks [6, 8]. The SALB approach examines the adjacent nodes' capacities after the fog node is overloaded and delivers the subtask to the node with the highest capacity and at least 40% of its capacity. Sub-tasks are distributed at random to fog nodes in the random technique. The Proportional approach receives information on each neighbor's capacity and chooses the best node based on the size of the subtask.

Following that, the graphs created by applying the Q-L algorithm to the load balancing problem are provided. Finally, the results of applying all four algorithms are discussed, along with a comparison of how well they performed in terms of delay, user response time, and load balancing.

Fig. 5 displays the progressive augmentation of the cumulative reward with each repetition of the proposed technique. As mentioned earlier, the reward is equivalent to the reciprocal of the processing delay for the subtask assigned to the fog node. The awarded reward will drop as the subtask's processing time increases, depending on whether the cloud provisioning node handles it. The action that yields the highest Q-value is chosen in the decision to transfer the load. According to the effectiveness of the suggested incentive, the proposed technique uses Q-Learning-based load assignment decision to reduce processing duration and overhead likelihood. With an increase in task processing rate, cumulative reward rises. Due to the fact that many tasks are queued up in the nodes, the cumulative reward also continuously falls as the quantity of incoming tasks rises. In this method, the network delay and user response time are decreased as the fog node eventually learns to assign processing of subtasks to the node that causes the least amount of delay.

Fig. 6 demonstrates how the average execution time has decreased dramatically as a result of program repetition and increased learning. In this method, the network delay and user response time are decreased as the fog node figures out which node is the least delay-prone and starts to delegate subtask execution to it. Furthermore, as seen in Fig. 7, the standard deviation of the nodes' load decreases as learning grows.

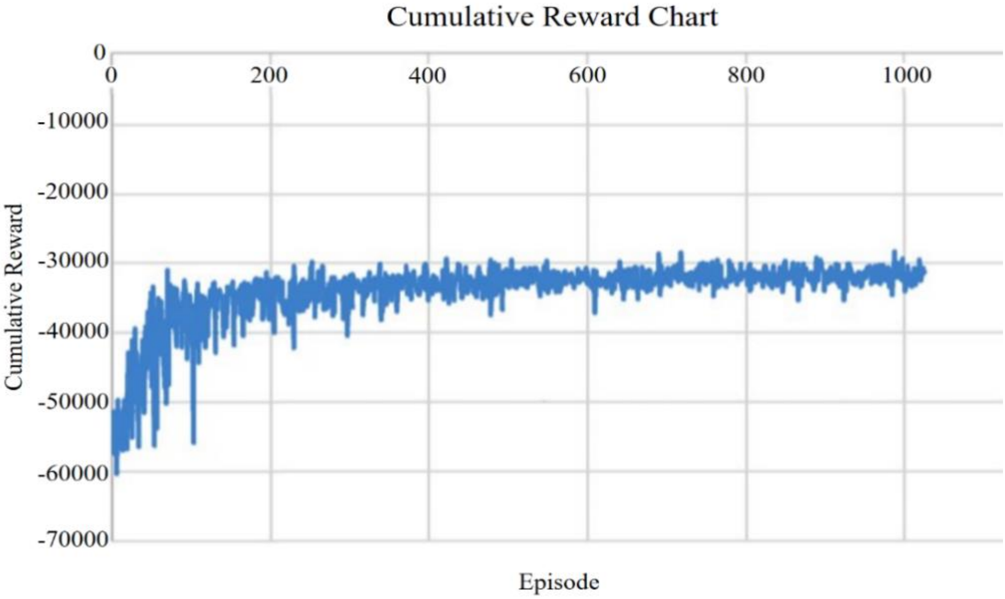

Fig. 5. Increasing payout with each cycle of the suggested method.

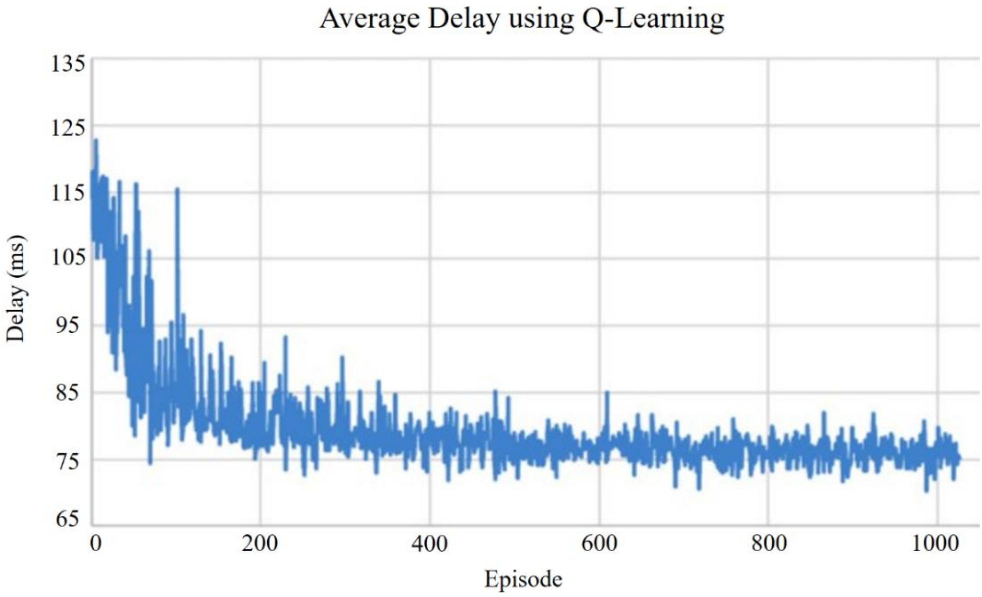

Fig. 6. Average task execution delay in Q-Learning method.

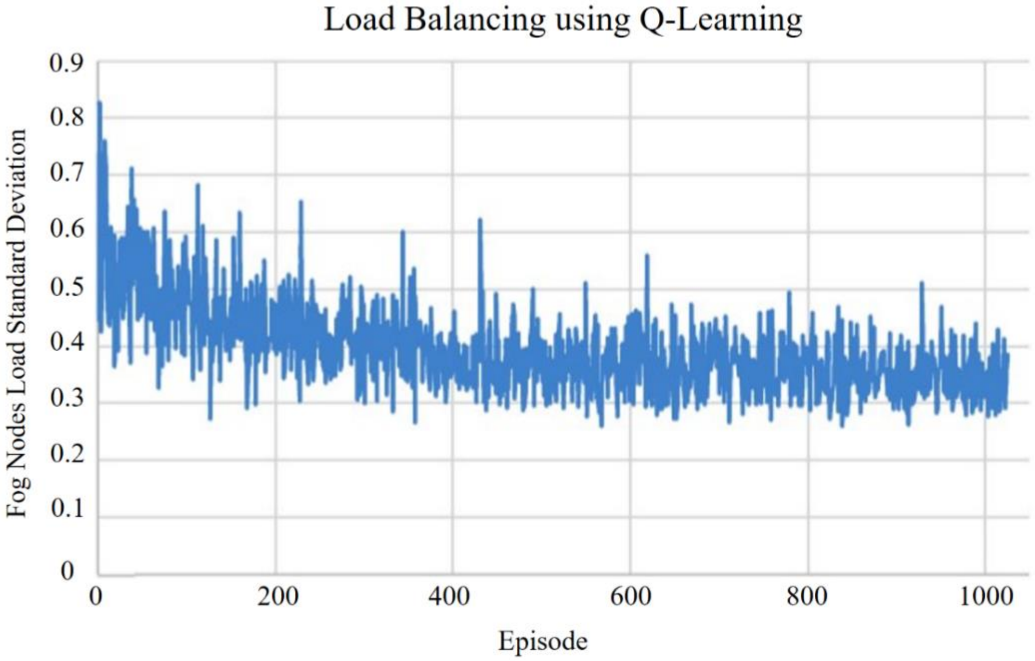

Fig. 7. Standard deviation of load on nodes in Q-Learning algorithm.

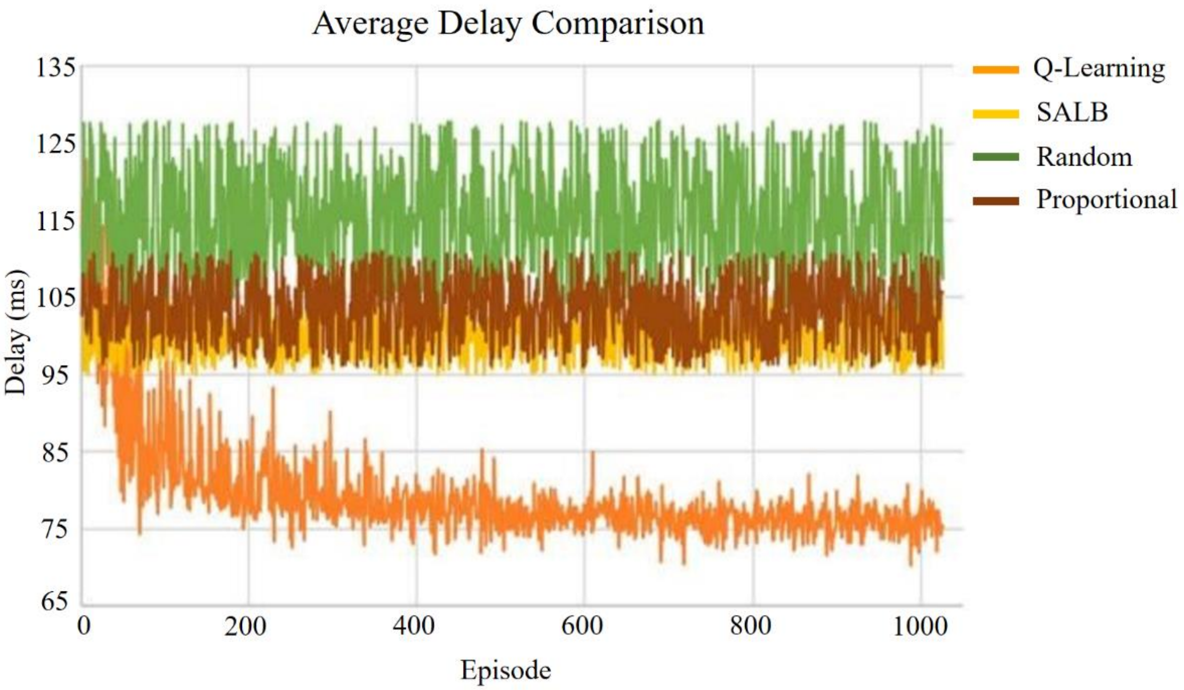

Fig. 8. Average task execution delay.

As a result, the network's job distribution and processing may be guaranteed to be balanced, and load balancing is enhanced. Just as mentioned before, the fog node detects which node causes the least delay and starts sending the subtask processing to that node. If the sub-task is sent to a node with more capacity and can therefore handle the incoming sub-task more quickly, the processing latency of the sub-task is decreased. By giving the subtask to the fog node with the greatest capacity, overhead with minimal strain on other nodes are avoided.

The pressure on the nodes' standard deviation diminishes as learning progresses. As a result, the load balance is enhanced and it is possible to guarantee that the tasks are dispersed and carried out in the network in a balanced manner. As previously noted, the fog node eventually learns to assign the subtask's processing to the node that causes the least delay. If a subtask is assigned to a node that has more capacity and can handle the incoming subtask more quickly, the processing latency is decreased. By giving the work to the fog node with the greatest capacity, overhead and underloading of other nodes are avoided. The outcomes of the execution of all four algorithms are now reviewed, along with a performance comparison. It is anticipated that the Q-Learning algorithm will considerably enhance the network's load balancing capabilities. According to the evaluation's findings, Fig. 8 illustrates how choosing a task based on Q-Learning minimizes task execution latency in accordance with the suggested reward function. The proposed load balancing technique uses reinforcement learning to evenly spread the load across the nodes, enabling the nodes to complete sub-tasks faster.

The cumulative reward drops as the task arrival rate rises because fewer tasks can be processed by fog nodes due to the relatively high amount of subtasks that are queued at them. However, the suggested load balancing method produces a beneficial reward in that the delay is also reduced in the same proportion. This is because the load is distributed properly across the fog nodes. Additionally, unlike the approaches that were examined, no time-consuming computations were required in the suggested load balancing method to determine the capacity and location of surrounding nodes. As a result, as shown in this figure, the time it takes for the suggested approach to work is when contrasted with alternative methods, it is greatly decreased. When the standard deviation of the four methods for node load is compared, the average task execution delay is checked. Fig. 9 shows that the dispersion of the nodes' loads is initially lower in the SALB algorithm than in other approaches, but that it has dramatically decreased within the suggested approach as an agent learning has increased. This demonstrates that the suggested strategy evenly distributes the duties around the network, minimizing the likelihood of overhead in the nodes.

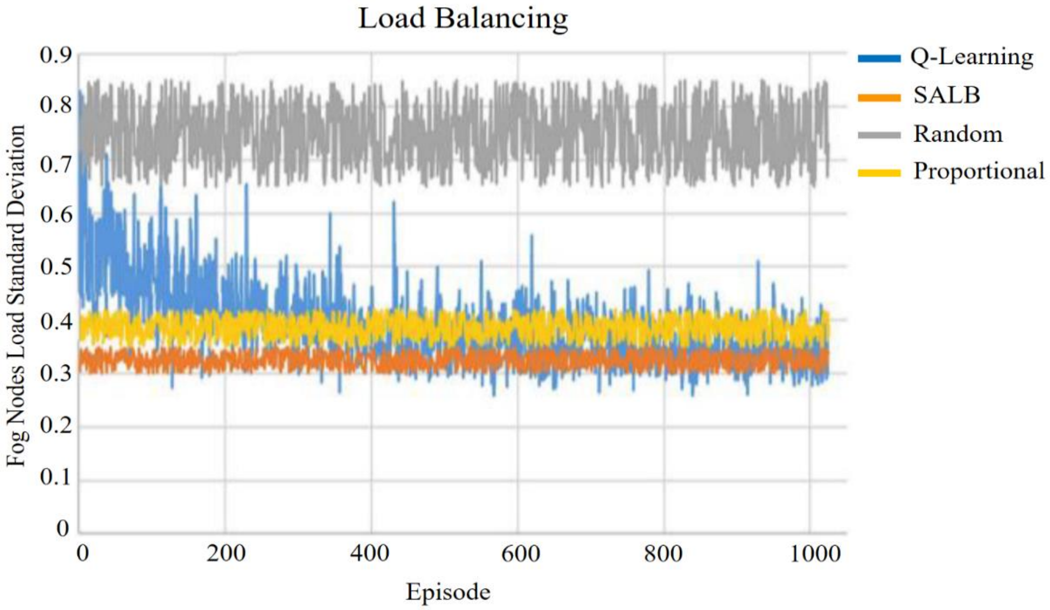

Fig. 9. Dispersion of node loads averaged out.

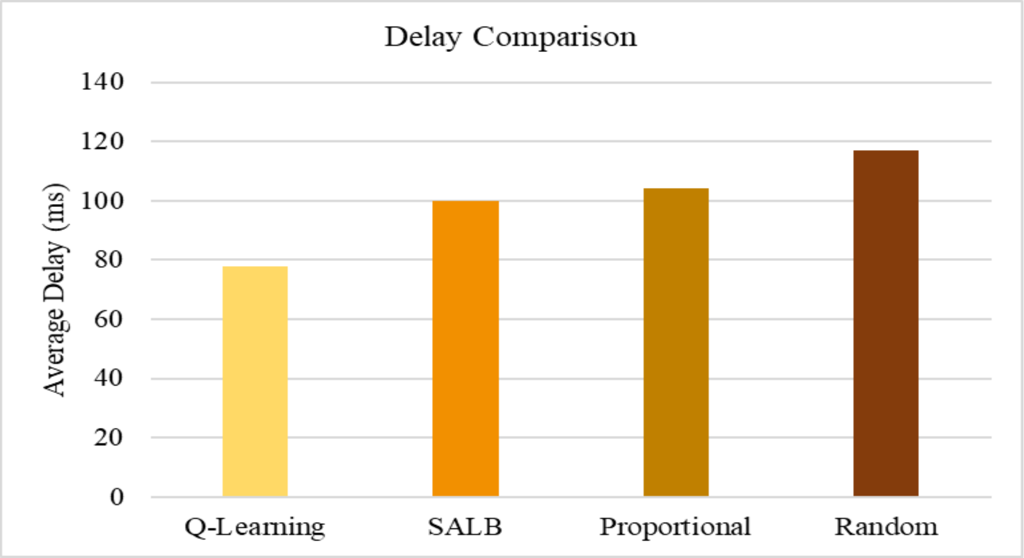

Fig. 10. Comparison of total delay for different methods.

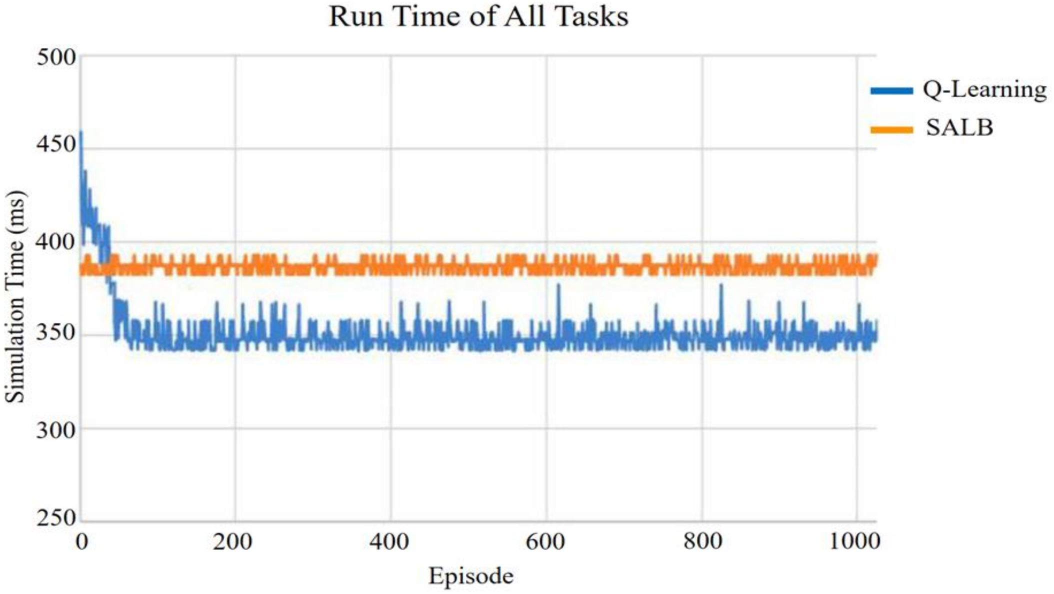

Fig. 11. Time to execute all tasks.

The overall execution time for the jobs using all four approaches is shown in Fig. 10. The average execution time of the input jobs from the first to the last algorithm iteration is used to calculate the overall delay. The examination reveals that the Q-Learning approach has the least overall delay when compared to other methods, which indicates that this method performs at a higher level of excellence.

Fig. 11 compares the execution times of both the suggested approach and the SALB method for each task that is entered into the system. The suggested solution significantly outperformed the SALB method in terms of the amount of time it took to execute all of the jobs that were input into the system during the simulation. Due to this, the suggested approach and system perform better than alternative methods that were also considered. The results show that the fog node considers the queue states, capacities, and the number of mobile devices linked to each node while deciding whether to disperse the load using the Q-Learning method. So, the unsuccessful allocation can be reduced by the proposed approach. Based on the results of the evaluation mentioned earlier, the proposed load balancing method is more stable than current load balancing approaches, and it significantly reduces both the network delay and the user response time.

VI. Conclusion

This article's goal is to outline a strategy for enhancing load balancing in fog nodes. Task distribution and load balancing are difficult problems in fog computing because of unique characteristics including topology dynamics and resource heterogeneity, and the adoption of conventional approaches to address these difficulties is inefficient. The application of machine learning algorithms, including reinforcement learning, is one of the cutting-edge methods for tackling complicated issues. In this article, the Q-Learning algorithm is used to demonstrate load balancing in a fog environment. By utilizing the experience that the learning agent acquires through interacting with the environment, this algorithm generates a long-term optimal strategy. As an agent, each fog node in the proposed technique searches the fog environment for low-load nodes suitable for allocating sub-tasks to reduce processing time and overhead with the use of the Markov decision process. The proposed solution has been tried with various numbers of mobile devices and fog nodes in the network, and it has produced successful results. According on simulation results, the suggested algorithm greatly reduces processing delay, user response time, and the likelihood of task assignment failure when compared to existing approaches. Some of the limitations of this research can include the following:

1) *Hypothetical system model:* This research assumes a system model and specific features for fog nodes, task distribution and network communication. These assumptions may not always hold true in practical deployments and potentially limit the generalizability of the findings.

2) *Limited scalability testing:* The scalability of the proposed algorithm may not have been extensively tested across a wide range of network sizes and configurations. Performance evaluation at different scales can provide valuable insight into algorithm robustness.

According to the study, the following can be considered for future research:

1) *Dynamic adaptation:* Enhancing the algorithm to dynamically adapt to changes in network conditions, such as node failures, varying workloads, or the mobility of fog nodes, to ensure robustness and scalability.

2) *Optimization techniques:* Investigate advanced optimization techniques to improve the efficiency and convergence speed of the reinforcement learning algorithm, potentially including deep reinforcement learning or other advanced methods.

3) *Security and privacy considerations:* Review the security and privacy implications of the proposed load

balancing approach, including potential vulnerabilities and mitigation strategies to protect sensitive data and ensure system integrity.

4) Integration with edge devices: extending the algorithm to combine edge devices and optimize the allocation of work in both fog nodes and edge devices, taking into account factors such as device capabilities, energy constraints, and communication protocols.

Construction of an Art Education Teaching System Assisted by Artificial Intelligence

Xianyu Wang[1]*, Xiaoguang Sun[2]
School of Fashion, Henan University of Engineering, Zhengzhou, 451191, China

***Abstract*—With the continuous progress of art education and artificial intelligence technology, traditional music teaching models are facing transformation. This article aims to construct an art education and teaching system based on artificial intelligence, especially for teaching music sound recognition. Through in-depth research, we have designed a music sound recognition system that uses Mel frequency cepstral coefficient (MFCC) for feature parameter extraction, and combines BP neural network algorithm to construct a music sound learning model. The main purpose is to improve the efficiency and accuracy of music teaching through artificial intelligence technology. The main challenge we face in this process is how to effectively extract the features of music sounds and accurately identify different tones through algorithms. By using the MFCC algorithm, we have successfully solved this problem as it can effectively describe the time-frequency characteristics of music sound. Our proposed music sound learning model is based on a BP neural network, which trains the network to learn the mapping relationship between music sound and pitch. The experiment used piano sound as an example to verify the accuracy and reliability of the system. The simulation experiments conducted in MATLAB environment show that our system can accurately recognize and extract the main frequency of music, and has higher performance compared to traditional methods.**

Keywords*—Feature extraction BP neural network; Tone recognition; smart art teaching; MEL frequency cepstral coefficient; MFCC algorithm; time frequency characteristics

I. INTRODUCTION

The Internet era's art education is progressively moving toward online and intelligent learning due to the economy's rapid growth. As a new discipline, artificial intelligence is mainly used to expand the methods and theories of human intelligence. The advent of artificial intelligence brings many opportunities for the development of science and technology but also makes art design face more challenges. The changes in market demand, the prominence of design immediacy problems, and the changes in design subjects make the existing art design face more challenges [1], [2].

Different listeners have their preferences for musical styles, and people usually experience and appreciate music from the tune, tone, and rhythm. In music dissemination, the music signal is transmitted to the human ear first; after receiving it, the human ear converts the music waveform into a bioelectric signal and then transmits it. Bioelectrical signals are transmitted to the brain through the nervous system. Finally, the brain analyzes the bioelectrical signals to further learn from the human experience of music. The brain plays a major role in the music appreciation process. In general, the role of the brain is to reduce high-dimensional musical signals to several musical dimensions that people care about, such as rhythm, melody, and harmonic intensity and intensity. These elements describe our experience and understanding of music. Therefore, learning a music data model based on music feature parameters can effectively reduce redundant data in music data and finally obtain more accurate data describing music. Tone recognition is a pattern recognition problem. There are rule-based audio classification methods, pattern matching methods, etc., but these methods still need to be improved. The rule-based audio classification method is simple to operate. Still, because of its simplicity, it is only suitable for identifying audio types with simple features, such as mute, which is difficult to satisfy for complex and multi-feature music classification applications. The pattern-matching method must establish a standard pattern for each audio type and then compare and match the input pattern with the standard pattern, which requires much computation and low classification accuracy. The hidden Markov model (HMM) method has a strong dynamic time series modeling ability, and the calculation amount is small, but the classification decision-making ability could be better. Artificial intelligence provides a good foundation for the research work of self-learning ability and automatic audio classification [3].

The modern art education system has gradually begun to be refined, including art education work evaluation, art education curriculum evaluation, and art education timeliness evaluation. In the quality evaluation of art theory courses, as early as the 1990s, some scholars in our country discussed the art education teaching system concept. Later, some domestic scholars explored and spread it, but it has yet to form a large-scale impact. The early research scholars analyzed how to improve the teaching quality of art courses from a macro level. They believed ideological teaching should integrate theory with practice, based on classroom teaching, enrich students' theoretical knowledge reserves, and strengthen display and application. Lin D. et al. [4] first proposed an intelligent system for teaching art theory courses in colleges and universities and tried to introduce artificial intelligence algorithms into art education. By exploring the application of artificial intelligence algorithms in art teaching, this paper proposes a music recognition method based on BP neural network for the problems existing in traditional music recognition methods. The cepstral coefficient method is used to extract the musical features, and the Mel cepstral coefficients are used to form the feature vector.

This article is dedicated to exploring the innovative application of artificial intelligence in the field of music sound recognition, providing intelligent and personalized solutions for art teaching. We use Mel frequency cepstral coefficient (MFCC) for feature parameter extraction and combine it with BP neural network algorithm to construct a music sound learning model to optimize the effectiveness of music teaching. Through the research in this article, we hope to bring revolutionary changes to the field of music education, achieve more efficient and precise teaching, and stimulate students' creativity and musical potential. This is not only an in-depth exploration of the application of artificial intelligence in the field of art education and teaching, but also a beneficial attempt to innovate music education and teaching methods.

II. Related Work

With the advancement of technology and the development of media art, artificial intelligence technology has penetrated into various art fields, especially in the application of complex situational teaching in folk music, which is becoming increasingly prominent. Li and Bin [5] discussed how artificial intelligence can assist in the teaching of complex folk music situations and promote the modernization of traditional folk music education from the perspective of media art. Media art, as a new field that integrates technology and art, has brought a new perspective to traditional folk music teaching. In this context, folk music teaching is no longer limited to traditional master apprentice inheritance or classroom teaching, but can realize the sharing of teaching resources and diversification of teaching methods through multimedia, Internet and other modern technical means. Complex situation teaching emphasizes teaching in actual or simulated real situations to improve students' practical abilities and ability to cope with complex situations. In the teaching of folk music, complex situational teaching is particularly important because folk music is often closely linked to specific cultural and historical backgrounds. The introduction of artificial intelligence technology has provided strong support for the teaching of complex situations in folk music. Computer assisted analysis, as a technical means, can quantitatively and qualitatively analyze artistic images. By utilizing algorithms such as image recognition, machine learning, and deep learning, CAA can deeply explore the style, techniques, themes, and other aspects of artistic works, providing insights that traditional methods find difficult to obtain. Shen [6] collected a large amount of image data from art works and analyzed them using CAA to discover the stylistic differences and evolutionary trends among different art genres and artists, thus constructing a more comprehensive and detailed theory of art history. CAA reveals the decision-making process, technological application, and style formation of artists in the creative process, which helps us understand the internal logic and laws of artistic creation and provides new theoretical support for artistic creation. Neural networks are computational models that simulate the structure of human brain neurons, with powerful feature learning and classification capabilities. In vocal speech recognition, neural networks can automatically extract sound features by learning a large amount of vocal data, achieving accurate recognition of vocal signals.

The vocal speech recognition technology based on neural networks can not only recognize basic elements such as melody and rhythm of songs, but also further analyze deeper information such as the singer's timbre, pitch accuracy, and emotions. Vocal voice evaluation is a quantitative evaluation of a singer's performance. Traditional vocal evaluation mainly relies on the subjective judgment of professional judges, while neural network-based vocal speech evaluation technology can provide more accurate and comprehensive evaluation through objective analysis of vocal signals. Neural networks can learn the evaluation criteria and preferences of professional judges, thereby achieving automatic evaluation of the singer's voice quality, skill application, emotional expression, and other aspects [7]. Mei et al. [8] explore the possibility of constructing art theory from the perspective of art images based on AI assisted analysis, and analyze its impact on art research and creation. AI assisted analysis refers to the automated and intelligent analysis of artistic images using artificial intelligence algorithms [9]. Through technologies such as deep learning and image recognition, AI can deeply explore the style, techniques, composition, and other aspects of artistic works, providing a more detailed and objective interpretation than traditional methods. This technology not only improves the accuracy and efficiency of analysis, but also provides a new perspective and method for art research. Traditional research on art history mainly relies on the knowledge and experience of experts, while AI assisted analysis can reveal the evolution laws of art styles, schools, and trends through mining and analyzing a large amount of art image data, providing a more comprehensive and objective theoretical basis for art history. AI can analyze the image data during the artist's creative process to reveal the artist's creative ideas, technical application, and style formation process. This helps us to have a deeper understanding of the internal logic and laws of artistic creation, providing new support for the theory of artistic creation [10].

Although artificial intelligence has made significant progress in the field of music recognition, it still faces many challenges and limitations. Traditional voice recognition methods often rely on manually extracted features, which are time-consuming and difficult to ensure the comprehensiveness and effectiveness of the features. In addition, musical sound has a high degree of complexity and diversity, and different instruments and performance styles can bring difficulties to sound recognition. Therefore, it is particularly important to develop a system that can adaptively, efficiently, and accurately recognize music sounds.

This article proposes a music sound learning model based on MFCC and BP neural network. Firstly, the MFCC algorithm is used to extract feature parameters of music sound, which can effectively describe the time-frequency characteristics of music sound. Then, these feature parameters are used as inputs for the BP neural network, and the mapping relationship between music sound and pitch is learned through training the network. Finally, the trained network is used to recognize new music sounds, thereby achieving the recognition and extraction of the main frequency of music.

III. Artistic Music Tone Recognition and Feature Extraction

A. Principles of Art Music Tone Recognition

There are two main recording formats for artistic musical tone information: WAVE format and Musical Instrument Digital Interface (MIDI) format. MIDI is a standard for transmitting music signals between electronic musical instruments. It includes hardware interface standards and asynchronous serial transmission protocols for electronic music signals between different hardware. The transfer rate is 31.25k (±1%) baud. Since the music file in MIDI format records the whole process of the score and performance, many basic features of music can be directly extracted. Therefore, the identification of music features mostly adopts the music files in MIDI format, and this paper mainly aims at identifying the music files in MIDI format.

From the physical level analysis, music consists of the fundamental frequency, frequency multiplication, and signal amplitude. These three factors correspond to three important concepts in musicology. The physical quantity determined by the fundamental frequency of the musical tone signal is called pitch. The fundamental frequency and the multiplied frequency signal jointly constitute the requirements for the timbre. Finally, the amplitude of the signal is the sound intensity in musicology. From the level of emotional characteristics, pitch, length, timbre, fundamental tone, tone name, and rhythm are six vectors that reflect the characteristics of music.

1) Pitch: The higher the pitch of the signal, the higher the dominant frequency, and vice versa. However, the corresponding relationship between pitch and dominant frequency is not a simple linear relationship but an approximate logarithmic relationship.

Changes in pitch can be expressed in tunes. For singers, the pitch mainly reflects the changes in the singer's voice. For music sung by a soprano singer, the frequency of the music signal is higher. For bass singers, the signal frequency is very low during music analysis. In the process of picking up musical tones, it is common to detect the length of time between peaks and the amplitude of the peaks. The smaller the amplitude, the smaller the pitch. The amplitude cannot represent the pitch, and the frequency must be considered comprehensively. In this way, the displayed tones are the high and low frequencies.

Define *f* as a function that evaluates the pitch attribute of a MIDI file. The musical emotion of a MIDI song file is mainly reflected in the master track. Let the number of audio tracks be *m*. In the process of identifying the emotion of the music, the relevant extraction of the pitch characteristics of each audio track, such as the average value of the pitch characteristics of each audio track, is carried out, and determine the pitch feature vector x_f of the piece according to the corresponding properties of the main audio track. Therefore, suppose that the type of music emotion to be detected is *n*, $n \geq 1$, and the eigenvalue of the emotion type under the action of the current pitch value is $pi(xf)$, $i\in$ [1, 2, ..., n], then each emotion the part of the type related to the pitch attribute index of the song, as shown in Formula (1).

$$f(x_f) = Max(p_i) \tag{1}$$

2) Length: To measure the pitch characteristics of a musical piece, a function g is defined as an evaluation standard. Generally speaking, the longer the pitch, the more sad and melancholy elements it expresses in the emotional components. In the pitch identification of MIDI files, the pitch attribute is mainly determined according to the length of its duration. Define the threshold value of the pitch length switch as x_{switch} and the interval of note switch as x_g, then the value of the pitch length evaluation function g is as follows:

$$g(x_g) = \begin{cases} long, x_g < x_{switch} \\ short, x_g > x_{switch} \end{cases} \tag{2}$$

3) Tone: In the MIDI standard, 128 timbres are defined. 128 timbres are divided into k categories, and the function h for extracting the timbre features of the current music is as follows:

$$h_{x_i} = \begin{cases} 1, x_i \in C_1 \\ 2, x_i \in C_2 \\ \ldots \\ M, x_i \in C_M \end{cases} \tag{3}$$

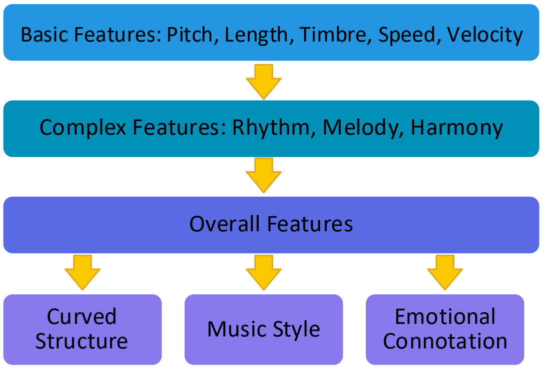
4) Fundamental and overtones: The fundamental tone is the main frequency, which is the trigger frequency when the piano strings vibrate over the full length; the overtone, also known as the harmonic frequency, is the vibration frequency at which the strings are triggered in the non-full field. From the physical characteristics of the above analysis, it can be known that the fundamental frequency is the lowest frequency of vibration triggered by the strings. The values of overtones are integer multiples of the fundamental. In the normal operation of the piano, the fundamental tone determines the pitch of the tone, and the fundamental tone and the overtone together determine the timbre of the tone of the signal.

5) Sound name: The so-called sound name is the name attribute of a certain musical sound. Often referred to in music, octaves correspond to octaves in signal processing. That is, the pitch of two single notes differs by one octave, and the main frequency value differs by one time. Divide one octave of the signal into 12 semi-treble pitches: C, #C, D, #D, E, F, #F, G, #G, A, #A, B. There is the tone name of the tone signal or the fundamental tone level. The name of the piano is based on the twelve-tone equal temperament system.

6) Rhythm: Different music has different emotional matting speeds. The basic understanding is that some music is fast and others are slow. For example, Disco music gives us a sense of speed. In contrast, blues music is slower and emotionally sad, and this music can display the number of syllables output per second or minute by digitizing the rhythm. After noise reduction, the computer detects the number of audio signal peaks per minute. The number of peaks per minute can accurately express the rhythm of speech. Then, by extracting the signal envelope and marking the peaks of the envelope contour, the envelope peak value per second of the whole music is calculated and recorded as the peak frequency, which is used to measure the rhythm intensity of the music. Peak frequency means that the music has a strong rhythm. Generally speaking, this music is mainly disco.

B. *Extraction of Musical Tone Features*

As shown in Fig. 1, the identification of musical functions can also be divided into three levels: basic musical functions, complex characteristics, and general musical characteristics.



Basic Features: Pitch, Length, Timbre, Speed, Velocity
Complex Features: Rhythm, Melody, Harmony
Overall Features
Curved Structure
Music Style
Emotional Connotation

Fig. 1. The characteristic structure of music.

After preprocessing the musical tone signal, the next thing to do is to digitize the musical tone signal and extract its characteristic parameters, that is, replace the entire musical tone signal with a set of characteristic parameters the computer can process. This link is crucial and directly related to the performance of the recognition model in the next link. Feature extraction, or front-end processing, is crucial in recognizing musical tones. Measuring the distance between feature parameters to determine the intrinsic features of musical sounds is the fundamental step in its extraction process. In musical tone recognition, the characteristic parameters generally used are parameters that can reflect the short-term spectral envelope. The mainstream algorithms include Linear Prediction Cepstrum Coefficient (LPCC) and Mel Frequency Cepstral Coefficients (MFCC) f.

When configuring the implemented tone recognition algorithm, a series of parameters need to be set for each algorithm. These parameters will affect the performance and accuracy of the algorithm. The following are several aspects that typically need to be considered when configuring parameters for linear prediction cepstral coefficients (LPCC) and Mel frequency cepstral coefficients (MFCC):

1) Filter order: This refers to the order of the filter or model used for linear predictive analysis. It determines the complexity of the dynamic characteristics of the sound signal that the model can capture. A higher filter order can capture finer structures, but it may also lead to overfitting and increased computational complexity.

2) Window function and window length: The window function and window length used to analyze sound signals determine the time resolution and frequency resolution of the analysis. The commonly used window functions include the Hamming window and the Hanning window. The window length is usually selected based on signal characteristics and the required time-frequency resolution.

3) Pre emphasis: In order to eliminate possible DC bias during the sound production process, pre emphasis is usually performed before signal analysis. Pre emphasis is usually achieved by applying a high pass filter.

4) Iteration count: When solving the LPC coefficient, multiple iterations may be required to converge to a stable solution. The number of iterations should be sufficient to ensure convergence, but excessive iterations may increase computation time.

The linear prediction cepstral parameters (LPCC) map the linear prediction parameters (LPC) in the cepstral domain. Cepstral technology is a well-known homomorphic signal processing method, and its calculation steps generally need to go through the following three steps: fast Fourier transform, logarithmic operation, and phase correction. The LPCC feature extraction algorithm assumes that the musical sound signal is autoregressive and uses the LPC parameters to obtain the cepstral coefficients. The LPCC parameters are insufficient for the anti-noise performance of the system. In the normal range of use, noise signals will inevitably be, which may lead to large errors in the final recognition results. Therefore, MFCC parameters with an anti-noise performance ratio are generally used as a feature extraction method for musical sound signals in practical applications.

5) MFCC: Based on Fourier and cepstral analysis, the spectrum in the time domain can be transformed through the nonlinear spectrum and finally converted to the cepstral spectrum for research. One of its major features is its good identification effect and anti-noise ability, but its calculation amount is complicated compared with LPCC. MFCC reflects the pitch auditory characteristics of the human ear, and it is not computationally intensive and is widely used in speech processing. The research results show that MFCC can be used as an audio classification feature and can improve the accuracy of audio classification. Among them, the relationship between the Mel scale and the specific time domain frequency is shown in Fig. 2.

The calculation process of the MFCC feature is as follows:

The MFCC parameters rely on the Mel frequency filter bank of equal bandwidth set by it, perform D transformation on each frame of signal to calculate the amplitude spectrum, and then transform the amplitude spectrum into the Mel domain with the Mel scale, and filter by the Mel filter bank of equal bandwidth.

$$e[j] = log\left(\sum_{k=0}^{N-1} w_j[k] \times |s[k]|\right), j = 1,2,\ldots.,p \qquad (4)$$

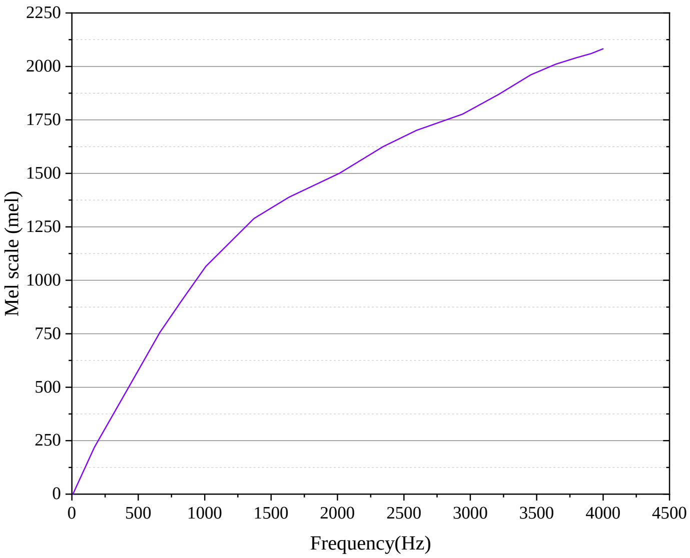


Fig. 2. Relationship between mel scale and frequency in the time domain.

Where: $e[j]$ represents the logarithmic energy output of the jth filter; $w_j[k]$ represents the weight corresponding to the kth point of the jth triangular filter; $|s[k]|$ represents the transformation to Mel scale Discrete Fourier Transform (DFT) spectrum amplitude on; P is the number of filters, generally 24. Taking the discrete cosine transform of the logarithmic energy of the filter, the following cepstral domain MFCC coefficients can be obtained:

$$x_i = \sqrt{\frac{2}{p}}\sum_{j=1}^{p}\left(e[j] \times cos\left(\frac{i\pi}{p}(j-0.5)\right)\right), i = 1,2,\ldots,L \quad (5)$$

Among them, L is the dimension of the MFCC. Generally, $L \leq P$, this paper takes 12 dimensions.

The MFCC dynamic characteristic parameters of the music signal can mainly be described by the different spectrums of these static characteristics, combining the first-order and second-order differences as the dynamic feature. These dynamic and static information complement each other, which can greatly improve the recognition performance of the system [11].

C. Research on Tone Recognition Model

After introducing the first two important links of the music sound recognition system, the related algorithms of preprocessing and feature parameter extraction, the system needs to match the model, which is the most important link in the music sound recognition process, matching the optimization degree of model training. The recognition rate of matching using this model is closely connected to it. Consequently, the training of the model is crucial for accurately recognizing musical tones, and users must supply numerous original databases. Therefore, it is necessary to establish a musical tone database before starting the musical tone recognition research. A collection of 88 piano syllables recorded in various settings is available in the database. The individual file should be distinct from others and accurately represent the original musical sound data in a well-balanced way. The essence of model training is to extract the inherent connections and laws of the data using a large amount of data under certain training standards. The unknown musical tone signal is used as input to act on the model, and it is matched and compared to see which template library data is more closely related to obtaining the recognition result. The training process related to the recognition rate of the entire system must meet the training of large data volume and the high efficiency of learning speed.

Artificial neural network (ANN) is a frontier research field for simulating human brain structure and thinking process. ANN can continuously adjust their parameters in training process weights and topology structure to adapt to the environment and the demand of the system performance optimization; it has the characteristics of fast speed and high recognition rate in pattern recognition and has been the research direction and hotspot of music recognition system at home and abroad.

In general, the neural network-based music sound recognition system has great potential for development. Still, the research on the application method for large-scale problems has just started, especially for the actual music sound recognition system. Neural networks generally have the disadvantage of too long training and recognition time.

IV. Realization of Intelligent Art Education System

A. Analysis of BP Neural Network Algorithm

The core algorithm model of the intelligent art teaching system adopts the back-propagation network. The learning algorithm of error backpropagation to train and adjust the weights of the nonlinear differentiable functions of the multi-layer network. It belongs to the multi-layer forward feedback neural network, and the activation function of its neurons belongs to the sigmoid function, which can complete any nonlinear mapping from the input layer to the output layer.

Theoretically, any nonlinear signal can be approximated if the system has one or more S-functions. Therefore, the recognition accuracy can be enhanced through increasing the number of network layers. Still, with the increase of the network layers, the network learning time and calculation amount will also increase significantly, leading to a decrease in the relative performance of the system. Therefore, some balance must be struck between recognition progress and system speed. Generally speaking, the three-layer structure of the BP network, that is, the single-hidden layer network, can achieve a balance between the two by increasing or decreasing the number of neurons in the hidden layer. In the specific design, different numbers of neurons in the hidden layer can be used for experimental comparison to obtain the optimal number of neurons in the hidden layer. Fig. 3 shows the basic structure of the BP neural network, which includes three-layer architecture of input layer, hidden layer, and output layer.

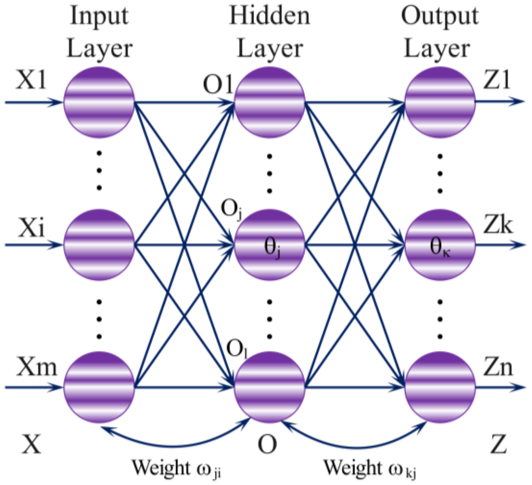

Fig. 3. BP neural network structure.

The first layer is the input layer. For the intelligent art teaching system, the quantities input to the BP neural network can be summarized as the characteristic parameters of the music signal. Set the input sample pair as (X, Y), where the input layer variable X is m, corresponding to n expected values Y.

The second layer is the hidden layer. The number of neurons in the hidden layer O is l. According to the function transfer formula of the hidden layer, the output expression of the jth hidden layer neuron O_j is:

$$O_j = f(\sum_{i=1}^{m} \omega_{ji} x_i - \theta_j), \quad j = 1,2,\cdots,l \tag{6}$$

Among them, ω_{ji} is the weight between the jth hidden layer neuron and the ith input layer neuron, θ_j is the threshold of the jth hidden layer neuron, and f is the hidden layer transfer function [11].

The third layer is the output layer, which outputs the evaluation index of the note signal. The output expression of the kth neuron z_k of the output layer is:

$$z_k = g(\sum_{j=1}^{l} \omega_{kj} O_j - \theta_k), \quad k = 1,2,\cdots,n \tag{7}$$

Among them, ω_{kj} is the weight between the kth output layer neuron and the jth hidden layer neuron, θ_k is the threshold of the kth output layer neuron, and g is the output layer transfer function [12], [13].

It is clear that the error E between the output value z_k and the expected value y_k is:

$$E = \frac{1}{2}\sum_{k=1}^{n}(y_k - z_k)^2$$
$$= \frac{1}{2}\sum_{k=1}^{n}\{y_k - g[\sum_{j=1}^{l}\omega_{kj} f(\sum_{i=1}^{m}\omega_{ji}x_i - \theta_j) - \theta_k]\}^2 \tag{8}$$

In the BP neural network, iteration aims to correct the weights and thresholds so that the error function E can decrease at the fastest speed. Taking the negative gradient direction makes the error function decrease the fastest, which is also very consistent with the teaching model of the influencing factors of interactive art learning [14], [15].

It can be seen that to ensure that the predicted value is as close to the expected value as possible, the correction formulas of the weights and thresholds in the iterative process must satisfy the following formulas

$$\begin{cases} \omega_{ji}(t+1) = \omega_{ji}(t) + \Delta\omega_{ji} = \omega_{ji}(t) - \lambda_1 \frac{\partial E}{\partial \omega_{ji}} \\ \omega_{kj}(t+1) = \omega_{kj}(t) + \Delta\omega_{kj} = \omega_{kj}(t) - \lambda_2 \frac{\partial E}{\partial \omega_{kj}} \\ \theta_j(t+1) = \theta_j(t) + \Delta\theta_j = \theta_j(t) - \lambda_1 \frac{\partial E}{\partial \theta_j} \\ \theta_k(t+1) = \theta_k(t) + \Delta\theta_k = \theta_k(t) - \lambda_2 \frac{\partial E}{\partial \theta_k} \end{cases} \tag{9}$$

where, t is the number of iterations, and λ_1 and λ_2 are the hidden and output layers' learning rates, respectively [16], [17].

B. BP Neural Network Learning Steps

Learning the BP neural network involves the following special steps s follows:

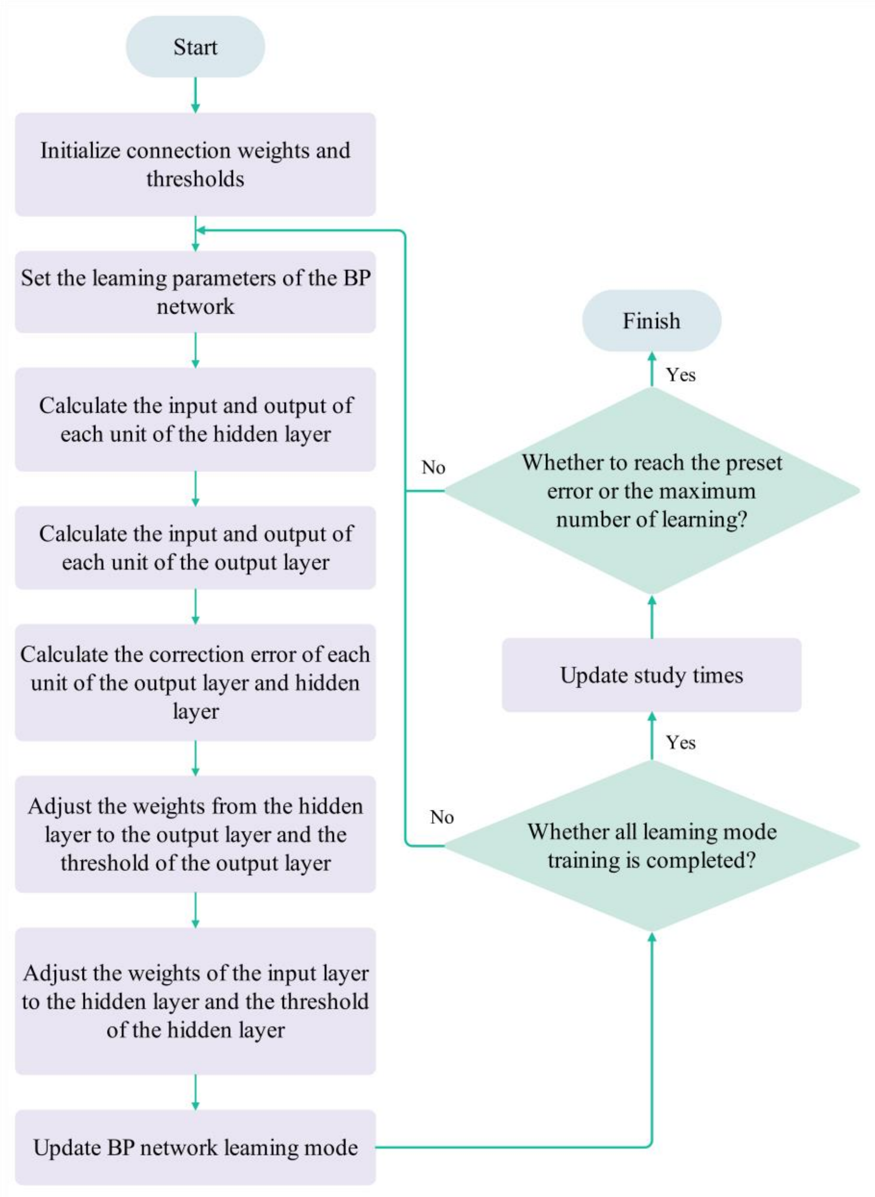
The first step is to initialize the connection weights and thresholds of the entire network, assign the connection weights ω_{ji}, ω_{kj} and the thresholds θ_j, θ_k to any number within (-1, 1) respectively, set the error function E, and determine the calculation accuracy and the maximum learning times M of the BP neural network [18]–[20].

The second step randomly selects the ith input sample and the corresponding expected output: X_i= [x_1, x_2, ... , x_i], Y_i=[y_1, y_2, ... ,y_i].

The third step is to calculate the input value and output value of each neuron in the hidden layer.

The fourth step is to calculate the partial derivative of the error function for each neuron in the output layer according to the error between the expected output value of the BP neural network and the theoretical value, as shown in Formula (10).

$$\frac{\partial E}{\partial z_k} \quad (k = 1,2,\cdots,n) \tag{10}$$



Start
Initialize connection weights and thresholds
Set the leaming parameters of the BP network
Calculate the input and output of each unit of the hidden layer
Calculate the input and output of each unit of the output layer
Calculate the correction error of each unit of the output layer and hidden layer
Adjust the weights from the hidden layer to the output layer and the threshold of the output layer
Adjust the weights of the input layer to the hidden layer and the threshold of the hidden layer
Update BP network leaming mode
Whether all leaming mode training is completed?
No
Yes
Update study times
Whether to reach the preset error or the maximum number of learning?
No
Yes
Finish

Fig. 4. BP neural network learning steps.

Step five involves calculating the derivative of the error function for each neuron in the hidden layer concerning the connection weight between the hidden and output layers, the derivative of the output layer, and the output value of the hidden layer, following the Formula (11).

$$\frac{\partial E}{\partial o_j} \quad (j = 1,2,\cdots,l) \tag{11}$$

Step six involves updating the connection weights based on the partial derivatives of each neuron in the output layer and the output of each neuron in the hidden layer [21], [22]

In the seventh step, the connection weights are updated according to the partial derivatives of each neuron in the hidden layer and the input of each neuron in the input layer.

The eighth step is calculating the global error, as shown in Formula (8).

In the ninth step, randomly select a new input sample as the BP neural network input and return to the third step until all input samples are trained.

The tenth step is to randomly re-select an input sample from the *m* input samples and return to the third step until the global error function *E* of the entire network is less than the preset precision [23]–[26].

The flowchart of the BP algorithm is shown in Fig. 4.

C. *The Software Basis of Art Teaching System*

The BP network structure of the music intelligent system has been stated as before. The intelligent system operates in a combination of software and hardware. A database server is arranged in the server environment, and the system is set to 8G memory, 500G solid-state hard disk, dual CPU processors system, and Gigabit Ethernet. The software adopts SQL Server

2000 as the database management system. SQL Server contains many tools for databases that can store, retrieve, and manage databases using the SQL language and GUI applications [27].

Ideal for mobile, wireless, and embedded applications, SQL Server CE provides important relational database functionality in a compact form factor, along with flexible data access and the familiar SQL Server experience. Extending enterprise applications to .NET Compact Framework greatly enhances the development of the user's mobile space.

SQL Server 2000 provides the same performance as many advanced database managers.

1) Rich programming interfaces and development tools: Query Analyzer is provided as a development tool for writing Transact-SQL script programs. Query Analyzer provides users a graphical working environment for writing and debugging Transact-SOL programs. Supports most commonly used database application programming interfaces, such as ADO, OLE DB, ODBC, etc. These tools allow programmers to directly control the interaction between the hemp program and the database and include APIs such as ADO that support rapid program development. These tools can develop a database application program with strong functions quickly.

2) Dynamic automatic management and configuration: SQL Server 2000 can be configured autonomously and dynamically during operation. For example, when the task of the database service increases, it will dynamically and autonomously apply for more system resources; when the work is reduced, the system resources will be released; when data is inserted or deleted in the database, the size of the database can be automatically adjusted to Adapt to new situations [28], [29].

3) Dynamic realization of database concurrency control: In SQL Server 2000, row-level blockade can be implemented on data. When dealing with the concurrency control problem of the database, the strength of data blocking will be dynamically adjusted according to different situations to achieve the best state of data blocking and sharing. For example, when a query needs to access a limited amount of data in a table, a row-level lock will be added to the data; when a query needs to access the vast majority of data in a table, a page-level lock will be added to the data, and take steps to make this query complete as quickly as possible. All the concurrency control performed by SQL Server 2000 is performed automatically in the background, and users do not need to interfere and participate [30].

V. Verification of Intelligent Art Teaching System

A. System Parameter Settings

In the BP neural network, the input layer uses 12 neurons, which are used to correspond to the 12-dimensional characteristic parameters of the musical sound signal; the output layer uses one neuron, which corresponds to the main frequency of the musical sound; the number of neurons in the hidden layer is 20.

Taking the piano music as an example to verify the system, considering that the piano keys only contain 88 keys, the data is relatively small, so choose a dedicated microphone and sound acquisition card to collect the 88 keys of the piano three times and use MIDI The format saves 264 musical sound data, forming the BP neural network input unit, normalized processing of the input data, and using the MATLAB toolbox to directly read the musical tone signal, main frequency value assigned to every note is known as the training output unit.

By setting the relevant decomposition filter bank in MATLAB, the musical sound signal is decomposed by Daubechies 4th-order wavelet, and the low-pass decomposition coefficients are retained. After that, the wavelet is reconstructed by setting the low-pass reconstruction filter bank, and the removal of high-frequency components is obtained. The perfect signal is Fourier transformed to obtain its spectrogram, as shown in Fig. 5.

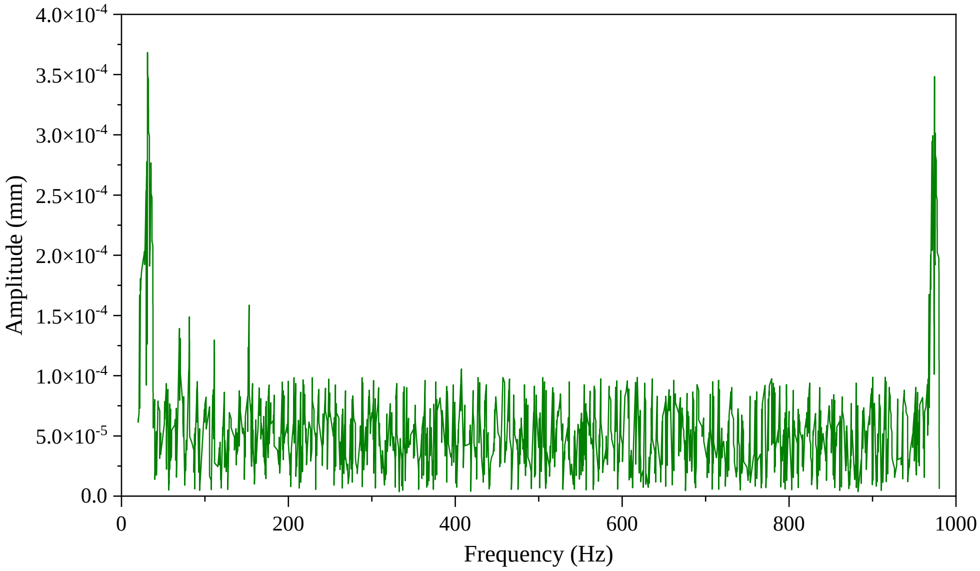


Fig. 5. Spectrogram of fourier transform.

B. Feature Parameter Extraction

After analyzing the characteristic parameters of the MFCC algorithm, a 12-order extraction algorithm has been chosen for the accuracy of musical tone recognition and to balance the amount of calculation. The length of the audio signal FFT transformation is 256, with a sampling frequency of 20500Hz and each frame having a length of 256 points. Then, the music file passed the Fourier transformation is read, and the Melbankm function normalizes the Mel filter bank coefficients. After that, the DCT parameters are solved, the pre-emphasis filter is filtered, and the music signal is re-framed. Ultimately, the musical sound signal's MFCC parameters are extracted, and the five frames of characteristic parameters are taken, as shown in Fig. 6.

C. Result Analysis

Select the characteristic parameters of 234 keys as the input of the training data and the corresponding main frequency value as the expected output result of the training, set the input neuron to 12, the output neuron to 1, the number of hidden layer neurons to 20, the maximum number of iterations is 2000, and the expected error is 10e-9. The BP neural network is trained in MATLAB, and the remaining 30 key characteristic parameters are selected as verification data. The error performance curve of the system is shown in Fig. 7. It is evident that after 1943 training times, the error reaches 10e-9.

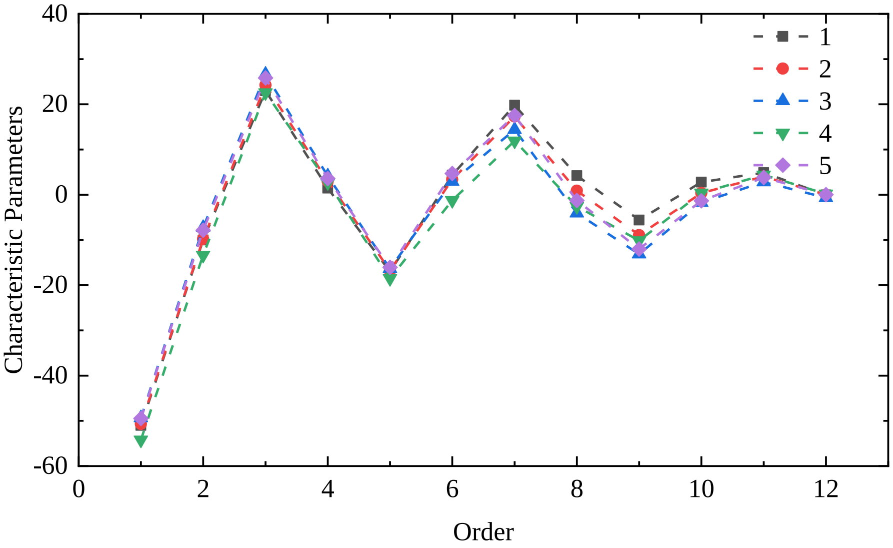

Fig. 6. Characteristic MFCC parameters.

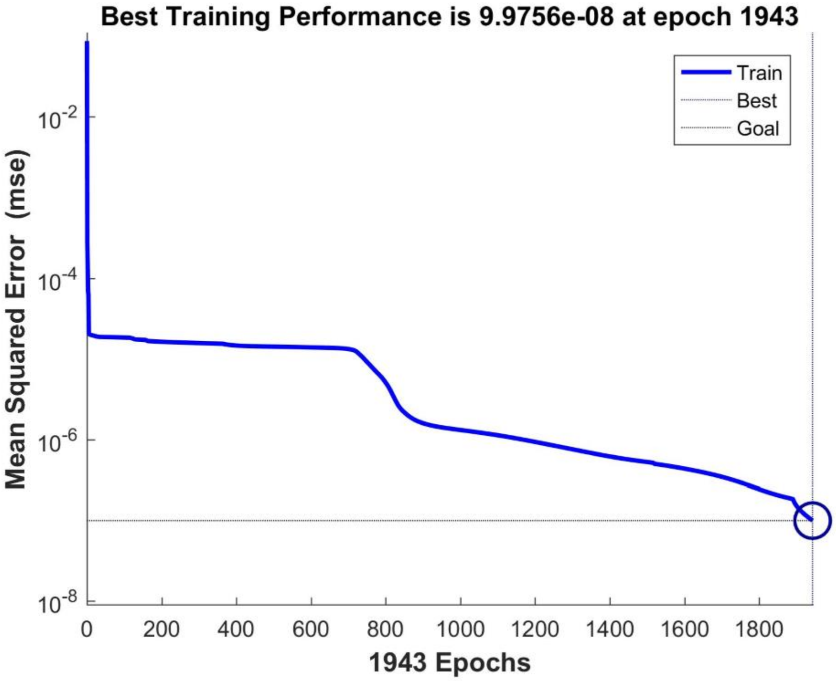

Fig. 7. BP network training performance.

The output result of the music sound teaching system using MFCC parameters as characteristic parameters for BP network matching is shown in Fig 8. It is observed that the expected value of the main frequency signal and the predicted value are consistent, with a relatively high recognition rate. It verifies the correct feasibility of the route proposed in the current paper using the BP neural network algorithm for musical tone recognition. However, from the identification results of musical tones in Table I and the relative error values in Fig. 9, it is clear that due to the compromise in wavelet filtering, identification errors in different situations will occur in low-frequency signals outside the selected area, while the relative error values of individual samples larger, which requires further investigation in subsequent studies.

TABLE I. TONE RECOGNITION RESULTS

Number	Expected value	Expected pitch names	Predictive value	Predictive pitch names

VI. Conclusion

The intelligent music teaching system can provide better learning concepts for art learners. Feature parameter extraction is done via MFCC, which is based on the BP neural network intelligent algorithm, and SQL Server is used as the music database management system to build a network matching of music signals to realize better the effect of the interactive teaching music intelligent system. This paper uses the piano sound signal to verify the system, and the BP learning algorithm is built in MATLAB. The verification results show that the predicted value of the network has achieved a high recognition effect, but there are certain errors in individual areas. The next research phase will involve using larger-scale model samples to realize artificial intelligence, resulting in improved accuracy across a wider range of applications. This will ensure greater stability in terms of usability and the ability to integrate various artificial intelligence algorithms to enhance the training algorithm of neural networks and create a more universal music intelligence system.

***Abstract*—Big data analysis can provide valuable insights not easily obtained from traditional data scales. However, addressing scheduling issues in big data can be challenging due to the vast amount and diverse nature of the data. To overcome this, a scheduling model based on Markov decision process is proposed. The deep Q-network algorithm is used for directed acyclic graph task scheduling. To improve this model further, the gradient strategy algorithm is introduced. From the results, when the dataset size was about 500, the hybrid algorithm achieved a recall rate of 0.96, outperforming the gradient strategy algorithm (0.83), deep Q-network algorithm (0.79), and estimated earliest completion time algorithm (0.63). Although the estimated earliest completion time algorithm had longer training times under different dataset sizes, the hybrid algorithm's training time was slightly longer than the gradient strategy algorithm and slightly shorter than the deep Q-network algorithm. Overall, the proposed algorithm exhibits superior performance and significant value in solving engineering problems.**

Keywords—Big data; Task scheduling; Policy gradient; Deep Q-network

I. Introduction

Big data refers to a data collection generated due to its large volume, diverse types, and inability to be processed by traditional processing methods. These data typically have high speed and high diversity [1]. Compared with traditional data, big data has a larger data scale, more data types, and lower value density [2]. The data volume of big data is basically calculated at the PB level. Therefore, analyzing big data requires extremely high computational power. However, at current, the processing power of a single processor has reached its limit. Relying solely on increasing processor frequency cannot meet the current demand for big data analysis. Influenced by the development of cloud computing technology, more enterprises and research institutions are inclined to use big data analysis platforms to complete data analysis work. Traditional task scheduling algorithms are usually based on static rules, which may be inflexible and unable to adapt to real-time changing environments. In the big data environment, the nature of tasks and the availability of resources may dynamically change, which makes traditional algorithms unable to effectively cope. Some traditional algorithms may become complex when processing large-scale data, leading to an increase in computational complexity. Meanwhile, it is easy to fall into local optima, which can affect the performance of task scheduling. Therefore, a scheduling model based on Markov decision process is proposed. This model applies the Deep Q-network (DQN) algorithm to task scheduling in Directed Acyclic Graph (DAG). Then, to address the shortcomings of the DQN algorithm, a Policy Gradient (PG) algorithm is introduced to improved it. The research content has four parts. The first part briefly introduces the research topic of scheduling optimization models. The second part is to analyze the main methods used in this study. The third part analyzes the results. The fourth part is a summary for the study and prospects for future research.

II. Related Works

The scheduling model is a model established for scheduling problems. Ammari A C et al. proposed a scheduling strategy based on an improved firefly algorithm for delay constrained applications in distributed green data centers. Multiple heterogeneous applications were efficiently scheduled with less cost and energy. The proposed scheduling strategy model based on the improved firefly algorithm could meet the scheduling problem of distributed green data centers [3]. With the development of cloud and mobile applications, the integration demand for applications and services in business processes is also increasing. Many integrated platforms used heuristic algorithms to schedule tasks executed by computing resources. Therefore, Freire D L et al. proposed a queue priority algorithm. This algorithm was based on particle swarm optimization, which could handle massive amounts of data in integrated task scheduling. The algorithm could execute the integration process and schedule the data under high data volume [4]. Zhou J et al. found that crowd perception could solve the massive data collection faced by most data-driven applications. Therefore, a workflow framework was first proposed, which captured the unique execution logic of perception tasks. Then, a phased approach was proposed to decouple the original scheduling problem. From the experimental results, the proposed model had good performance in solving scheduling problems [5].

Mishra A et al. found that task scheduling was crucial for improving the performance of large-scale collaborative and distributed electronic science applications. Therefore, a meta-heuristic crow search algorithm was proposed to address the scheduling problem of multiple tasks across heterogeneous virtual machines. This method could demonstrate better model performance compared with traditional models [6]. The computing demand in various application fields is increasing day by day. To meet this requirement, on-site programmable gate arrays have been widely used. Therefore, Tianyang L et al. summarized the current research status of hardware task dynamic scheduling based on the three basic elements of

*Corresponding Author.

existing on-site programmable gate array processing: time, resources, and power consumption. The optimization effects of various scheduling methods were analyzed and evaluated from multiple dimensions. The research results indicated that the research could make a certain contribution to scheduling problems based on field programmable gate arrays [7]. Ye W et al. proposed a new unmanned aerial vehicle assisted edge computing system. The system dispatched edge nodes assisted by drones to provide communication and computational assistance for completing tasks generated by ground clients. Firstly, a trajectory design and task allocation problem were proposed, aiming to optimize the appropriate trajectory of each drone and schedule tasks for each ground client. A maximum drone trajectory and task allocation algorithm was proposed, which solved the task allocation problem by jointly optimizing the trajectory of the drone and the task scheduling of the ground client. The proposed method demonstrated good scheduling performance [8]. Wang et al. found that two-stage mixed flow workshop scheduling with batch machines and jobs arriving over time was complex and challenging. For online scheduling problems, traditional heuristic rules can quickly respond to dynamically arriving jobs, but their performance is poor and unstable. Therefore, a scheduling model based on the DQN algorithm was proposed. It transformed the online scheduling problem into a collaborative Markov decision process by defining the state space, action space, and reward function of different agents. The experimental results showed that the model could effectively combine online batch formation and scheduling, minimizing the total delay time [9]. Sun C et al. found that task scheduling and load balancing in heterogeneous computing environments received increasing attention in recent years. Therefore, a new task scheduling and load balancing method based on optimized deep reinforcement learning is proposed. This method first formulates the task scheduling problem into a Markov decision process. Then a dual deep Q-learning network was used to search for the optimal task allocation solution. The research results indicated that the proposed method model had shorter task response time and better load balancing effect [10].

In summary, many scholars have conducted research on task scheduling and achieved some results. In this study, a scheduling model based on Markov decision process is proposed, which applies DQN algorithm to DAG task scheduling. Then, to address the shortcomings of DQN algorithm, the PG algorithm is introduced to improve the model.

III. Big Data Task Scheduling Optimization Model Based on Deep Q-Network

The first section of this chapter provides an explanation for DAG task scheduling. The scheduling problem is optimized into a Markov decision model. A task scheduling algorithm based on DQN is proposed. In the second section, a PG algorithm is proposed to address the shortcomings of task scheduling algorithms based on DQN. Combined with the DQN algorithm, a scheduling model based on PG-DQN algorithm is proposed.

A. Directed Acyclic Graph Task Scheduling in Heterogeneous Environments

Cloud computing task scheduling refers to the rational allocation of tasks on cloud computing platforms to different computing resources, improving computing efficiency and resource utilization. Cloud computing servers usually have three parts, namely scheduling servers, work nodes, and data storage services. Performing computational tasks often requires the output of other tasks as input, which can be abstracted as a DAG representation. A DAG is a graph structure composed of nodes and directed edges. Each edge has a direction and there is no loop [11]. Starting from any node in the graph and following the direction of the directed edge, it will not return to that node. Its structure is shown in Fig. 1.

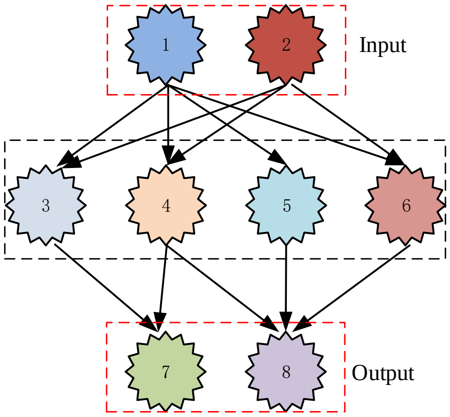

Fig. 1. DAG model diagram.

In Fig. 1, the node without a predecessor node task is the entry node, as shown in nodes 1 and 2 in the figure. There are no other nodes that rely on this node, such as node 7 and node 8. The computational cost of the task on each processor is shown in Eq. (1).

$$ECT_{V\times P}=\begin{bmatrix} ECT_{11} & \cdots & ECT_{1P} \\ \vdots & \ddots & \vdots \\ ECT_{V1} & \cdots & ECT_{VP} \end{bmatrix} \tag{1}$$

In Eq. (1), ECT represents the expected completion time. P refers to the computing node. V refers to the current task. The execution time is represented by the ECT matrix of $V\times P$, which is the time required to allocate each task to different nodes at the current moment [12]. In scheduling problems, the most common definitions are the earliest start time, earliest completion time, and maximum completion time. The earliest start time refers to the time when the task cannot start executing earlier than that, as shown in Eq. (2).

$$EST(v_i,p_j)=\max\left\{avail[j],\max_{v_k\in pred(v_i)}\{FT(v_k)+c_{k,i}\}\right\} \tag{2}$$

In Eq. (2), v_k represents the task. $FT(v_k)$ refers to the end time of the task execution. p_j represents a node. $avail[j]$ represents the earliest time used to calculate the node. $c_{k,i}$ represents the communication overhead between two tasks. When the direct precursor of a node is on the same processor as the node, the communication overhead between the two nodes can be considered as zero [13]. The earliest completion time indicates that the task cannot be completed earlier than that time, as shown in Eq. (3).

$$EFT(v_i, p_j) = EST(v_i, p_j) + \omega_{i,j} \tag{3}$$

In Eq. (3), $EST(v_i, p_j)$ refers to the earliest start time of the task. $\omega_{i,j}$ represents the time required for the task to perform calculations on the computing node. The earliest completion time is equivalent to the sum of the earliest start time and task execution time of the task [14]. The maximum completion time represents the time required to complete the last task in DAG, as displayed in Eq. (4).

$$Makespan = \max\{FT(v_{exit})\} \tag{4}$$

In Eq. (4), $Makespan$ represents the maximum completion time. v_{erit} represents the export task. The scheduling problem can be scheduled based on the execution time of the task. This process can be considered as a Markov decision process, which is a mathematical model used to describe stochastic decision problems. This method is based on an extension of Markov chain and decision theory. It is used to model sequential decision problems that include randomness and decision selection [15]. Its structure is shown in Fig. 2.

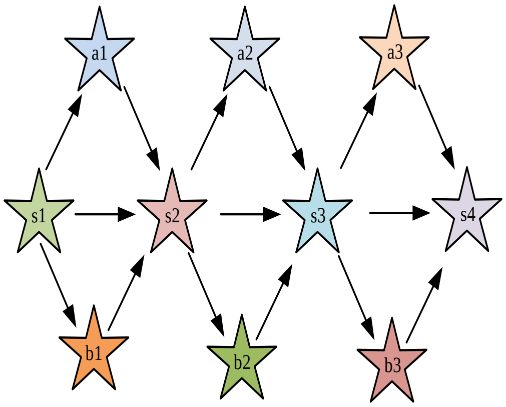

Fig. 2. Markov decision process.

From Fig. 2, the future state only depends on the current state and the currently selected action, rather than the past state and action. This nature makes the Markov decision process computable. Dynamic programming and other methods can be used to solve the optimal strategy [16-17]. The probability of a system transitioning from one state to another is defined as the state transition matrix, as shown in Eq. (5).

$$P = \begin{bmatrix} P_{11} & \cdots & P_{1n} \\ \vdots & & \vdots \\ P_{n1} & \cdots & P_{nn} \end{bmatrix} \tag{5}$$

In Eq. (5), P represents the state transition matrix. The goal of Markov decision process is to find a strategy that maximizes long-term cumulative rewards. The quality of a strategy is measured by defining a value function. It represents the long-term cumulative reward that can be obtained by adopting a certain strategy in a certain state, as shown in Eq. (6).

$$G_t = R_{t+1} + \gamma R_{t+2} + \cdots = \sum_{k=0}^{\infty} \gamma^k R_{t+k+1} \tag{6}$$

In Eq. (6), R_t represents the reward obtained from the environment after taking the action. t represents time. γ represents the attenuation factor, which reflects the future returns on the current value of the intelligent agent [18]. If the return is far from the current moment, the attenuation will be greater. To measure the value of a state, the expected cumulative reward is used as the state value, as displayed in Eq. (7).

$$v_\pi = E_\pi \left[\sum_{k=0}^{\infty} \gamma^k R_{t+k+1} \middle| S_t = s \right] \tag{7}$$

In Eq. (7), π represents the probability distribution of taking action. s represents the state. γ represents the attenuation factor. S represents the finite set state of the system. Based on the Markov decision process, a model is established for task scheduling problems in heterogeneous environments. The specific scheduling process is shown in Fig. 3.

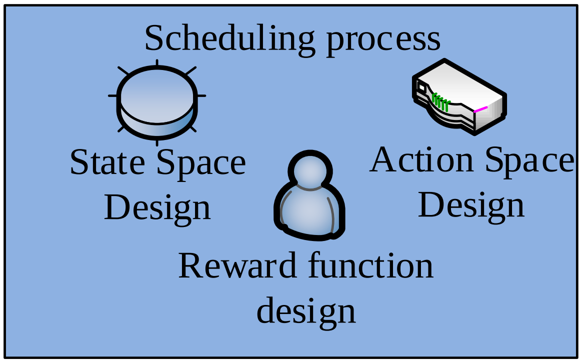

Fig. 3. Scheduling process.

The state space in a static environment is shown in Eq. (8).

$$S_t = [n, EST_1, \cdots, EST_M, T_{i,1}, \cdots, T_{i,M}] \tag{8}$$

In Eq. (8), t represents time. S_t represents the system state obtained by the scheduling model at t. M refers to the computing node. n refers to the current tasks. EST_j refers to the start time of the task in the processor. T represents the execution time. In task scheduling, the corresponding action space is shown in Eq. (9).

$$A_t = \{p_i \mid p_1, \cdots, p_M\} \tag{9}$$

In Eq. (9), A_t represents the action space. The model scheduling action at a certain moment is to schedule the current task to a computing node. The design of the reward function has significant impacts on the scheduling strategy. The designed reward function is shown in Eq. (10).

$$R_t = \max\{EST(v_i, p_j) \mid j = 1 \ldots q\} - \max\{EST(v_{i+1}, p_j) \mid j = 1 \ldots q\} \tag{10}$$

In Eq. (10), EST represents the start time of the task in the processor. In the Markov decision process, traditional methods lead to an extremely large state space, making modeling extremely slow and even impossible. Therefore, the reinforcement learning method is used to build models, which not only avoids the large state spaces, but also solves the continuous state spaces. DQN is used to build model. The core idea of DQN is to map the states and actions in the Markov decision process to a value function, namely the Q-value function. It is used to estimate the long-term return that can be obtained by taking an action in the current state. By learning this value function, DQN can select the optimal action in different states to maximize cumulative returns. DQN uses deep neural networks to approximate Q-value functions. The input of a neural network is a state. The output is an estimate of the Q-value for each action. After continuously adjusting the weights of the neural network, the estimation of Q value is closer to the true Q value. DQN uses an experience replay mechanism to train neural networks, which balances the sample correlation by saving and reusing previous experiences, improving training efficiency and stability.

The iterative process of the task scheduling algorithm based on DQN is as follows. Firstly, the set of tasks waiting for scheduling is inputted. The priority queue of the tasks is initialized. For tasks that meet the conditions, they will be arranged at the end of the queue. Secondly, the network parameters are initialized and weights are randomly generated. When there are tasks in the priority queue, the first task in the queue is selected as a pending scheduling task. Then the state is obtained. The action with the highest Q value is calculated. The task is scheduled to the corresponding computing node based on the action. Then, the return is calculated, and the DQN is backpropagated. Finally, the system status is updated.

B. Task Scheduling Optimization model Based on Deep Q-Network

The DQN algorithm has wide applicability and strong expressive ability. Combining deep learning with reinforcement learning, the DQN algorithm can be applied to various sequential decision problems, including game agent control, autonomous driving, robot path planning, etc. Therefore, it has high universality and flexibility. The DQN algorithm uses deep neural networks to approximate value functions, which can handle high-dimensional and complex state spaces [19]. Therefore, the DQN algorithm can provide better expressive power and performance when dealing with large-scale problems. The DQN algorithm combines deep learning and reinforcement learning, utilizing deep neural networks to learn the approximation of value functions. It can effectively deal with continuous state and action space problems, achieving good performance. The DQN algorithm uses experience replay and fixed target network methods to improve the sample utilization efficiency and training stability, avoiding the sample correlation and instability in traditional reinforcement learning methods.

However, the DQN algorithm model has some problems, such as the inability to represent random policies and difficulty in convergence. Therefore, the PG algorithm is adopted to improve the DQN algorithm. The PG algorithm is a method used to solve reinforcement learning problems by optimizing policy parameters to maximize cumulative rewards. Unlike traditional value function methods, the PG algorithm directly optimizes the policy function by using policy parameters as learnable parameters. The most commonly used method in PG algorithms is to use gradient ascent to update policy parameters. The core idea of the algorithm is to estimate the expected cumulative reward by sampling multiple trajectories. The gradient ascent method is used to update policy parameters to maximize expected rewards. To maximize cumulative rewards, a gradient ascent is applied to the cumulative rewards. The strategy function is shown in Eq. (11).

$$\pi(a \mid s, \theta) = P_r\{A_t = a \mid S_t = s, \theta_t = \theta\} \tag{11}$$

In Eq. (11), s represents the environmental state at time t. θ represents the model parameters. P_r represents the probability that a task is assigned to a computing node for execution. The task scheduling and model parameter optimization process is shown in Fig. 4.

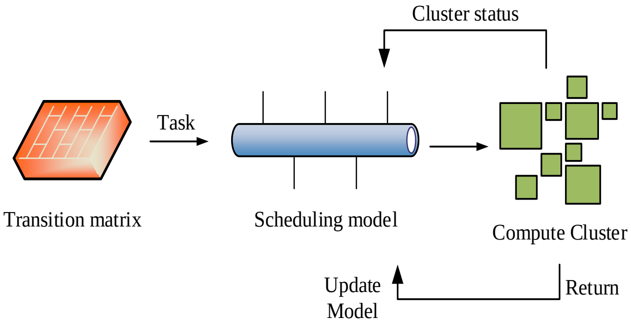

Fig. 4. Task scheduling and model parameter optimization process.

From Fig. 4, the scheduling model obtains a computing cluster through computing nodes. Then the computing cluster influences and updates the scheduling model through cluster status and returns [20]. For scheduling tasks, each task executes the above process to form a scheduling trajectory. The probability of generating scheduling trajectories is shown in Eq. (12).

$$P(\tau \mid \pi) = \rho_1(s_1) \prod_{t=0}^{T} P(s_{t+1} \mid s_t, a_t) \pi(a_t \mid s_t) \tag{12}$$

In Eq. (12), τ represents the scheduling trajectory. π represents the scheduling strategy. t represents the time step. The expected cumulative reward is shown in Eq. (13).

$$J(\pi_\theta) = \underset{\tau \sim \pi_\theta}{E}[R(\tau)] \tag{13}$$

In Eq. (13), $R(\tau)$ represents the cumulative reward. The training model needs to maximize the cumulative return. Therefore, the parameters are updated through the gradient ascent method. The iterative process based on PG is displayed in Fig. 5.

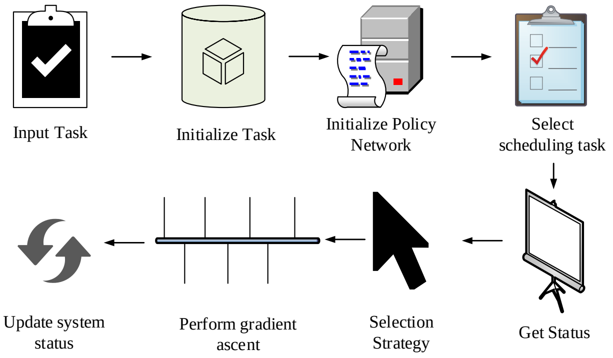

Fig. 5. The process of task scheduling algorithm based on PG.

In Fig. 5, the first step is to input a set of tasks waiting for scheduling, and initialize the priority queue of the tasks. For tasks that meet the conditions, they will be arranged at the end of the queue. Next, the policy network is initialized. If there are tasks in the priority queue, the first task in the queue is selected as a pending scheduling task. Then the state is obtained and the probability values for executing various scheduling actions are output. Based on the probability value, the current strategy action is selected. According to the policy action, the task is scheduled to the corresponding computing node. Then the reward of the scheduling action is calculated. Finally, the policy network is backpropagated and the system state is updated through the gradient ascent. The PG method is combined with the DQN algorithm to schedule tasks. The PG algorithm is responsible for outputting behavior, while the DQN algorithm evaluates behavior based on returns. Moreover, both the PG algorithm and the DQN algorithm simulate and update functions through neural networks. The combination of the two methods will result in better performance, as shown in Fig. 6.

In Fig. 6, all threads share a neural network, which includes the PG network and the DQN network. Each thread contains a neural network that is the same as the public network. Each network can be updated separately.

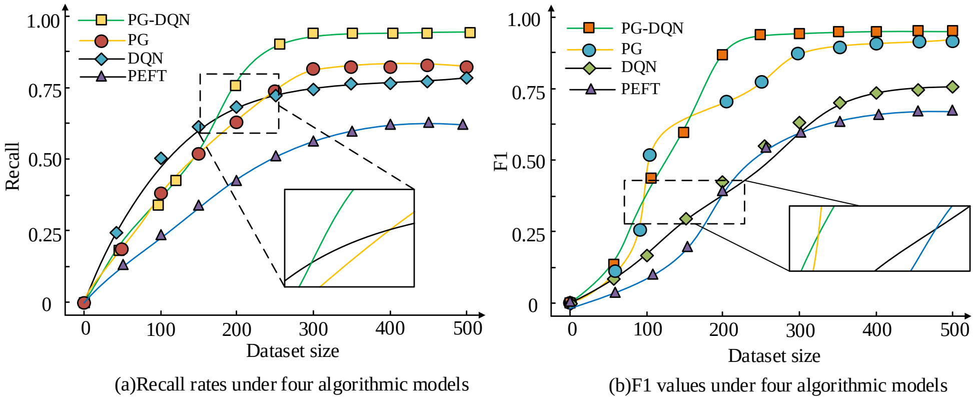
IV. Performance Analysis of Big Data Task Scheduling Optimization Model based on Deep Q-Network

The first section of this chapter introduces the Predict Earliest Finish Time (PEFT) algorithm. It is compared with the proposed algorithm. Chapter 2 compares the cumulative rewards and the maximum completion time for dynamic scheduling models.

A. Performance Analysis of Static Task Scheduling Optimization Model based on Improved Deep Q-network

The operating system used in this experiment is Windows 10. The CUP is the Intel Core i7-4710MQ processor, with a main frequency of 2.5GHz and 8.00GB of memory. The estimated earliest completion time algorithm and PG algorithm are compared with the algorithm used in this study [21-22]. The result is shown in Fig. 7.



(a)Recall rates under four algorithmic models

(b)F1 values under four algorithmic models

Fig. 7. Recall rates and F1 values of four methods.

Fig. 7(a) shows the recall rates of four algorithms on different datasets. Fig. 7(b) displays the F1 values of four algorithms on different datasets. In Fig. 7(a), the recall rates of the four models all increased with the increase of the training set. The proposed PG-DQN algorithm performed well among the four methods. When the dataset size was around 500, the recall rates of PG-DQN, PG, DQN, and PEFT were 0.96, 0.83, 0.79, and 0.63. In Fig. 7(b), the F1 values continued to increase with the increase of the training set. When the dataset size was 500, the F1 values of the four algorithms were 0.97, 0.90, 0.76, and 0.65, respectively. The proposed PG-DQN exhibits good performance in terms of recall and F1 value among the four models. Moreover, the PG-DQN has good performance on smaller datasets. The scheduling length ratio in the scheduling task is used as an indicator for comparison. Fig. 8 displays the results.

In Fig. 8, compared with the traditional PEFT, DQN and PG had a smaller scheduling length ratio. The proposed PG-DQN had a smaller scheduling length ratio than the other three algorithms when scheduling 200-1000 tasks. The PG-DQN can explore more reward actions. The proposed PG-DQN algorithm performs well. It can still maintain good performance in multiple tasks. The training time and scheduling time are compared. Fig. 9 displays the results.

Fig. 9 (a) shows the training time on different datasets and Fig. 9(b) presents the processing time of the algorithm under different task quantities. From Fig. 9(a), the FEPT exhibited longer training time under different dataset sizes. The training time of the PG-DQN was slightly longer than that of the PG and slightly shorter than that of the DQN. This is because the proposed algorithm model is a hybrid model of two methods, resulting in a more complex structure and more calculated parameters. In Fig. 9(b), the proposed PG-DQN only had slightly higher processing time than the PG in various quantities of task scheduling. Although the proposed PG-DQN does not take the least time, considering the scheduling performance, the overall performance of the PG-DQN is still better.

B. *Performance Analysis of Dynamic Task Scheduling Optimization model based on Improved Deep Q-network*

The experiment randomly generates 100 DAG tasks, each containing 10 sub-tasks, which are used as the dataset. The result is shown in Fig. 10.

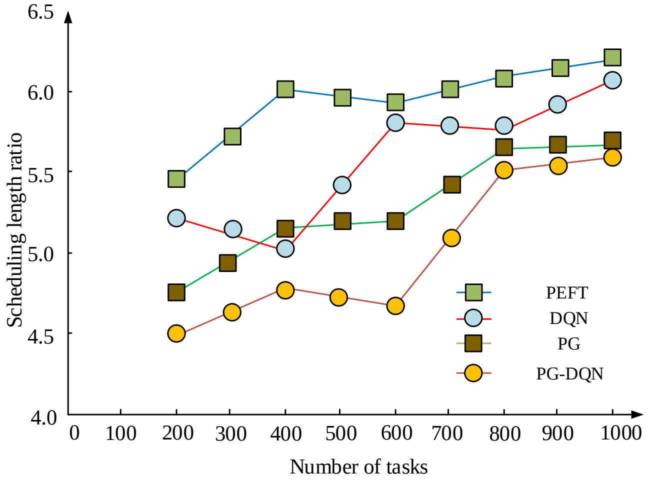


Fig. 8. The relationship between the scheduling length ratio index of different algorithms and the number of tasks.

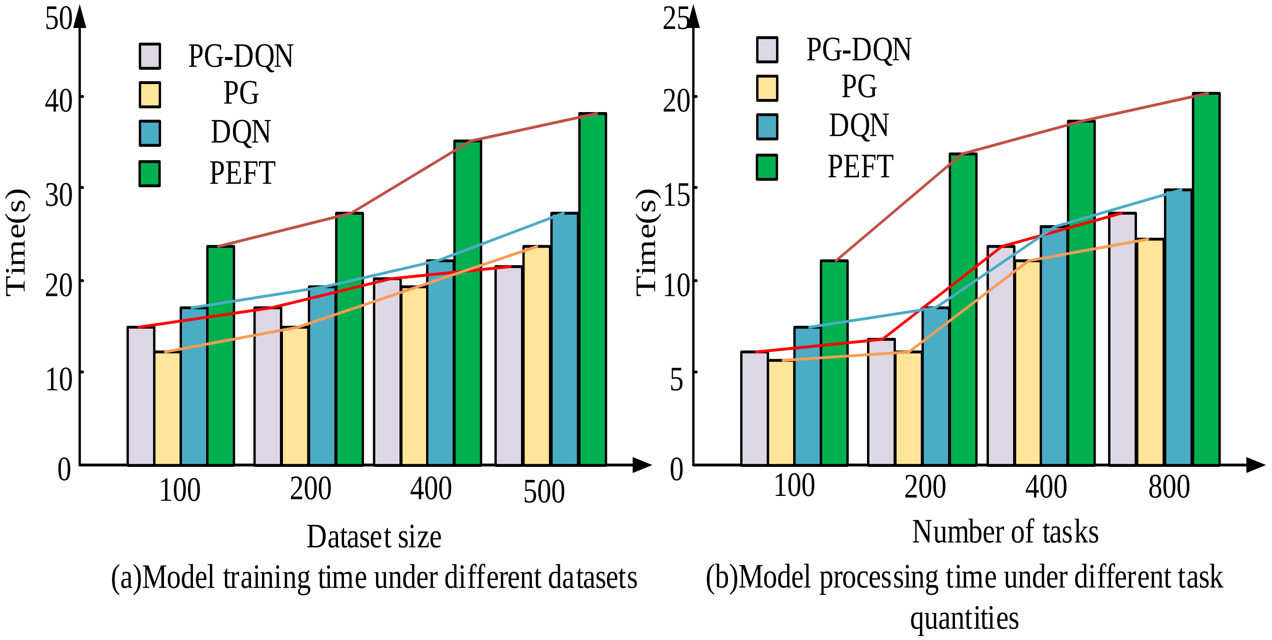
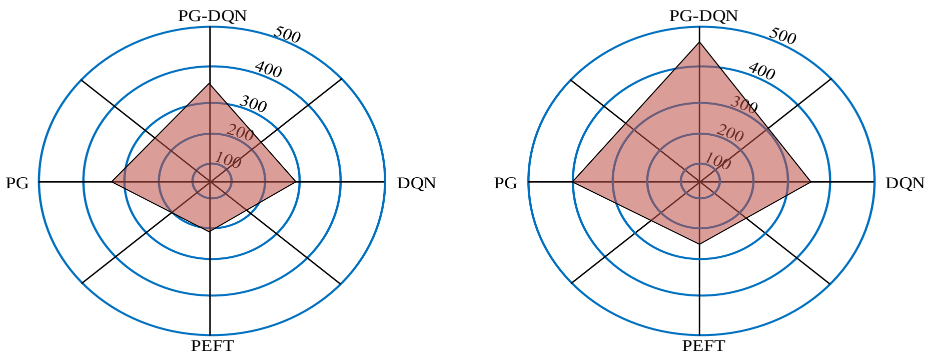


(a)Model training time under different datasets

(b)Model processing time under different task quantities

Fig. 9. Calculation time required for scheduling different algorithms.



(a) Cumulative rewards for different task scheduling algorithms with 100 iterations

(b) Cumulative rewards for different task scheduling algorithms with 500 iterations

Fig. 10. Cumulative rewards of task scheduling algorithm under different iterations.

Fig. 10(a) presents the cumulative rewards of different task scheduling algorithms at 100 iterations. Fig. 10(b) displays the cumulative rewards of different task scheduling algorithms at 500 iterations. In Fig. 10(a), at 100 iterations, the cumulative reward for the PG-DQN, PG, DQN, and PEFT were 350, 320, 290, and 210, respectively. In Figure 10 (b), at 500 iterations, the cumulative reward for the PG-DQN, PG, DQN, and PEFT were 460, 400, 350, and 260, respectively. The cumulative return of the model is lower when the number of iterations is small. After reaching 500 iterations, the cumulative return of the model is good. The proposed PG-DQN has the highest cumulative return among the four models, indicating that the PG-DQN has good performance. The maximum completion time is compared, as displayed in Fig. 11.

Fig. 11(a) displays the maximum completion time at different iterations. Fig. 11(b) displays the maximum completion time at different task quantities. According to Fig. 11 (a), when the number of iterations was 100, 300, 500, and 700, the maximum completion time of PG-DQN was 723s, 654s, 591s, and 576s, respectively, which were lower than the other three algorithm models. In Fig. 11(b), when the scheduling tasks were 100, 200, 300, and 400, the maximum completion time of PG-DQN was 342s, 387s, 410 s, and 442s, respectively. The proposed algorithm model has good model performance at different iterations and task quantities. 50 users are randomly selected and divided into an average of five groups to rate the model, as shown in Table I.

According to Table I, the scores of the five groups on the PG-DQN were 84.4, 97.2, 92.5, 94.7, and 90.1, respectively. The scores for the PG were 80.2, 94.5, 90.4, 90.6, and 86.5, respectively. The scores for the DQN were 78.6, 80.7, 85.4, 87.6, and 82.4, respectively. The scores for the PEFT were 76.8, 78.3, 82.4, 86.1, and 78.1. The PG-DQN has better scores among the four models, which has received widespread praise.

TABLE I. USER EVALUATION FORM

/	Group 1	Group 2	Group 3	Group 4	Group 5
PG-DQN	84.4	97.2	92.5	94.7	90.1
PG	80.2	94.5	90.4	90.6	86.5
DQN	78.6	80.7	85.4	87.6	82.4
PEFT	76.8	78.3	82.4	86.1	78.1

V. Conclusion

The task scheduling algorithm has significant value for the platform operation efficiency. A scheduling model based on Markov decision process is proposed, which applies DQN algorithm to DAG task scheduling. Then, to address the shortcomings of DQN algorithm, the PG algorithm is introduced to improve the model. According to the results, the recall rates of the four models increased with the increase of the training set. When the dataset size was around 500, the recall rates of the PG-DQN, PG, DQN, and PEFT were 0.96, 0.83, 0.79, and 0.63. The F1 values of the four algorithms were 0.97, 0.90, 0.76, and 0.65. Under different dataset sizes, the training time of the PG-DQN was slightly longer than that of the PG and slightly shorter than that of the DQN. In various task scheduling quantities, the proposed PG-DQN only had slightly higher processing time than the PG. At 100 iterations, the cumulative reward for the PG-DQN, PG, DQN, and PEFT were 350, 320, 290, and 210, respectively. At 500 iterations, the cumulative reward for the PG-DQN, PG, DQN, and PEFT were 460, 400, 350, and 260, respectively. The proposed method has good scheduling performance. However, there are also shortcomings in the research. The study only considers the execution time prediction for single threaded tasks. Future research will be conducted on multi-threaded tasks. For the task scheduling model, in the future, parameters will be adjusted based on the existing foundation. The model structure will continue to be optimized to achieve better scheduling results. The model architecture will also be considered for multi-objective optimization, such as fairness between tasks and priority scheduling of tasks.

VI. Discussion

The scheduling model is a model established for scheduling problems. This study proposes a scheduling model based on Markov decision process, which applies the DQN algorithm to DAG task scheduling. Then, to address the shortcomings of the DQN algorithm, a PG algorithm is introduced to combine it and improve the model. The experimental results showed that the DQN algorithm had a smaller scheduling length ratio compared with the traditional PEFT algorithm and PG algorithm. The proposed PG-DQN algorithm had a smaller scheduling length ratio than the other three algorithm models when scheduling 200-1000 tasks, indicating that the PG-DQN algorithm model can explore more rewarding actions. Under different dataset sizes, the FEPT algorithm exhibits longer training times. The training time of PG-DQN algorithm model was slightly longer than that of PG algorithm and slightly shorter than that of DQN algorithm. This is because the proposed algorithm is a hybrid model of two methods, resulting in a more complex structure and more calculated parameters. When the number of iterations were 100, 300, 500, and 700, the maximum completion time of PG-DQN was 723s, 654s, 591s, and 576s, respectively, which were lower than the other three models. When the scheduling tasks were 100, 200, 300, and 400, the maximum completion time of PG-DQN was 342s, 387s, 410 s, and 442s, respectively. The research results indicated that the proposed method model has better performance and efficiency.
